10 **Abstract**

11 C<sub>4</sub> photosynthesis suppresses the oxygenation activity of Ribulose Bisphosphate Carboxylase Oxygenase  
12 and so limits photorespiration. Although highly complex, it is estimated to have evolved in sixty-six plant  
13 lineages, with the vast majority lacking sequenced genomes. Transcriptomics has recently initiated  
14 assessments of the degree to which transcript abundance differs between C<sub>3</sub> and C<sub>4</sub> leaves, identified novel  
15 components of C<sub>4</sub> metabolism, and also led to mathematical models explaining the repeated evolution of  
16 this complex phenotype. Evidence is accumulating that this complex and convergent phenotype is partly  
17 underpinned by parallel evolution of structural genes, but also regulatory elements in both *cis* and *trans*.  
18 Furthermore, it appears that initial events associated with acquisition of C<sub>4</sub> traits likely represent  
19 evolutionary exaptations related to non-photosynthetic processes.

## 20 Introduction

21  $C_3$  plants inherited a carbon fixation system developed by the photosynthetic bacteria, with primary  
22 carbon fixation being catalysed by the enzyme Ribulose Bisphosphate Carboxylase Oxygenase (RuBisCO).  
23 The oxygenase activity of RuBisCO generates the toxic intermediate phosphoglycollate, and although this  
24 can be detoxified and carbon partially recovered by the photorespiratory pathway, energy is expended in  
25 the process. As the oxygenase function of RuBisCO increases with ambient temperature, it is thought that  
26 in tropical and sub-tropical habitats, significant selection pressure led to the convergent evolution of  
27 carbon concentrating mechanisms [1]. Phylogeny indicates that land plants have repeatedly evolved either  
28 temporal (Crassulacean Acid Metabolism) or spatial carbon concentrating mechanisms ( $C_4$  photosynthesis)  
29 [2].

30 Although highly complex, the  $C_4$  pathway is estimated to have evolved in at least sixty-six lineages of  
31 plants [3]. Initial analysis of clades that contain  $C_3$  and  $C_4$  species but also ' $C_3$ - $C_4$ ' intermediates identified  
32 the most common early traits likely associated  $C_4$  photosynthesis, and this led to the development of  
33 models that depict the evolution of this complex phenotype along a relatively linear path of trait acquisition  
34 [4]. More recently, probabilistic modelling within a Bayesian framework identified flexibility in when  $C_4$   
35 component traits evolve, but also found four major paths likely associated with acquisition of these traits  
36 [5]. Despite this flexibility in the acquisition of  $C_4$  component traits, the core  $C_4$  metabolic machinery has  
37 converged upon a similar architecture in all  $C_4$  lineages. For example, in all  $C_4$  species,  $HCO_3^-$  is initially fixed  
38 by phosphoenolpyruvate carboxylase (PEPC) (Figure 1), which has a higher affinity for  $HCO_3^-$  than RuBisCO  
39 does for  $CO_2$  [6].  $C_4$  acids then diffuse down a concentration gradient into insulated cellular, or sub-cellular  
40 [7] compartments where  $C_4$  acid decarboxylases increase the local concentration of  $CO_2$  around RuBisCO,  
41 thereby reducing its oxygenation activity. In most  $C_4$  species, an altered arrangement of cells within the leaf  
42 known as Kranz anatomy facilitates the compartmentation of carboxylation and decarboxylation (Figure  
43 1A). There are three basic biochemical pathways defined by the predominant  $C_4$  acid decarboxylase that  
44 releases  $CO_2$  around RuBisCO, but there are also at least 25 forms of Kranz anatomy documented (Figure 1A  
45 and 1B).

46 Progress in understanding  $C_4$  leaf anatomy has recently been critically assessed [8]. Here we focus on  
47 how deep sequencing is influencing our understanding of  $C_4$  biochemistry and argue that combined with  
48 allied technologies it is opening up a new era of  $C_4$  research. These approaches are helpful for at least three  
49 reasons. First, many years of mutant screens, biochemistry and molecular biology have so far failed to  
50 unlock many of the molecular components that regulate or induce the  $C_4$  system [9,10], sequencing offers  
51 the opportunity to identify candidate genes for these traits. Second, the  $C_4$  pathway should correctly be  
52 viewed as a system. Deep sequencing now makes it possible to move from analysis of individual genes and  
53 their gene products, to assessing the simultaneous behaviours of both the system and its components.  
54 Third, computational advances that have been driven by deep sequencing datasets provide the opportunity  
55 to study the natural diversity of all  $C_4$  lineages, rather than being limited to well-studied 'model' species for

56 which genome sequence is available. With this as background, we now assess how deep sequencing has  
57 influenced the understanding of core components of the C<sub>4</sub> cycle, the *trans*-factors likely responsible for  
58 their compartmentation between mesophyll (M) and bundle sheath (BS) cells of the C<sub>4</sub> leaf, and also the  
59 evolutionary processes that have governed the transition from the ancestral C<sub>3</sub> photosynthetic system to  
60 the derived C<sub>4</sub> metabolic pathway.

## 61 **Defining mRNAs associated with C<sub>4</sub> photosynthesis**

62 Approximately forty genes encoding core C<sub>4</sub> cycle enzymes and components of the Calvin-Benson-  
63 Bassham cycle (CBB) have long been known to be involved in C<sub>4</sub> metabolism. RNA-seq has been used to  
64 report mRNA signatures associated with the 'NAD-ME', 'NADP-ME' or 'PEPCK' biochemical sub-types [11–  
65 13], and along with theoretical and modelling approaches, has provided clear evidence that often two of  
66 the decarboxylases operate in parallel, with their relative contributions varying depending on conditions  
67 [14–17]. However, our understanding of what changes leaf anatomy such that contact between tissues  
68 involved in carbon assimilation and reduction is increased (Figure 1A), and also what sets up and then  
69 maintains the patterns of gene expression required for the C<sub>4</sub> cycle are rudimentary. These factors are  
70 important, as an understanding of C<sub>4</sub> genetics has implications for strategies being adopted to engineer the  
71 pathway into C<sub>3</sub> crop species, dictating whether efforts should be focused on alterations to individual  
72 genes, transcriptional regulators or hormone metabolism and signalling. Deep sequencing has allowed  
73 estimates of the extent to which global patterns of mRNA abundance differ between C<sub>3</sub> and C<sub>4</sub> leaves. This  
74 approach was initiated in the *Cleomaceae*, which in addition to containing C<sub>3</sub> and C<sub>4</sub> species, is  
75 phylogenetically the closest-C<sub>4</sub>-containing clade to C<sub>3</sub> *Arabidopsis thaliana* [18]. 603 genes showed  
76 differential mRNA abundance in C<sub>4</sub> compared with C<sub>3</sub> leaves [12]. Furthermore, in addition to confirmation  
77 that mRNAs encoding core C<sub>4</sub> and CBB cycles were up and down-regulated respectively, previously  
78 unidentified characteristics of the C<sub>4</sub> leaf as well as new components of the C<sub>4</sub> cycle were reported. For  
79 example, reduced abundance of mRNAs encoding ribosomal sub-units in C<sub>4</sub> compared with C<sub>3</sub> leaves was  
80 reported [12], while *BASS2*, which was subsequently shown to encode the long-sought-after pyruvate  
81 transporter associated with C<sub>4</sub> photosynthesis was up-regulated [19]. Subsequent analysis has led to  
82 increased numbers of genes being linked to the C<sub>4</sub> cycle [13] and Table 1. The highest reported differences  
83 in transcript abundance between C<sub>3</sub> and C<sub>4</sub> tissues are derived from *Eleocharis*, a species that is able to  
84 switch from C<sub>3</sub> to C<sub>4</sub> depending on whether it is aquatic or terrestrial (Table 1). However, a proportion of  
85 the mRNAs reported to be differentially abundant in C<sub>4</sub> compared with C<sub>3</sub> *Eleocharis* are likely associated  
86 with the different light and temperature conditions caused by the aquatic to terrestrial switch [20].

87 Comparison of estimates of the number of changes associated with each of the three biochemical sub-  
88 types (Figure 1) led to suggestions that establishment of the PEPCK C<sub>4</sub> sub-type requires the fewest  
89 changes, in part because of reduced requirements for alterations in photosystem accumulation between  
90 mesophyll and bundle sheath cells [11]. An overview of statistics from these studies (Table 1) shows that as  
91 sequencing depths have increased there has been an increase in the predicted number of differentially  
92 expressed genes, likely due to better quantification of low abundance transcripts. However, as no  
93 annotated genomes were available for these species, the data are based either on cross-species mapping of  
94 reads, or gene models created by *de novo* transcriptome assembly [21–23]. Both of these approaches  
95 introduce inaccuracy compared with direct read mapping to a well-annotated genome. It is important to  
96 note that the absolute number of differentially expressed genes detected through congeneric comparisons

97 is clearly dependent on the phylogenetic distance, statistical cut-offs, quality of transcriptome assemblies  
98 and number of species sampled (Table 1). As the number of independent C<sub>4</sub> lineages that are assessed with  
99 RNA-seq increase, estimates of the conserved alterations to mRNA abundance will become more reliable.  
100 However, it is clear from the current estimates which range from hundreds to thousands of genes showing  
101 differential expression in C<sub>4</sub> compared with C<sub>3</sub> leaves, research needs to focus on identification of key  
102 transcription factors and signalling events that underlie these patterns of gene expression.

103

#### 104 **Compartmentation of gene expression between cell-types of the C<sub>4</sub> leaf**

105 As with analysis of any organ or tissue, the C<sub>4</sub> leaf is composed of multiple distinct cell types, and the  
106 specialisation of M and BS cells in C<sub>4</sub> leaves (Figure 1) is considered a hallmark of the C<sub>4</sub> pathway. The first  
107 publications on global mRNA populations of M and BS cells of C<sub>4</sub> leaves were conducted on maize and  
108 supported existing knowledge of genes known to be differentially expressed between these cell types  
109 [24,25]. Analysis of two independent C<sub>4</sub> lineages from the grasses indicated that the absolute abundance of  
110 mRNAs in M and BS cells of grasses that evolved C<sub>4</sub> photosynthesis independently was statistically more  
111 convergent than other differentially expressed genes [26]. This implies that strong selection pressures  
112 acted on genes associated with the C<sub>4</sub> pathway to generate very similar expression in separate C<sub>4</sub> lineages.  
113 As the M and BS transcriptomes of more C<sub>4</sub> species become available this quantitative convergence could  
114 be used to generate a predictive framework that allows unknown components of C<sub>4</sub> photosynthesis to be  
115 identified. Although it has long been clear that transcriptional, post-transcriptional and post-translational  
116 processes all play a part in generating the C<sub>4</sub> metabolic system [9], omics approaches are now initiating  
117 non-biased and systems level quantification of their importance. For example, quantitative proteomics and  
118 transcriptomics indicated that the ratio of each cognate protein to its mRNA varies during C<sub>4</sub> leaf  
119 development, and that the ratio is often highest where protein function is most relevant [27]. Taken  
120 together, these findings start to provide an oversight of the extent of post-transcriptional and post-  
121 translational regulation in the C<sub>4</sub> leaf.

122 Transcriptomic datasets derived from M and BS cells of C<sub>4</sub> leaves highlight an area of ignorance, namely  
123 the mRNA populations associated with these two cell types in leaves of ancestral C<sub>3</sub> plants. Without this  
124 information it has not been possible to define how much patterns of gene expression have altered in M and  
125 BS cells of C<sub>4</sub> compared with those cells in C<sub>3</sub> leaves. A major hurdle was our inability to isolate M and BS  
126 cells from C<sub>3</sub> leaves, however immunopurification of ribosomes from specific cell types [28] has initiated  
127 our understanding of the BS in C<sub>3</sub> *Arabidopsis thaliana*. Although it was previously known that veinal cells of  
128 C<sub>3</sub> plants possessed characteristics of C<sub>4</sub> photosynthesis [30,31], ribosome tagging and deep sequencing of  
129 associated mRNAs indicated that components of the C<sub>4</sub> cycle are also preferentially expressed in the C<sub>3</sub> BS  
130 [29]. This work also highlighted a role for the C<sub>3</sub> BS in sulphur metabolism, a characteristic that had  
131 previously been reported of the C<sub>4</sub> BS [32]. Thus, as more C<sub>3</sub> lineages are sampled, we will develop a much  
132 clearer understanding of the extent to which metabolic characteristics currently associated with C<sub>4</sub>

133 photosynthesis are actually ancestral and present in either M or BS cells of C<sub>3</sub> leaves. We therefore  
134 conclude that technologies are in place to significantly improve our understanding of M and BS cells in both  
135 C<sub>3</sub> and C<sub>4</sub> plants. Data from these approaches are being used to formulate models that relate to the  
136 molecular drivers associated with the repeated evolution of this complex trait, and it is this that will be  
137 explored in the next section.

138

### 139 **Insights into the molecular drivers of C<sub>4</sub> metabolism**

140 It has been clear for some time that prior to their recruitment into C<sub>4</sub> photosynthesis, the major proteins  
141 of C<sub>4</sub> photosynthesis typically accumulate at relatively low levels in a constitutive manner in C<sub>3</sub> leaves [33].  
142 Through comparison with a gene expression atlas of closely related species, it is now proposed that  
143 expression of orthologues to C<sub>4</sub> genes show a variety of expression patterns, and peak in various tissues, in  
144 the C<sub>3</sub> ancestral system [34]. Deep sequencing data has also now provided the insight into the extent to  
145 which genes of the C<sub>4</sub> cycle become co-regulated with photosynthesis genes in leaves of both C<sub>4</sub>  
146 monocotyledons and dicotyledons [23,35]. Overall, these data imply that during the evolution of C<sub>4</sub>  
147 photosynthesis, genes of the C<sub>4</sub> cycle are co-opted into the gene regulatory networks that govern  
148 photosynthesis gene expression in the ancestral C<sub>3</sub> state [23,34].

149 The identification of transcription factors responsible for these alterations in expression of genes  
150 encoding components of the C<sub>4</sub> cycle is an area where significant progress still needs to be made. However,  
151 comparative transcriptomics has now identified candidate regulators for the C<sub>4</sub> cycle in maize [24,25,35–  
152 37], *Setaria* [26,38], *Flaveria* [13] and *Gynandropsis gynandra* (formerly known as *Cleome gynandra*)  
153 [23,34]. Interestingly, independent lineages of C<sub>4</sub> plants appear to have up-regulated homologous  
154 transcriptional regulators in either M or BS cells. This has been reported for two independent lineages of C<sub>4</sub>  
155 grasses [26] but also for the C<sub>4</sub> dicotyledon *G. gynandropsis* and the C<sub>4</sub> monocotyledon maize [23]. These  
156 data indicated that M or BS preferential expression is not only associated with parallel evolution of  
157 regulatory DNA [39] and histone marks [40], but also the recruitment of transcription factors [23,26].

158 Another striking finding facilitated by deep sequencing has been quantification of the extent to which  
159 specific members of multi-gene families are recruited into the C<sub>4</sub> pathway. This was initially reported after  
160 phylogenetic reconstructions of individual genes such as *PEPC* [41], but the extent of this process was not  
161 clear. Transcriptomics has now quantified this phenomenon in *Alloteropsis*, which contains C<sub>3</sub> and C<sub>4</sub>  
162 subspecies [42]. In maize and *Setaria*, which represent two independent lineages of C<sub>4</sub> grass, 87% of C<sub>4</sub>  
163 cycle proteins that are up-regulated in C<sub>4</sub> leaves are syntenic orthologues, indicating that the same  
164 ancestral gene has repeatedly been recruited into the pathway [26]. Again, the mechanism behind this  
165 phenomenon is not clear, but it is possible that these orthologues are repeatedly used into the C<sub>4</sub> pathway  
166 because they are part of pre-existing gene regulatory networks that are recruited into C<sub>4</sub> photosynthesis.  
167 These data further emphasize that the highly complex C<sub>4</sub> photosynthesis trait is underpinned by a mixture  
168 of both convergent and parallel evolution [39,42].

169 The combination of deep sequencing and metabolic flux modelling has demonstrated the power of an  
170 integrated approach, and lead to an enticing hypothesis concerning the repeated evolution of C<sub>4</sub>  
171 photosynthesis. Comparing C<sub>3</sub>, C<sub>3</sub>-C<sub>4</sub> and C<sub>4</sub> species in *Flaveria*, RNA-seq data coupled to metabolic  
172 modelling predicted that loss of the full photorespiratory pathway in the M cells of C<sub>3</sub> plants, which is the  
173 most common biochemical alteration thought to initiate C<sub>4</sub> evolution [2], leads to a nitrogen imbalance  
174 between M and BS cells [43] (Figure 2). The most parsimonious alterations to central metabolism that  
175 corrects this imbalance in the leaf is to induce, and compartment, the key components of the C<sub>4</sub> cycle into  
176 either M or BS cells (Figure 2). These data strongly imply that the metabolic remodelling during these early  
177 stages of C<sub>4</sub> evolution represent an evolutionary exaptation that was initially not related to photosynthetic  
178 efficiency *per se*. Thus, it now appears that metabolic and also morphological alterations to C<sub>3</sub> leaves were  
179 both unrelated to photosynthesis [5,42,44]. Later in the evolutionary process it is thought that each  
180 alteration to the C<sub>4</sub> cycle leads to a steady increase in photosynthetic performance [45], and this is then  
181 followed by evolutionary fine-tuning mediated by amino acid substitutions that modify allosteric regulation  
182 of these proteins for the C<sub>4</sub> leaf [46]. In the future, deep sequencing will also allow us to determine whether  
183 parallel changes to amino acids are associated with parallel or convergent evolution to the nucleotides  
184 encoding them. Moving ahead, perhaps a similar combined modelling, sequencing and hormone approach  
185 is required to make progress in understanding the molecular basis of Kranz anatomy.

186

### 187 *Summary*

188 The use of deep sequencing in C<sub>4</sub> research is in its infancy, and so far is mostly limited to RNA-seq. It is  
189 also true that the initial phase has identified many genes that could be important for C<sub>4</sub> photosynthesis, but  
190 for which functional analysis has not yet been undertaken. However, it is clear that use of deep sequencing  
191 has initiated an unbiased and objective study of C<sub>4</sub> photosynthesis in species that previously lacked any  
192 transcriptomic or genomic resources. As outlined above, deep sequencing and improved computational  
193 pipelines for data analyses have started to provide significant new insight. This includes defining core  
194 components of the C<sub>4</sub> cycle, identifying variations in C<sub>4</sub> metabolism both within and between species, and  
195 also providing inference into evolutionary mechanisms associated with the polyphyletic appearance of this  
196 highly complex system.

325 **Figure Legends**

326 **Figure 1:** Schematics illustrating variation in leaf anatomy and C<sub>4</sub> biochemical cycles of C<sub>4</sub> leaves. **A.**  
 327 Diagrams representing transverse sections through a C<sub>3</sub> leaf, and four anatomical variations in Kranz  
 328 anatomy. Images are based on those reported by [47]. B. The three main cycles that have classically been  
 329 used to define the three biochemical sub-types of C<sub>4</sub> photosynthesis. AlaAT = Alanine aminotransferase,  
 330 AspAT = Aspartate aminotransferase, CA= Carbonic anhydrase, PEPC = Phosphoenolpyruvate carboxylase,  
 331 PEPCCK = Phosphoenolpyruvate carboxykinase, NADP-MDH = NADP-dependent malate dehydrogenase,  
 332 NADP-ME = NADP-dependent malic enzyme, NAD-ME = NAD-dependent malic enzyme, PPKK =  
 333 Pyruvate,orthophosphate dikinase, CBB = Calvin Benson Bassham cycle, Ala = alanine, Asp = aspartate, Mal  
 334 = malate, OAA = oxaloacetic acid, Pyr = Pyruvate, PEP = phosphoenolpyruvate.

335

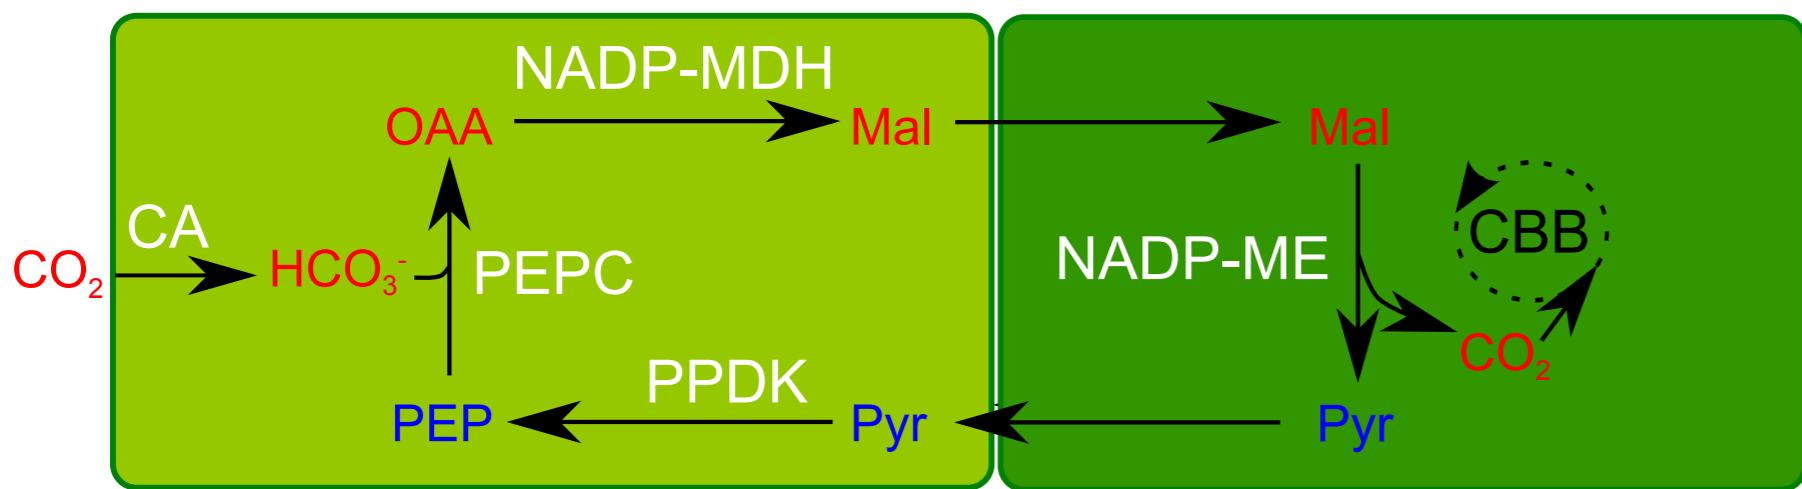

336 **Figure 2: Impacts of deep sequencing on understanding C<sub>4</sub> metabolism.** Representation of model  
 337 predicting initial events associated with the evolution of C<sub>3</sub>-C<sub>4</sub> intermediacy (based on [43]). Loss of  
 338 photorespiration in the mesophyll cells would lead to lead to an imbalance in nitrogen metabolism  
 339 between mesophyll and bundle sheath cells, and accumulation of ammonia (yellow circle) in the bundle  
 340 sheath. Upregulation of a C<sub>4</sub>-like pathway rebalances this nitrogen imbalance. The three panels represent  
 341 photorespiration (C<sub>2</sub> cycle) operating in both mesophyll and bundle sheath cells of a C<sub>3</sub> leaf (A), the C<sub>2</sub> cycle  
 342 being lost in the mesophyll cells of C<sub>3</sub>-C<sub>4</sub> intermediate species, and the subsequent development of a C<sub>4</sub>-like  
 343 cycle (B), and finally complete implementation of the C<sub>4</sub> cycle (C). Abbreviations as in Figure 1, as well as  
 344 Glu = glutamate, Gly= glycine, 2-OG = 2-oxoglutarate, Ser = serine. Dashed lines indicate low metabolic flux.  
 345 Red circles represent carbon atoms while yellow circles represent amine groups.

	Bräutigam et al. (2011) <sup>12</sup>	Gowik et al. (2011) <sup>13</sup>	Bräutigam et al. (2014) <sup>11</sup>	Chen et al. (2014) <sup>20</sup>
Total number of DE transcripts	603	3582	1168	8848
Transcripts more abundant in C <sub>3</sub>	258	1418	792	4184
Transcripts more abundant in C <sub>4</sub>	345	2164	376	4664
% Transcriptome DE	1.4	NA*	6.1	13.5

**Table 1: Comparisons of transcript abundance in closely related C<sub>3</sub> versus C<sub>4</sub> photosynthetic tissues.** The total number of transcripts annotated as being differentially expressed (DE) in each study is listed, along with the numbers up or down regulated. Data expressed as percent of the total transcriptome are also reported for each study. Bräutigam *et al.* 2011 assessed C<sub>4</sub> *Gynandropsis gynandra* versus C<sub>3</sub> *Tarenaya hassleriana*. Gowik *et al.* 2011 assessed C<sub>4</sub> *Flaveria bidentis* and *Flaveria trinervia* as well as C<sub>3</sub>-C<sub>4</sub> *Flaveria ramosissima* and C<sub>3</sub> *Flaveria pringlei* and *Flaveria robusta*. Bräutigam *et al.* 2014 assessed *Panicum maximum* and *Dicanthelium clandestinum*. Chen *et al.* 2014 assessed C<sub>4</sub> and C<sub>3</sub> culms of *Eleocharis baldwinii*. \*NA: the values for DE transcripts were based on multispecies comparisons which prohibits expressing the number of DE transcripts as a percentage of transcriptome.
