27 **Abstract**

28 Rabies virus (RABV) remains one of the most important global zoonotic pathogens. RABV
29 causes rabies, an acute encephalomyelitis associated with a high rate of mortality in humans
30 and animals and affecting different parts of the world, particularly in Asia and Africa.
31 Confirmation of rabies diagnosis relies on laboratory diagnosis, in which molecular
32 techniques such as detection of viral RNA by reverse transcription polymerase chain reaction
33 (RT-PCR) are increasingly being used.

34 In this study, two real-time quantitative RT-PCR assays were developed for large-spectrum
35 detection of RABV, with a focus on African isolates. The primer and probe sets were targeted
36 highly conserved regions of the nucleoprotein (N) and polymerase (L) genes.

37 The results indicated the absence of non-specific amplification and cross-reaction with a
38 range of other viruses belonging to the same taxonomic family, *i.e Rhabdoviridae*, as well as
39 negative brain tissues from various host species. Analytical sensitivity ranged between 100 to
40 10 standard RNA copies detected per reaction for N-gene and L-gene assays, respectively.
41 Effective detection and high sensitivity of these assays on African isolates showed that they
42 can be successfully applied in general research and used in diagnostic process and epizootic
43 surveillance in Africa using a double-check strategy.

59 **1. Introduction**

60

61 Rabies is a lethal and neglected zoonotic disease with significant public health impact in
62 many parts of the world, especially in developing countries (1, 2). Rabies can affect
63 almost all mammals, including humans (3). Indeed, rabies causes at least 59,000 human
64 deaths annually worldwide, with 36.4% of them occurring in Africa alone (1, 4).
65 Human exposures occur mainly through dog bites and children are the most affected by the
66 disease, with 4 out of every 10 deaths occurring in children under the age of 15 (3, 5).
67 However, in some industrialized countries, rabies virus transmission was also reported
68 through transplantation of organs from donors whose rabies infection had not been
69 recognized. These cases of rabies virus transmission by tissues transplantation were mostly
70 due to a long incubation period in the donor (6, 7, 8).
71 Rabies is an incurable disease and clinical presentation in humans can be sometimes difficult
72 to distinguish from encephalitis symptoms caused by other viral infections (9). In this context,
73 laboratory diagnosis is essential to confirm the diagnosis (10). Moreover, the diagnosis of
74 rabies is often confirmed late in the course of the disease or *postmortem* because prognosis
75 depends on history of exposure and clinical findings, and timely and reliable diagnosis may be
76 very important for the prevention of rabies in the relatives of the patient and the healthcare
77 workers.
78 This fatal encephalitis is caused by virus members of the *Lyssavirus* genus (order
79 Mononegavirales, family *Rhabdoviridae*) including *Rabies virus* (RABV). RABV is a
80 neurotropic enveloped pathogen encompassing a negative single-stranded RNA that is around
81 12 kb (kilobases) in size. As for all lyssavirus members, the RABV genome encodes five
82 proteins with the nucleoprotein (N), the phosphoprotein (P), the matrix protein (M), the
83 glycoprotein (G) and the polymerase (L) separated by four non-coding intergenic regions
84 (IGRS) of different lengths and surrounded by two untranslated regions (UTR) (5). In
85 addition, RABV presents a wide range of animal host reservoir and a large genetic diversity,
86 with particularly four phylogenetic groups circulating in Africa with Africa 1 and 4 lineages,
87 and with Africa 2 and 3 clades (11, 12). Thus, diagnostic tools which are able to broadly
88 detect RABV are required.
89 Currently, the "gold standard" technique for confirming *postmortem* cases is the direct
90 fluorescent antibody test (FAT) (13, 14). For *intra-vitam* diagnosis, this method can detect
91 viral nucleocapsid antigens in tissues section of skin biopsies. However, viral antigens are
92 often only detectable at the final phase of the disease and not always by the FAT. Also, this

Accepted Manuscript

ACCEPTED MANUSCRIPT

93 technique presents limits in the case of *ante-mortem* non-neural sample material or
94 decomposed tissues. Furthermore, repeated sampling of skin biopsies is not practical for
95 improvement of sensitivity of the FAT (10, 14, 15). To overcome the limits of FAT, several
96 conventional and hemi-nested reverse transcription polymerase chain reaction assays (RT-
97 PCR) targeting the N or L gene, have been developed (16, 17, 18, 19, 20, 21, 22) and widely
98 applied for *the intra-vitam* diagnosis of human rabies routine diagnosis. Indeed, the N gene is
99 the most conserved region among the RABV genome which is the reason for its frequent use
100 as target for rabies virus diagnostic assays (23). Also, the L gene harbours highly conserved
101 regions which have targeted for molecular detection (22, 24). Despite a higher sensitivity,
102 hemi-nested RT-PCR presents some disadvantages in terms of workload, risk of
103 contamination, and time. Thus, several real time molecular tests targeting the N or L gene
104 have been developed to complement conventional diagnosis of rabies and rabies-related
105 viruses (10, 21, 25, 26, 27, 28, 29, 30). However, none of them have been validated against
106 African strains from a large diversity of geographical origins, except a recent study (31).
107 In this paper, we describe the validation of two sensitive and specific real-time RT-PCR
108 assays with TaqMan probes targeting conserved regions of the N and L genes, which were
109 developed for broad detection of African RABV strains. The detection capacity on clinical
110 specimens and sensitivity of the assays suggest their suitable application in human as well as
111 veterinary diagnostic fields. The assays could complement and add value to existing methods.
112

113 **2. Materials and methods**

114

115 **2. 1. Primers and probes design**

116 Initially, in order to design an assay capable of detecting African RABV isolates, full length
117 genome sequences of two Africa 2 isolates available on GenBank database, corresponding to
118 DRV-NG11 (GenBank Ac. No. KC196743) and CAR_11/001h (GenBank Ac. No.
119 KF977826), were used. Multiple alignments were carried out using clustalW algorithm
120 implemented in the Mega 6.0 software (32). We selected conserved regions of the N gene and
121 the L gene for development of two detection systems. Both primers and TaqMan probes were
122 designed using Primer3web® software (version 4.0.0, Whitehead Institute for Biomedical
123 Research). To avoid non-specific cross-reactions with others lyssaviruses, primers and probe
124 were validated by BLAST analysis on NCBI. To ascertain their broad spectrum of detection,

ACCEPTED MANUSCRIPT

125 all primers and probes were analyzed *in silico* with sequences of a large panel of isolates from
126 different parts of Africa. Primers and probes were synthetized by TIBMol-Biol (Berlin,
127 Germany).

128

129 **2. 2. Samples and viral RNA extraction**

130 A total of 16 RABV isolates from experimentally infected mouse brain tissues preserved in
131 the archive of the national reference center for rabies virus (NRC-Rabies) at Institut Pasteur of
132 Dakar, Senegal (NRC-Rabies IPD) and previously confirmed as rabies positive by FAT, was
133 used in this study. In addition, 61 other RABV isolates from FAT-confirmed primary brain
134 samples or experimentally infected mouse brain samples, provided by the NRC-Rabies at
135 Institut Pasteur, Paris, France (NRC-Rabies IPP) (14), were also included. Furthermore, in
136 order to assess the specificity of the two RABV detection assays, a panel of 20 primary brain
137 specimens provided by NRC-Rabies IPP from a range of important animals for rabies virus
138 transmission, and previously confirmed to be negative by FAT, was also tested. In addition,
139 15 other major representatives of rhabdoviruses other than RABV and from the archive of
140 NRC-Rabies IPD were also tested. Finally, 19 clinical specimens including skin biopsy, saliva
141 and cerebrospinal fluid (CSF) samples received at NRC-Rabies IPP and collected from human
142 patients suspected of rabies infection were evaluated with both of these molecular tools. All
143 extractions from isolates provided by NRC-Rabies IPD were performed using the QIAamp®
144 Viral RNA Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions.
145 The RNA was suspended in a final volume of 60 µl elution buffer and kept at –80°C until
146 testing. For samples and isolates provided by NRC-Rabies IPP, extraction and storage were
147 performed as previously described (31).

148

149 **2. 3. Real-time RT-PCR (RT-qPCR) assays**

150 A similar RT-qPCR protocol was used for the detection of both N and L genes. All samples
151 were tested in duplicate and RT-qPCR was performed using the Quantitect Probe RT-PCR kit
152 (Qiagen, Hilden, Germany) in a 20 µl reaction mixture containing 2x QuantiTect probe RT-
153 PCR master mix, 0.25 µl of QuantiTect RT mix, 400 nM PCR primers and 200 nM TaqMan
154 probes and 5 µl of 1:10 diluted RNA in RNase-free water. Positive controls containing master
155 mix with standard RNA of each system and negative controls consisting of master mix with
156 sterile RNase-free water were included in each run. The reaction was carried out on a 7500
157 Fast Real Time system cycler or on a 7500 Real Time system cycler (Applied Biosystems,

ACCEPTED MANUSCRIPT

158 Foster City, US) using the following temperature profile: 1 cycle of reverse transcription at
159 50°C for 10 min, 1 cycle of denaturation at 95°C for 15 min, followed by 40 cycles of 95°C
160 for 15 s and 60°C for 1 min. The RT-qPCR reactions were analyzed using the 7500 software
161 (v2.0.1).
162

163 **2. 4. Specificity testing**

164 The specificity, representing the probability that the assay gives a negative result without
165 presence of the targeted nucleotide region, was calculated by the formula $Sp = a / (a + c)$;
166 where **a** is the number of true negatives samples and **c** is the number of false positives. The
167 specificity was determined using a panel of FAT negative samples and a panel of non-RABV
168 rhabdoviruses.
169

170 **2. 5. Analytical sensitivity assessment**

171

172 **2. 5. 1. Standard curves generation**

173 Plasmids were generated by inserting the amplified RT-qPCR amplicons into pCRII (Life
174 Technologies, GmbH, Darmstadt) and standard RNAs were synthetized with T7 RNA-
175 polymerase by TIB MolBiol (Berlin, Germany) according to manufacturer's
176 recommendations.
177 Serial 10-fold dilutions of standard RNAs, from 10^8 to 1 molecule, were prepared in RNase-
178 free water. Corresponding mean Cq (quantification cycle) values obtained per triplicates per
179 standard dilution were then plotted proportionally to the logarithm of the input copy numbers
180 to generate a quantitative standard.
181

182 **2. 5. 2. Analytical testing**

183 The quantitative standards were used to evaluate the diagnostic assays performances such as
184 limit of detection (LOD), the coefficient of correlation (R^2) and the amplification efficiency
185 (E) values. The LOD value represents the concentration where at least 50% of replicates of
186 each dilution were detected. A linear model regression test was performed using R (version
187 3.0.2, *The R Foundation for Statistical Computing*) to determine the value of R^2, indicating
188 the goodness of regression. The E value was calculated with the formula $\mathbf{E = 10^{(-1/slope)}-1}$.
189 Relative RABV genome copies in tested samples was calculated through the formula **q=**

Accepted Manuscript

ACCEPTED MANUSCRIPT

190 $\mathbf{10^{(Cq-b)/a}}$; where **a** is the slope, **b** is the intercept from a standard curve of each specific
191 target gene and **Cq** is the quantification cycle number. Furthermore, the Pearson correlation
192 efficient where a coefficient of 1 represents a good correlation was also calculated.
193
194 **2. 5. 3. Determination of sensitivity**
195 The sensitivity is defined as the probability that an assay give positive results in the presence
196 of specific target. This was calculated by the formula **Se = d/ (d+b)**; where **b** represents the
197 number of false negatives and **d** is the number of true positives. Positive and negative
198 predictive values were also calculated by formulas **PPV= d / (d+c)** and **NPV= a/ (b+a),**
199 where **a** is the number of true negatives samples and **c** is the number of false positives**.**
200 Moreover, a **ROC** («Receiver Operating Characteristic») analysis was performed, using the
201 statistical software XLSAT (Version 2015.5.01.23654, *Copyright Addinsoft 1995-2015*) to
202 identify the threshold value below which the test should be considered positive. Accuracy of
203 assays was measured by the area under the ROC curve **(AUC)** with 95% confidential interval
204 (CI) of AUC. An area higher than 0.9 represents an excellent test and a value of 0.5, a
205 worthless test (33, 34).
206 Finally, the comparability between Cq values given by these two quantitative assays was
207 assessed using a Bland-Altman analysis where the agreement between these two
208 measurements was quantified by using a graphical approach. Statistical limits of agreement
209 are calculated by using the mean and the standard deviation of the differences between assays
210 with 95% CI (35).
211
212 **2. 5. 4. Repeatability and inter-laboratory concordance**
213 The inter-assay and intra-assay repeatability were determined by coefficients of variation
214 (**CVs**) of Cq value. Indeed, RNA of the RABV isolate SA217695SEN was extracted and
215 amplified 10 times in the same run, for the assessment of intra-assay repeatability and in 10
216 different runs by the same operator, in the same laboratory to evaluate inter-assay
217 repeatability. Inter-laboratory concordance was evaluated using a range of anonymous
218 samples which have been initially received, extracted and analyzed at the NRC-R IPP in the
219 framework of its participation in 2015 in an inter-laboratory trial organized by the European
220 Union reference laboratory for rabies, which is located in Nancy, France (36). The test panel
221 tested with the two newly developed RT-qPCR consisted of nine anonymous samples, either
222 uninfected or infected with various lyssavirus species and which have been previously

Accepted Manuscript

ACCEPTED MANUSCRIPT

223 extracted by NRC-R IPP and storage at -80°C until use. Details of this trial have been
224 provided elsewhere (36).
225 Results obtained with both of these tools were compared to previous RT-qPCR results of the
226 NRC-R IPP in terms of Cohen's kappa coefficient ***(k)***, which is measure of the agreement
227 between two raters. Statistical analysis was performed using XLSAT where the statistical
228 significance was set to $p < 0.05$.
229

230 **2. 5. 5. Comparison with conventional hemi-nested RT-PCR**

231 Suckling newborn-mices were inoculated experimentally by the RABV isolate
232 SA217695SEN and a virus titer of 6.7 10^7 ID_{50}/mL was obtained according to the method of
233 Reed and Muench (1938) (37). Ten-fold serial dilutions of this virus stock were used to
234 compare the sensitivity of the two RT-qPCR methods with that of a conventional hemi-nested
235 RT-PCR (RT-hnPCR) in the conditions which have been previously described (22).
236

237 **2. 5. 6. Clinical sensitivity testing**

238 Testing of a collection of nineteen RABV-positive or negative specimens including CSF,
239 saliva and biopsy skin, was also carried out in duplicate to confirm the reliability of the new
240 L-gene RT-qPCR.
241
242

243 **3. Results**

244

245 **3. 1. Primers analysis**

246 BLAST analysis of designed primers and probes showed high homology with target regions
247 of RABV sequences available from GenBank database. *In silico* analysis also revealed limited
248 number of mismatches for primers and probes with sequences from other parts of Africa
249 belonging to lineage Africa 1 and clade Africa 2 (Supplementary **Table A.1**) (Supplementary
250 **Figures A.1 and A.2**). The TaqMan probes were labeled 5' FAM (6-carboxyfluorescein) / 3'
251 BlackBerry Quencher (BBQ) and details are listed in **Table 1**.
252

253 **3. 2. Specificity**

ACCEPTED MANUSCRIPT

254 In order to ensure the specificity of the new systems and to evaluate the occurrence of non-
255 specific cross-reactivity, 16 isolates previously characterized RABV field samples and 15
256 different rhabdoviruses other than RABV species were tested in duplicate with both of the
257 assays (**Table 2**). Fluorescent detection was obtained only with RABV isolates whereas non-
258 targeted viruses were not detected. These results suggested that the designed primer pairs and
259 probes exhibited no cross-reactivity with other species of lyssavirus (with Mokola and Lagos
260 bat lyssaviruses) or other rhabdoviruses (**Table 2**). The amplicons size for some RABV
261 isolates detected with each system was verified by 2% agarose gel electrophoresis and the
262 amplified fragments were sequenced using the respective forward and reverse primers of the
263 corresponding systems. A BLAST analysis of obtained sequences showed high identity rate
264 with the target region of the RABV isolate CAR_11/001h (GenBank Ac. No. KF977826)
265 belonging to the Africa 2 phylogenetic clade. Then, these primers and probes were highly
266 selective for RABV detection. In addition, we analyzed a panel of 20 FAT-negative primary
267 brain samples from different vertebrate hosts important in RABV transmission. All were
268 negative with both assays and confirmed that specificity was complete (Supplementary **Table**
269 **A.2).**

270

271 **3. 3**. Analytical **sensitivity**

272 Diagnostic test performances of the new assays were assessed using several parameters.
273 Analytical curves generated showed a LOD of 100 and 10 copies per reaction obtained for N-
274 gene assay and L-gene assay, respectively with RABV isolate SA217695SEN (**Figure 1**).
275 Regression line slope values were determined for N gene and L gene assays, with -3.08 and -
276 3.1, respectively, which are close to the optimal slope value of -3.3. Significant respective
277 linear regression p-values of 1.833e-09 and 6.977e-12 for N gene and L gene assays,
278 respectively, and coefficients of correlation ($\mathbf{R^2}$) values higher than 0.99 indicated the
279 goodness of the regression lines. Furthermore, high efficiency values (**E**) were obtained with
280 both of these assays. A Pearson correlation test between the two regression curves revealed a
281 coefficient of 0.99 ($p < 0.0001$) suggesting that correlation between the Cq values obtained by
282 both RT-qPCR methods was excellent (**Figure 1**).
283 To ascertain the broad detection capacity of established assays, various RABV isolates from
284 different parts of the world, were tested. Considering detection of African RABV isolates, the
285 L-gene system was able to detect all isolates tested while the N-gene assay detected only 90%
286 of strains giving no-fluorescence signal with four isolates belonging to Africa-1 lineage,

ACCEPTED MANUSCRIPT

287 including isolates from Somalia (93002SOM and 93006SOM), Tanzania (96013TAN) and
288 Morocco (87012MAR) (**Table 3a**). Furthermore, the L-gene system also detected 100% of
289 tested isolates from other counties of the world. Considering these isolates, the N-gene assay
290 had a limited detection scale (55%) with no fluorescence signal with 9 isolates from Poland
291 (96140POL), Germany (92001GER), Saudi Arabia (87001ARS), Turkey (94009TUR), Laos
292 (99008LAO), Afghanistan (02052AFG), Russia (91041RUS) and one skunk isolate from
293 USA (91004USA) (**Table 3b**) (38).
294 Results of all previous tests summarized in **Table 4** were used for sensitivity determination
295 and ROC analysis as previously described (39). A sensitivity of 100% and 78.70% (CI 95%;
296 68.40-89.00%) was found for the RABV L-gene assay and RABV N-gene assay, respectively,
297 when compared to the reference technique. In addition, a PPV of 100% for each assay and
298 NPVs of 100% and 72.91% (CI 95%; 56.76-82.79%) for L gene assay and N gene assays
299 were obtained respectively (Fischer's exact test $p < 0.0001$). All previously FAT- negative
300 samples provided an undetermined mean Cq value after 40 cycles. Based on the results of the
301 ROC analysis, we determined a Cq of 39.70 as the cut-off value below which reactions are
302 positives for the L-gene assay and the N-gene assay, considering a 95% confidence interval.
303 A Cq value above these cut-off values or an undetectable Cq was considered negative. An
304 AUC of 1 was determined for each assay revealing that the tests have an excellent accuracy
305 (**Figure 2**). Furthermore, Bland-Altman plot analysis also reported a non-significant bias
306 (mean difference) of 1.920 ± 6.875 (95% limits of agreement: -11.56 to 15.40), demonstrating
307 that these two methods are approximatively equivalent (**Figure 3**).
308 Intra-run and inter-run CVs of 1.67 % and 2.20 %, respectively, were found for the RABV N-
309 gene assay while the RABV L-gene assay showed intra-run and inter-run CVs of 1.08 % and
310 2.16 %, respectively; indicating that assays are robust and highly repeatable(**Table 4**). In
311 addition, the ***k*** of 1 ± 0.31 (95% CI; 0.38-1.61) indicates that assays are accurate, detecting
312 only RABV strains and giving 100% concordance to previous results obtained by the NRC-R
313 IPP using a RT-qPCR (31) with the same samples ($p= 0.001$), and concordant with the results
314 expected for this inter-laboratory trial with RABV isolates (**Table 5**).
315 Simultaneously, both RT-qPCR assays and conventional hemi-nested RT-PCR were
316 performed as previously described (22) on 13 ten-fold dilutions of the RABV isolate
317 SA217695SEN with a titer of 6.7 10^7 ID_{50}/mL. The RABV L-gene assay detected until
318 0.00067 ID_{50}/mL, corresponding to 28 genome copies using the L-gene quantification
319 equation. However, conventional hemi-nested RT-PCR and RABV N-gene assay presented a

Accepted Manuscript

ACCEPTED MANUSCRIPT

320 detection limit of 6.7 ID_{50}/mL, corresponding to 75 copies of genome using N-gene
321 quantification equation (**Table 6**).
322 The RABV L-gene RT-qPCR assay was selected as the most sensitive technique for detection
323 of RABV and was thus applied for the screening of human clinical samples from patients
324 suspected of rabies infection. The clinical detection of RABV RNA was analyzed in duplicate
325 using a panel of human samples from the archive of the NRC-R IPP and which were
326 previously tested using a RT-qPCR assay (31). Compared to the latter technique considered as
327 the reference test, all 4 previous RABV-positive samples were correctly detected with RABV-
328 L TaqMan probe assay, whereas any cross-reactivity was detected with all 15 RABV-negative
329 specimens. Thus, the proposed RABV-L gene assay gave a 100% concordance to the previous
330 diagnosis results obtained with the RT-qPCR assay performed by NRC-R IPP (31),
331 demonstrating its effectiveness to detected RABV in clinical specimens with high sensitivity,
332 and its suited use as diagnostic tool in human RABV cases (**Table 7**).
333
334
335 **4. Discussion**

336 Despite rapid and sensitive RABV methods developed in recent years (27, 28, 30, 31, 42),
337 only a few of them have been validated for the detection of African RABV strains with a large
338 diversity of origin (21, 30, 31). Development of rapid and suitable molecular diagnostic tools
339 for large-scale detection RABV isolates is important for routine diagnostic testing and
340 epidemiological surveillance, particularly in Africa where rabies remains endemic. In this
341 study, we developed two TaqMan real-time assays for broad detection of African RABV
342 isolates in samples and for *intra-vitam* diagnosis in humans and *post-mortem* diagnosis in
343 animals. These assays are based on conserved regions on N and L RABV genes.
344 Oligonucleotide sequences for each assay were designed for wide detectability of African
345 RABV isolates (**Table 1,** Supplementary **Figures A.1** and **A.2**) (22). Regarding the specificity
346 assessment and their selectivity to detect RABV on a large range of samples, the new primers
347 pairs and probes showed a high specific rate and no cross detection of other tested
348 rhabdoviruses and none of the 6 other lyssaviruses species tested. These results were also
349 confirmed by sequencing a selected number of amplicons obtained from positive results.
350 Moreover, evaluation of the analytical sensitivity proved that assays can detect a low amount
351 of RABV RNA with estimated LODs ranging from 100 to 10 copies of RNA target per
352 reaction, which indicates that our assays are highly sensitives, similar to previously reported

ACCEPTED MANUSCRIPT

353 assays for viral RNA detected by TaqMan real-time RT-PCR (21, 31, 40, 41, 42). In addition,
354 the high coefficients of determination (**R^2**) and very good efficiencies (**E** >100%) demonstrate
355 that they can both be successfully applied to quantitative analysis of viral loads in tested
356 samples infected with RABV.
357 However, with the high genetic diversity of RABV, development of a single sensitive real
358 time assay covering all widely known phylogroups remains a challenge (43, 27). During the
359 validation of the N-gene and L-gene based RT-qPCR assays, the broad detection spectrum
360 was assessed through a large panel of RABV isolates representing different continents, with a
361 focus on African isolates. Indeed, African strains were detected by both assays with a high
362 coverage rate, mainly with the L gene-based assay. Thus our assays offer good performances
363 on detection of African isolates and could be a useful complement for a recent published
364 method (31) which presents some limits in detection of RABV isolates from Senegal
365 belonging to the Africa 2 clade. Evaluation of the broad detection performance of our assays
366 on isolates from other regions of the world displayed an excellent coverage level of the
367 RABV L-gene RT-qPCR, whereas the RABV N-gene assay was limited with important non-
368 African RABV strains. The reduced sensitivity of the N-gene assay despite good *in silico*
369 profiles and performance demonstrated by the assays could be explained with the presence of
370 secondary structure formation of the target area which may make it less accessible for the N-
371 gene oligonucleotides during the RT-step (44, 45). All the RABV isolates tested (61 isolates
372 belonging to the phylogenetic lineage cosmopolitan and clades Africa 2 and 3) were
373 successfully detected, mainly with the L gene-based assay which provides a test with a large
374 spectrum of RABV detection.
375 Although in the comparative analysis, the L gene-based assay offered better performances
376 than the N-gene assay regarding sensitivity and predictive values, it seems reasonable to
377 perform a double-check strategy on tested samples, using both assays in order to increase
378 reliability during use in routine rabies identification or epidemiological surveys as previously
379 reported for others lyssaviruses (46, 31). Moreover, high AUC value found in ROC analysis
380 predicted that both assays are useful for accurate detection of RABV in positive samples.
381 Furthermore, the assays showed a good agreement between measurements as shown by the
382 Bland-Altman analysis results, confirming their ability to be used efficiently for RABV
383 detection. Additionally, inter-assay and intra-assay variability below 3% and strong inter-
384 laboratory concordance results ensure the repeatability and the RABV specificity of the two
385 assay systems. Our assays, particularly the L-gene based assay, could be used accurately in
386 different geographical contexts for RABV detection.

387 We used ten-fold dilutions of the RABV isolate SA217695SEN with a titer of 6.7 10^7
388 ID_{50}/mL and obtained with L-gene assay lower LOD value than with the hemi-nested RT-
389 PCR (22), although it has to be confirmed with a larger panel of isolates. The L-gene based
390 assay was able to detect RABV with as low as 6.7 10^{-4} ID_{50}/mL and could be successfully
391 applied in RABV diagnostic process, particularly on decomposed material or samples with
392 low viral load (15, 47). Furthermore, compared to the hemi-nested RT-PCR, the established
393 RT-qPCRs offer some important advantages in reduction of workload and run time, while
394 providing a higher sensitivity compared to the conventional RT-PCR.
395 Based on its better performances, the L gene-based assay was chosen for determination of the
396 detection capacity with clinical specimens in comparison with a previously existing RT-qPCR
397 (31) considered as the reference technique. We evaluated the usefulness of the L-gene based
398 assay for the *intra-vitam* diagnosis of rabies in human using a collection of positive and
399 negative specimens including skin biopsy, saliva and cerebro-spinal fluid. Compared to the
400 RT-qPCR assay from the NRC-R IPP (31) considered as the reference test, our L-gene based
401 assay provided a strong concordance and the sensitivity was also high. This technique could
402 be useful in clinical diagnostic as reliable quantitative tools for *ante-mortem* rabies diagnosis
403 in humans (22, 31).
404 Finally our assays, particularly the L-gene based assay, could be a complement for existing
405 methods for rabies diagnosis (21, 31, 46, 48, 49) with a high specificity, sensitivity and
406 repeatability and more suitable for broad detection of African RABV strains.

a: Expected results by European Union Reference Laboratory for Rabies during interlaboratory trial 2015 (36).

Assays detected only RABV strains and gave results 100% concordant with previous results obtained with the combo RT-qPCR (31) from NRC-R IPP, used as reference technique. A Cohen's kappa coefficient (k) of of 1±0.31 (95% CI; 0.38-1.61) (p= 0.001) were obtained.

Assays were also concordant with expected results of interlaboratory trial on the same samples.

Accepted Manuscript

593 ## Highlights

594 - Two reliable real-time quantitative RT-PCR assays were developed for RABV detection

595 - Primer and probe sets were targeted to highly conserved regions in nucleoprotein and
596 polymerase

597 - Sensitivity ranged between 100 to 10 standard RNA copies per reaction for N-gene
598 and L-gene assays, respectively.

599 - These assays can be successfully applied on African isolates for research and
600 diagnostic
