## Abstract

### Background

Anxiety disorders have been linked to an increased risk of incident coronary heart disease in which inflammation plays a key pathogenic role. To date, no studies have looked at the association between proinflammatory markers and agoraphobia.

### Methods

In a random Swiss population sample of 2890 persons (35-67 years, 53% women), we diagnosed a total of 124 individuals (4.3%) with agoraphobia using a validated semi-structured psychiatric interview. We also assessed socioeconomic status, traditional cardiovascular risk factors (i.e., body mass index, hypertension, blood glucose levels, total cholesterol/high-density lipoprotein-cholesterol ratio), and health behaviors (i.e., smoking, alcohol consumption, and physical activity), and other major psychiatric diseases (other anxiety disorders, major depressive disorder, drug dependence) which were treated as covariates in linear regression models. Circulating levels of inflammatory markers, statistically controlled for the baseline demographic and health-related measures, were determined at a mean follow-up of  $5.5 \pm 0.4$  years (range 4.7 – 8.5).

### Results

Individuals with agoraphobia had significantly higher follow-up levels of C-reactive protein ( $p = 0.007$ ) and tumor-necrosis-factor- $\alpha$  ( $p = 0.042$ ) as well as lower levels of the

by research grants from GlaxoSmithKline, the Faculty of Biology and Medicine of Lausanne, and the Swiss National Science Foundation (grants 3200B0-105993, 3200B0-118308, 33CSO-122661, 33CS30-139468 and 33CS30-148401). The funders had no role in the study design, in the collection, management, analysis or interpretation of the data, in the preparation, review or approval of the manuscript, and the decision to submit the manuscript for publication.

**Competing Interests:** Funding was received from GlaxoSmithKline (GSK) as an unrestricted grant to build the CoLaus study. There are no patents, products in development or marketed products to declare. This does not alter the authors' adherence to all the PLOS ONE policies on sharing data and materials.

cardioprotective marker adiponectin ( $p = 0.032$ ) than their non-agoraphobic counterparts. Follow-up levels of interleukin (IL)-1 $\beta$  and IL-6 did not significantly differ between the two groups.

## Conclusions

Our results suggest an increase in chronic low-grade inflammation in agoraphobia over time. Such a mechanism might link agoraphobia with an increased risk of atherosclerosis and coronary heart disease, and needs to be tested in longitudinal studies.

## Introduction

Increasing evidence suggests that anxiety disorders are linked to elevated levels of circulating biomarkers indicating low-grade inflammation. Based on experimental data, it has been hypothesized that it is particularly the experience of acute stress in anxiety states, which leads to these increments [1]. Most of the research on the association between anxiety disorders and inflammation stems from studies on posttraumatic stress disorder (PTSD) and the referring potential pathophysiological pathways have extensively been described [2–5]. It is assumed, that a prolonged or excessive activation of the acute stress response system in PTSD may increase the risk for excessive systemic inflammation [6, 7] by long-term adaptations of bodily systems. One such adaptation might consist of a decrease of cortisol levels and a consecutively insufficient glucocorticoid signaling, causing excessive levels of cell-mediated and proinflammatory cytokines, as well as excessive stimulation of the hypothalamic-pituitary-adrenal (HPA) axis [8–10].

However, it may also well be that the presence of a proinflammatory state precedes the actual development of PTSD [7, 11]. Since not all trauma-exposed individuals subsequently develop PTSD [12], it is hypothesized that the development of PTSD is associated with biological vulnerability factors, which are already present before the onset of symptoms. In a recent review, such pre-existing vulnerability factors in the glucocorticoid signaling pathway for the development of PTSD have been presented [5].

Sparse evidence from relatively small clinical studies also suggests that inflammatory activity is increased in patients with panic disorder [13] and generalized anxiety disorder [14].

In comparison to PTSD, knowledge about the association between inflammation and agoraphobia is scarce—despite the fact that agoraphobia is one of the most prevalent, persistent and disabling of the mental disorders [15], with a well-known poor prognosis and frequent incomplete remission [15, 16]. Therefore it is a lifetime diagnosis in most of the cases. The main clinical feature of agoraphobia is the presence of anxiety about being in places or situations from which escape may be difficult (or embarrassing) or in which help may not be available in the case of a panic attack or the occurrence of panic-like symptoms [17, 18].

Two studies that have investigated inflammation in patients with agoraphobia and panic attacks so far did not show increased levels of inflammatory markers. However, measurements in one small study on 36 patients with agoraphobia and panic attacks were performed after *in vitro* stimulation of immune competent cells and, moreover, might be confounded by a four-arm pharmacological intervention design [19]. The other recent population-based study found no significant associations of circulating levels of C-reactive protein (CRP), tumor necrosis factor (TNF)- $\alpha$ , and interleukin (IL)-6 in individuals with a current panic disorder and/or

agoraphobia [20]. However, that study did not investigate an association between inflammation and agoraphobia separately and applied a cross-sectional design [20].

To date, there is no study that has investigated whether patients with agoraphobia show increased low-grade inflammation compared to individuals without agoraphobia, and whether agoraphobic individuals show an increase of low-grade inflammation over time in comparison to their non-agoraphobic counterparts, reflecting a cumulative and progressive immune function dysregulation.

The following study aimed to address this existing research gap by examining the association between agoraphobia and low-grade inflammation in a large population based sample. Thereby, changes in circulating levels of inflammatory markers, that is CRP, IL-1 $\beta$ , IL-6, TNF- $\alpha$ , and adiponectin, in patients with agoraphobia compared to those without this anxiety disorder were assessed prospectively, taking potential confounding factors commonly associated with inflammation activity, and other relevant psychiatric disorders (including other anxiety disorders), into account. We hypothesized that individuals with a lifetime diagnosis of agoraphobia might have higher levels of proinflammatory markers and lower levels of the “cardio-protective” adipo(cyto)kine adiponectin [21] than non-agoraphobic individuals and that these differences would increase over time.

## Materials and Methods

### Ethics statement

The Institutional Ethics Committee of the University of Lausanne approved the CoLaus and subsequently the PsyCoLaus study. All participants signed a written informed consent after having received a detailed description of the goal and funding of the study.

### Study participants and design

The data of the present paper stemmed from CoLaus|PsyCoLaus [22, 23], a cohort study designed to prospectively assess mental disorders and cardiovascular risk factors (CVRFs) in the general population. Blood and plasma samples were also collected for the study of biomarkers and genetic variants.

The study participants were selected from a random sample of 19'830 residents (35%) of the city of Lausanne, in the age range of 35 to 75 years, derived from the electronic database of the entire population of the 1st January 2003. Letters were sent to all subjects and among respondents ( $n = 15'109$ ) a final sample of 6736 subjects agreed to participate in CoLaus after having received additional information regarding the study. The baseline somatic assessment for the CoLaus study ( $n = 6736$ ) was conducted between June 2003 and May 2006 and has been described in detail elsewhere [22]. In a second step, we asked the 5535 subjects aged between 35 and 66 years to participate in PsyCoLaus. Subsequently, 67% of them accepted to take part in the psychiatric evaluation, and the final sample was comprised of 3719 individuals who underwent both the somatic and psychiatric exams (PsyCoLaus study) [23]. Ninety-two percent of them were Caucasians. The gender distribution of the PsyCoLaus sample (47% men) did not significantly differ from that of the general population in the same age range (mean age  $\pm$  SD:  $50.9 \pm 8.8$  years). Although the youngest 5-year band of the cohort was underrepresented and the oldest 5-year band overrepresented, participants of PsyCoLaus (mean age  $\pm$  SD:  $50.9 \pm 8.8$  years) and individuals who refused to participate revealed comparable scores on the General Health Questionnaire [24], French translation [25], a self-rating instrument completed at the somatic exam.

Among the 3174 participants who had complete data for agoraphobia from the psychiatric evaluation at baseline, the majority also took part in the somatic follow-up evaluation. At

follow-up 3100, 2792, 2792, 2792, and 2679 subjects provided a blood sample for measurements of the pro-inflammatory markers CRP, IL-1 $\beta$ , IL-6, TNF- $\alpha$ , and adiponectin, respectively. Participants with high-sensitivity CRP > 10 mg/L ( $n = 210$ ) at baseline and follow-up were excluded from the analysis, as these values are likely to be a sign of acute infection, resulting in a final study sample of 2890 subjects. The average duration between the somatic baseline and follow-up assessments was  $5.5 \pm 0.4$  years (range 4.7–8.5). The average duration between somatic and psychiatric evaluations at baseline was  $1.3 \pm 0.5$  years (0.2–5.7). There was no significant difference in time from somatic to psychiatric evaluation ( $p = 0.326$ ) and time to the follow-up assessment ( $p = 0.414$ ) for agoraphobics compared to the rest of the sample (Table 1).

## Assessment of agoraphobia

Diagnostic information on lifetime agoraphobia was collected using the semi-structured Diagnostic Interview for Genetic Studies (DIGS) [26]. The DIGS also assessed the severity of agoraphobia by a Global Assessment of Functioning score (GAF score) specific to the agoraphobia section. The DIGS was developed by the National Institute of Mental Health (NIMH) Molecular Genetics Initiative to obtain a more precise assessment of phenotypes through a wide spectrum of DSM-IV Axis I criteria. Psychiatric diagnoses were assigned according to the DSM-IV. We used the French translation of the DIGS [27] with excellent inter-rater reliability in terms of kappa and Yule's Y coefficients for major mood and psychotic disorders [28] as well as for substance use disorders [29], and 6-week test-retest reliability which was somewhat lower but still in the fair to good ranges [28, 29]. The inter-rater reliability for specific anxiety disorders was very good, whereas the 6-week test-retest reliability estimates were in the fair or good ranges [30]. Interviewers were required to be psychologists or psychiatrists, who were trained over a 2-month period. Their training included rating tapes and supervised co-ratings. To provide ongoing supervision throughout the study, each interview and diagnostic assignment was reviewed by an experienced senior psychologist. The psychiatric investigation was conducted approximately one year after the baseline somatic examination.

## Assessment of proinflammatory markers

Blood sampling to determine inflammatory levels took place at both the baseline and follow-up assessments. Venous blood samples (50 mL) were drawn in the fasting state and allowed to clot. Serum was preferred to plasma, as it has been shown that different anticoagulants may affect absolute cytokine levels differently [31, 32]. High-sensitivity CRP was assessed by immunoassay and latex HS (IMMULITE 1000-High, Diagnostic Products Corporation, LA, CA, USA) with maximum intra- and interbatch coefficients of variation of 1.3% and 4.6%, respectively. Serum samples were kept at  $-80^{\circ}\text{C}$  before assessment of IL-1 $\beta$ , IL-6, and TNF- $\alpha$  and sent on dry ice to the laboratory. Levels of these cytokines were measured using a multiplexed particle-based flow cytometric cytokine assay [33].

This methodology yields cytokine concentrations correlating well with those obtained by other methods such as ELISA [34, 35]. Milliplex kits were purchased from Millipore (Zug, Switzerland). The procedures closely followed the manufacturer's instructions. The analysis was conducted using a conventional flow cytometer (FC500 MPL, BeckmanCoulter, Nyon, Switzerland). Good agreement between signal and cytokine was found within the assay range ( $R^2 \geq 0.99$ ). Intra- and inter-assay coefficients of variation (CV) were respectively 15% and 16.7% for IL-1 $\beta$ , 16.9% and 16.1% for IL-6 and 12.5% and 13.5% for TNF- $\alpha$ . Adiponectin was assessed by ELISA (R&D Systems, Inc, Minneapolis, USA) with a maximum inter-assay CV of

8.3% and a maximum intra-assay CV of 8.3%. For quality control, repeated measurements were conducted in 80 subjects randomly drawn from the initial sample.

## Assessment of covariates

The somatic exam comprised measurements of body weight, height and blood pressure (triplicate measure on the left arm after at least a 10-min rest in the seated position). Venous blood samples were drawn from each participant after an overnight fast to measure the levels of glucose, total cholesterol, and high-density lipoprotein (HDL)-cholesterol. Continuous values of fasting blood glucose and the total cholesterol/HDL-cholesterol-ratio were used. According to the World Health Organization guidelines, overweight was defined as a body mass index (BMI) of 25 and to 30 kg/m<sup>2</sup> and obesity was defined as a BMI  $\geq$  30 kg/m<sup>2</sup> [36]. A diagnosis of hypertension was assigned in the case of systolic blood pressure  $\geq$  140 mmHg and/or diastolic blood pressure  $\geq$  90 mmHg. Information on gender and age, socioeconomic status (SES), physical inactivity and nicotine and alcohol consumption was taken from the DIGS. SES was assessed using the Hollingshead scale [37]. A subject was considered as physically active when he or she reported regular physical exercise for at least 20 minutes twice a week. Regular nicotine consumption was defined as a current or past history of smoking. Alcohol intake was assessed by self-reported alcohol consumption in the last seven days, expressed as the number of standard drinks. A standard drink was defined as a glass of wine, a bottle of beer or a shot of spirits, approximating 10–12 g ethanol [38]. Subjects were categorized as nondrinkers, low (1–6 drinks/week), moderate (7–13/week) and high (14+/week) alcohol consumers. Questionnaire-based data on alcohol consumption have been shown to correlate well with daily alcohol intake over the previous 4 years [39]. Lifetime major depressive disorder (MDD), other anxiety disorders (generalized anxiety disorder, panic disorder, posttraumatic stress disorder, social phobia) and drug dependence (marijuana, cocaine, solvent, hallucinogen, stimulant, sedative or/and narcotic dependence) were collected using the DIGS.

## Statistical analysis

All statistical analyses were performed using the IBM<sup>®</sup> PASW<sup>®</sup> 18.0 statistical software package (IBM Corporation, New York, USA) and the Statistical Analysis System, version 9.2 for Windows (SAS Institute Inc., Cary, NC, USA). Data are presented as means  $\pm$  standard deviation (range) or absolute numbers and percentages for continuous and categorical variables, respectively. We categorized the participants into two groups, those with and those without agoraphobia. To detect significant differences in covariates between the two groups, we applied the Mann-Whitney-U and Pearson's chi-square test for continuous and categorical variables, respectively. Lower limits of detection (LOD) for IL-1 $\beta$ , IL-6 and TNF- $\alpha$  were 0.2 pg/ml. Undetectable measures for IL-1 $\beta$ , IL-6 and TNF- $\alpha$  at baseline and follow-up were replaced by half the LOD (i.e., 0.1 pg/ml) as was previously suggested [33–35]. For adiponectin, and high-sensitivity CRP, all values were detectable at baseline and at follow-up. Given that as many as 37% and 25% of the values of IL-1 $\beta$  at baseline and at follow-up respectively were below the LOD, we dichotomized this variable at the median and applied logistic regression models. For subsequent analyses, inflammatory measures (CRP, IL-6, TNF- $\alpha$  and adiponectin) were log<sub>10</sub>-transformed to normalize distributions. The sum of log<sub>10</sub>-transformed and z-scored high-sensitivity CRP, IL-6 and TNF- $\alpha$  were used to create a composite score of inflammatory markers at baseline and at follow-up [40]. Only participants who had data available for all three of these markers were included in these analyses (n = 2569).

Associations between agoraphobia at baseline and CRP, IL-6, TNF- $\alpha$ , adiponectin and the composite score of inflammatory markers outcome levels at baseline or at follow-up were

determined using multiple linear regression models, separately for each outcome variable. For the associations between agoraphobia at baseline and inflammatory markers at follow-up, five models of increasing complexity were computed; first (model 1) only with an adjustment for value of the corresponding inflammatory measure at baseline and the duration between somatic evaluation at baseline and at follow-up (i.e., length of follow-up), and, subsequently (models 2–5), with the same adjustments as for model 1 and additional adjustments for demographic and health-related covariates. In model 2, we made adjustments for inflammatory measures at baseline and sociodemographic characteristics (age, gender, SES). In model 3, we additionally adjusted for physical CVRFs (hypertension, BMI, glucose, total cholesterol/HDL-cholesterol), in model 4, for behavioral CVRFs (smoking, alcohol consumption, physical activity), and finally, in model 5, for other relevant lifetime psychiatric disorders: major depressive disorders, other anxiety disorders (generalized anxiety disorder, panic disorder, posttraumatic stress disorder, social phobia) and drug dependence (marijuana, cocaine, solvent, hallucinogen, stimulant, sedative or/and narcotic dependence). Statistical significance was considered at  $p < 0.05$ . We did not adjust p-values for multiple comparisons for the following two reasons [41, 42]: a) the hypothesized relationships between agoraphobia and inflammatory measures were specified a priori; and b) the examined inflammatory measures are actual observations in nature and all indicative of the same biological process (i.e., chronic low-grade systemic inflammation).

## Results

### Characteristics of study participants

Baseline characteristics of the study sample ( $n = 2890$ ) are presented in [Table 1](#). On average, participants were 50 years old and 53% were female. Concerning CVRFs, quite a sizeable percentage of participants were former or current smokers (61%). Thirty-seven percent of participants reported moderate-to-high alcohol consumption and 44% were physically inactive. Lifetime agoraphobia was detected in 124 individuals (4.3% of all participants).

The comparison between agoraphobics and non-agoraphobics on demographic and health characteristics revealed significantly more women and more smokers, but fewer alcohol consumers of alcohol in the group with agoraphobia. Individuals with agoraphobia also showed a significantly higher prevalence of concomitant anxiety and major depressive disorders than their non-agoraphobic counterparts. The proinflammatory biomarkers at baseline ([Table 2](#)) did not differ significantly between subjects with agoraphobia and controls, even after adjustment for all covariates.

### Inflammatory measures at follow-up

The comparison of circulating levels of inflammatory measures at baseline and follow-up between agoraphobics and non-agoraphobics is presented in [Table 2](#) (log<sub>10</sub>-transformed means  $\pm$  standard deviations, values for IL-1 $\beta$  are given as prevalence). Mean values of the log<sub>10</sub>-transformed biomarkers levels did not significantly differ between agoraphobics and non-agoraphobics at baseline. After adjusting for CRP at baseline and all further covariates, mean log<sub>10</sub>-transformed CRP at follow-up was higher in agoraphobics than in non-agoraphobics at baseline. This absolute increase was statistically significant ([Table 3](#) and [Table 4](#);  $\beta = 0.087$  (95%-CI 0.024 to 0.151;  $p = 0.007$ ). The effect size of agoraphobia was similar to that of overweight, but lower than those of underweight and obesity. In contrast, it was higher than the effect sizes of smoking and alcohol consumption. Similarly, TNF- $\alpha$  levels were significantly higher among subjects with agoraphobia than among those without and the significance of this association was preserved in all five models ([Table 3](#) and [Table 7](#);  $\beta = 0.089$  (95%-CI 0.003 to 0.174;  $p = 0.042$ ). In addition, the effect size of agoraphobia for TNF- $\alpha$  was higher than those

of all the other covariates, except for drug dependence. In contrast to the other proinflammatory markers, the cardio-protective biomarker adiponectin was significantly lower in persons with than those without agoraphobia after adjustment for covariates (models 1–5; [Table 3](#) and [Table 8](#);  $\beta = -0.053$  (95%-CI -0.101 to -0.005;  $p = 0.032$ )). The effect size of agoraphobia for adiponectin was lower than those of gender, obesity and underweight, but higher than those of overweight, hypertension and alcohol consumption. Levels of IL-6 ([Table 3](#) and [Table 6](#)) and IL-1β ([Table 3](#) and [Table 5](#)) did not significantly differ between groups. The composite score of proinflammatory markers (including CRP, IL-6 and TNF-α) at follow-up was higher (model 5:  $\beta = 0.578$  (95%-CI 0.241–0.915; [Table 3](#) and [Table 9](#)) among subjects suffering from lifetime agoraphobia at baseline. The severity of agoraphobia (mean GAF score ± SD:  $53.9 \pm 0.9$  (range: 30–99)) was not significantly associated with the levels of the proinflammatory markers.

## Discussion

In this population-based sample of 2890 Swiss adults, individuals with agoraphobia, relative to their non-agoraphobic counterparts, showed a prospective increase in levels of circulating biomarkers indicating a low-grade inflammatory state over time. Especially, levels of CRP, but also of TNF-α increased over time, while the level of cardio-protective adiponectin significantly decreased from baseline to follow-up. The direction of the association between agoraphobia and IL-6 was also as hypothesized direction, although the association was not significantly, suggesting insufficient statistical power. Interestingly, the proinflammatory biomarkers and the adipo(cyto)kine adiponectin showed no difference between the two groups at baseline. The intriguing finding of discrepancies between the results from baseline and follow-up were not explained by the serial adjustments for potential confounders (including the length of follow-up). However, this might support the notion that the agoraphobic individuals in our sample are more vulnerable to a progressive immune function dysregulation over time. This might become rather evident at the age range examined (35–67 years).

Our findings of an association between agoraphobia and low-grade inflammation concur with studies on individuals with PTSD [[2–5](#), [7](#), [11](#)]. Whether psychobiological mechanisms, including HPA axis dysfunction, which have been identified to possibly link PTSD with

Values for inflammatory measures are given as unadjusted log10-transformed means  $\pm$  standard deviation, values for interleukin-1 $\beta$  are given as prevalence.

HDL, high-density lipoprotein; CRP, C-reactive protein; TNF, tumor necrosis factor; OR, odds ratio; 95CI, 95% confidence interval.

<sup>a</sup> Duration between somatic evaluation at baseline and somatic evaluation at follow-up.

<sup>b</sup> A value of "3" represents an SES of III (middle class) on the Hollingshead Scale.

<sup>c</sup> Systolic blood pressure  $\geq$  140 mmHg and/or diastolic blood pressure  $\geq$  90 mmHg.

<sup>d</sup> Physically active at least or more than 20 minutes twice a week.

<sup>e</sup> Generalized anxiety disorder, panic disorder, posttraumatic stress disorder, and/or social phobia.

<sup>f</sup> Marijuana, cocaine, solvent, hallucinogen, stimulant, sedative or/and narcotic dependence.

<sup>g</sup> Multiple regression with log10 transformed cytokine or CRP or adiponectin.

<sup>h</sup> Logistic regression with interleukin-1 $\beta$  concentration dichotomized at the median.

<sup>i</sup> Composite score of inflammatory markers includes CRP, interleukin-6 and TNF- $\alpha$ . Only participants who had data available for all three of these markers were included in these analyses.

doi:10.1371/journal.pone.0123757.t009

inflammation, also apply to agoraphobics needs to be investigated further in carefully planned mechanistic studies.

To our knowledge this is the first study that examined the prospective associations between agoraphobia and changes in proinflammatory biomarkers in a large population-based sample. The strength of the study is the use of both a thorough biological evaluation and a comprehensive psychiatric assessment which allowed us to collect data on environmental and health-related risk factors as well as on major psychiatric diseases. The overall prevalence of agoraphobia in this study was 4.3%, which is situated within the lower bound of prevalences reported in other studies, ranging from 1% to 22% [18]. We found a striking gender difference in the prevalence of agoraphobia with almost 4 out of 5 participants of the agoraphobic group being female (81%). This prevalence estimate is similar to that of another study reporting a women to men ratio of 4:1 for agoraphobia [43].

The PsyCoLaus study was designed to better understand the relationship between psychiatric disorders and cardiovascular diseases (CVD) [23], including the potential mechanisms involved in this link, such as chronic low-grade inflammation. Meta-analyses suggest that the prospective risk of incident coronary heart disease (CHD) is increased in individuals with an anxiety disorder, including phobic anxiety [44], as well as in those with elevated levels of inflammatory measures, including CRP and TNF- $\alpha$  [45, 46]. Enhanced inflammation is a key process in atherosclerosis, which, for instance, via crosstalking with the endothelium and coagulation system promotes endothelial dysfunction and prothrombotic changes that critically contribute to atherosclerosis progression and ultimately acute coronary syndromes [47, 48]. Abundant biobehavioral research strongly suggests that psychosocial risk factors, including psychiatric disorders may affect all of the biological processes that lead from initiation to overt manifestation of atherothrombotic diseases, a process that may take many decades to become clinically apparent [49, 50]. Taken together, this research together with findings from our study may imply that a chronic low-grade inflammatory state in agoraphobia contributes to atherothrombotic CVD in patients with agoraphobia independent of sociodemographic, life style and physical CVRFs, and other major psychiatric diseases.

This study should be placed into the context of at least two notable limitations. First, as a consequence of avoidance behaviors (e.g., travel to the study site), some of the most severe cases of agoraphobia may not have been included in our sample. This may limit the generalization of our findings to all patients with agoraphobia, and particularly to those who are referred to a mental health care setting for treatment. However, as persons with severe agoraphobia could potentially show even higher levels of inflammatory markers, our results are likely to entail a conservative estimate. Second, the gap between the psychiatric and somatic assessments was about one year, which might have diluted temporal relationships between agoraphobia and inflammation, thereby potentially explaining why IL-1 $\beta$  and IL-6 levels showed no significant associations. Also, this between assessment gap entailed the risk that some individuals attributed to agoraphobia had produced cytokine levels that preceded the onset of the disorder. In this regard, it was shown that anxiety symptoms are part of cytokine-induced sickness behavior resulting from peripheral inflammation signaling the brain to initiate adaptive behaviors in various states of immune activation [51]. However, full-blown agoraphobic symptoms are not usually viewed as typical for sickness behavior and, moreover, the associations in our study showed high robustness, even after adjustment for a set of important CVRFs.

To sum up, our study demonstrates that agoraphobia predicted an increase in low-grade systematic inflammation over time in comparison to a control group without agoraphobia. This finding is clinically relevant, suggesting that agoraphobia might exaggerate inflammation activity which, further downstream, might result in vascular pathology and ultimately atherosclerotic vascular disease. However, longitudinal studies with CVD endpoints are needed to

confirm this possibility. Future studies should also investigate which signs and symptoms of agoraphobia show a particularly strong association with chronic low-grade inflammation.

## Author Contributions

Conceived and designed the experiments: ENW MP PV RvK. Performed the experiments: ENW RvK. Analyzed the data: ENW JTW MFS RvK. Contributed reagents/materials/analysis tools: ENW EC JG MP PV RvK. Wrote the paper: ENW JTW CV JG RvK.
