28 **Abstract**

29

30 The purpose of this study was to compare the effects of L-citrulline (CIT) and L-
31 arginine (ARG) supplementation on nitric oxide (NO) biomarkers, pulmonary O₂
32 uptake (\dot{V}_{O_2}) kinetics and exercise performance. In a randomised, placebo-controlled,
33 cross-over study, ten healthy adult males completed moderate- and severe-intensity
34 cycling exercise on days 6 and 7 of a 7 day supplementation period with placebo
35 (PLA), 6 g·day⁻¹ of ARG and 6 g·day⁻¹ of CIT. Compared to PLA, plasma [ARG]
36 was increased by a similar magnitude with ARG and CIT supplementation, but
37 plasma [CIT] was only increased ($P<0.001$) with CIT supplementation. Plasma nitrite
38 concentration ($[NO_2^-]$) was increased with ARG ($P<0.05$), and tended to increase with
39 CIT ($P=0.08$), compared to PLA (PLA: 83 ± 25, ARG: 106 ± 41, CIT: 100 ± 38 nM);
40 however, mean arterial blood pressure was only lower ($P<0.05$) after CIT
41 supplementation. The steady state \dot{V}_{O_2} amplitude during moderate-intensity cycle
42 exercise was not significantly different between supplements, but CIT speeded overall
43 \dot{V}_{O_2} kinetics (PLA: 59 ± 8, CIT: 53 ± 5 s; $P<0.05$) during severe-intensity exercise,
44 improved tolerance to severe-intensity exercise (PLA: 589 ± 101, CIT: 661 ± 107 s)
45 and increased the total amount of work completed in the exercise performance test
46 (PLA: 123 ± 18, CIT: 125 ± 19 kJ; $P<0.05$). These variables were not altered by
47 ARG supplementation ($P>0.05$). In conclusion, these results suggest that short-term
48 CIT, but not ARG, supplementation can improve blood pressure, \dot{V}_{O_2} kinetics and
49 exercise performance in healthy adults.

62 **Introduction**

63

64 The multifaceted physiological signalling molecule, nitric oxide (NO), can be
65 synthesised endogenously through the nitrate-nitrite-NO pathway (37) and through
66 the five-electron oxidation of L-arginine (ARG) in a reaction catalyzed by the nitric
67 oxide synthase (NOS) enzymes (55). While studies have shown that dietary nitrate
68 supplementation can increase NO biomarkers, reduce blood pressure and improve
69 exercise economy/efficiency and exercise tolerance in healthy adults (see 4 for
70 review), the extent to which these variables are impacted by dietary ARG
71 supplementation is less clear (see 1 for review). However, when ARG treatment
72 increases NO biomarkers, exercise economy and exercise performance are improved
73 (5, 52), whereas exercise economy and exercise performance are not improved when
74 ARG treatment does not influence NO synthesis (9, 31, 35). Therefore, while there is
75 some evidence to suggest that ARG treatment might improve physiological responses
76 in conjunction with elevated NO synthesis, an optimal ARG administration procedure
77 to enhance NO synthesis and associated physiological responses has yet to be
78 established.

79

80 A significant obstacle to increasing ARG delivery to NOS via ARG supplementation
81 is that orally ingested ARG is subjected to a number of presystemic and systemic
82 elimination processes. Approximately 40% of ingested oral ARG is catabolised by
83 intestinal bacteria and arginases on the first pass (13, 67), with a further 10-15% of
84 systemic ARG extracted and metabolized by the liver (13, 44, 48, 59, 71). While both
85 acute (57) and short term (34) ARG ingestion have been shown to increase plasma
86 [ARG], the intracellular utilisation of this additional substrate by NOS might be
87 restricted by the competition between ARG, asymmetric dimethylarginine (ADMA)
88 and other ARG analogues for the transporter, y^+ carrier hCAT-2B (14). This
89 regulation of ARG transport and metabolism could account for the finding that only ~
90 1% of an oral ARG dose is utilised as substrate by NOS (11). Based on these
91 restrictions, it appears that oral ARG supplementation might not be the optimal
92 method to stimulate NO production through the NOS pathway.

93

94 L-citrulline (CIT) is co-produced with NO as an end product of NOS activity. It is
95 well documented that NOS-derived CIT is efficiently recycled into ARG for

96 subsequent NO production through the CIT-NO cycle (24). Therefore, exogenous
97 CIT administration might represent an attractive alternative to increase ARG
98 provision to NOS. An advantage of oral CIT treatment is that, unlike ARG,
99 catabolism of this amino acid in the intestines is limited since CIT is not metabolized
100 by arginases and bacteria, and the activity of argininosuccinate synthase, the enzyme
101 that initiates CIT metabolism, is low in enterocytes (68). Moreover, and also in
102 contrast to ARG, CIT is not extracted from the systemic circulation for clearance by
103 the liver (59, 65). Consequently, the majority of an oral CIT bolus passes into the
104 systemic circulation (43). CIT is then extracted by the kidneys to be converted, in
105 sequence, to argininosuccinate and ARG by the enzymes argininosuccinate synthase
106 and argininosuccinate lyase, respectively (15, 24, 59, 65, 70). Synthesis of ARG
107 from CIT is prevalent in other tissues (15, 23, 70) and this process is facilitated since
108 CIT does not compete with ADMA for cell transport (50, 69). Importantly, it has
109 been shown that oral CIT supplementation is more effective at increasing the
110 circulating (32, 57, 53, 62) and tissue (63) [ARG] compared to an equivalent dose of
111 ARG, and that CIT supplementation can increase NOS activation (63) and NO
112 biomarkers (46, 53). Therefore, these findings suggest that CIT might serve as an
113 important precursor for NO production.

114

115 Chronic supplementation with L-citrulline malate has been shown to enhance skeletal
116 muscle power output in concert with a greater oxidative energy turnover and a lower
117 power/pH ratio (7), and a lower ATP cost of muscle force production (19). These
118 data suggest that short-term L-citrulline malate supplementation might improve
119 skeletal muscle metabolism and/or contractile efficiency, which would be expected to
120 predispose to greater fatigue resistance. However, since these experiments
121 administered CIT as L-citrulline malate, and since malate is an important tricarboxylic
122 acid cycle intermediate that might itself influence muscle function (61), it is unclear
123 whether these beneficial effects can be attributed to CIT, *per se*. Hickner et al. (26)
124 reported compromised endurance performance in concert with a lower plasma
125 concentration of [nitrate] + [nitrite] ([NO_x]) in humans following the acute ingestion
126 of pure CIT. In contrast, seven days of supplementation with pure CIT has been
127 shown to improve endurance exercise performance in mice (55). While these data
128 suggest that chronic CIT supplementation has greater potential to improve endurance
129 exercise performance than acute CIT ingestion, this has yet to be investigated in

130 humans. Moreover, since NO biomarkers have not been assessed in studies reporting
131 positive effects of CIT on muscle function and metabolism (7, 19, 56), it is unclear
132 whether these improvements are linked to an increase in NOS-derived NO. It is also
133 unclear whether the improvements in muscle metabolism and performance with
134 chronic CIT (7, 19, 56) are linked to improved oxygen uptake (\dot{V}_{O_2}) kinetics.
135 Therefore, further research is required to assess whether short-term oral CIT can
136 influence NO synthesis and exercise performance, and the underlying mechanisms for
137 any performance gains with CIT.

138

139 The purpose of this study was to investigate the effects of short-term ARG and CIT
140 supplementation on plasma [ARG], [CIT] and [NO₂⁻], a sensitive marker of NOS
141 activity (34), as well as blood pressure, \dot{V}_{O_2} kinetics and exercise performance
142 compared to a taste- and energy-matched placebo. We hypothesised that, when
143 compared to placebo: 1) plasma [ARG] would be increased to a greater extent with
144 ARG than CIT; and 2) that CIT but not ARG would elevate plasma [NO₂⁻], reduce
145 blood pressure and improve \dot{V}_{O_2} kinetics, cycling efficiency and exercise
146 performance.

147

148 **Methods**

149

150 ***Subjects***

151 Ten healthy, recreationally-active males (mean \pm SD, age 19 ± 1 yr, height 1.80 ± 0.08
152 m, body mass 79 ± 11 kg) volunteered to participate in this study. None of the
153 subjects were tobacco smokers or users of dietary supplements. The procedures
154 employed in this study were approved by the Institutional Research Ethics Committee.
155 All subjects gave their written informed consent prior to the commencement of the
156 study, after the experimental procedures, associated risks, and potential benefits of
157 participation had been explained. Subjects were instructed to arrive at the laboratory
158 in a rested and fully hydrated state, at least 3 h postprandial, and to avoid strenuous
159 exercise in the 24 h preceding each testing session. Each subject was also asked to
160 refrain from caffeine and alcohol 6 and 24 h before each test, respectively. All tests
161 were performed at the same time of day (± 2 hours).

162

163 ***Experimental Design***

164 Subjects were required to report to the laboratory on eight occasions over 6-7 weeks
165 to complete the experimental testing. On the first visit to the laboratory subjects
166 completed a ramp incremental exercise test for determination of the gas exchange
167 threshold (GET) and the peak oxygen uptake ($\dot{V}_{O_{2peak}}$). Subjects were familiarized
168 with the two exercise performance tests employed in this study during the second
169 laboratory testing session. After these preliminary exercise tests, subjects returned to
170 the laboratory on days six and seven of 7-day supplementation periods with placebo
171 (PLA), L-arginine (ARG) and L-citrulline (CIT) to complete the experimental testing.
172 During these tests, resting blood pressure, pulmonary \dot{V}_{O_2} kinetics, muscle
173 oxygenation and exercise performance were assessed and a resting venous blood
174 sample was obtained. The supplements were administered orally in a randomized
175 order as part of a double blind, cross-over experimental design. Each
176 supplementation period was separated by 7-10 days of washout. Subjects were
177 provided with a food diary for the first supplementation intervention and were
178 instructed to replicate their diet over subsequent supplementation periods.

179

180 ***Incremental Test***

181 During the first laboratory visit subjects completed a ramp incremental cycle test on
182 an electronically-braked cycle ergometer (Lode Excalibur Sport, Groningen, the
183 Netherlands). Initially, subjects performed 3 min of baseline cycling at 0 W, after
184 which the work rate was increased by 30 W/min until the limit of tolerance. The
185 subjects cycled at a self-selected pedal rate (70-90 rpm) and this pedal rate along with
186 saddle and handle bar height and configuration was recorded and reproduced in
187 subsequent tests. Breath-by-breath pulmonary gas-exchange data were collected
188 continuously during the incremental tests and averaged over consecutive 10-s periods.
189 The $\dot{V}_{O_{2max}}$ was taken as the highest 30-s mean value attained prior to the subject's
190 volitional exhaustion in the test. The GET was determined from a cluster of
191 measurements including 1) the first disproportionate increase in CO₂ production (\dot{V}_{CO_2})
192 from visual inspection of individual plots of \dot{V}_{CO_2} vs. \dot{V}_{O_2} , 2) an increase in
193 expired ventilation (\dot{V}_E) / \dot{V}_{O_2} with no increase in \dot{V}_E / \dot{V}_{CO_2} , and 3) an increase in end-
194 tidal O₂ tension with no fall in end-tidal CO₂ tension. The work rates that would
195 require 90% of the GET (moderate-intensity exercise) and 70% Δ (GET plus 70% of
196 the difference between the work rate at the GET and $\dot{V}_{O_{2max}}$; severe-intensity

197 exercise) were subsequently calculated with account taken of the mean response time
198 for \dot{V}_{O_2} during ramp exercise (i.e., two thirds of the ramp rate was deducted from the
199 work rate at GET and peak).

200

201 ***Familiarization Tests***

202 To avoid any order effect on the performance results as a consequence of a potential
203 ‘learning effect’, subjects were familiarized with all performance tests prior to the
204 experimental testing. Subjects completed a severe-intensity step exercise test
205 terminating with an all-out sprint (exercise performance test) followed, after a 45 min
206 passive recovery period, by a severe-intensity constant-work-rate step exercise test
207 that was continued until the limit of tolerance (exercise tolerance test).

208

209 ***Supplementation Procedures***

210 Experimental testing was conducted during a 7-day supplementation period with
211 PLA, ARG and CIT. The PLA supplement consisted of 10.7 g of maltodextrin; the
212 ARG supplement consisted of 6 g L-arginine + 4.3 g of maltodextrin; and the CIT
213 supplement consisted of 6 g L-citrulline + 4.3 g of maltodextrin. All supplements
214 were energy-matched containing 40 kcal per serving. Pure maltodextrin, L-arginine
215 and L-citrulline powders were provided by NOW Sports Nutrition (NOW Foods,
216 Bloomingdale, IL, USA) and were mixed with 500 mL water and 75 ml blackcurrant
217 cordial in the proportions described above to produce the PLA, ARG and CIT
218 supplements. On days 1-5 of supplementation, subjects were instructed to drink the
219 beverage slowly over the course of the day. On days 6 and 7 of supplementation,
220 subjects were instructed to consume the beverage over a 10 minute window such that
221 the entire beverage had been consumed 60 min before the subject was required to
222 report to the laboratory.

223

224 ***Experimental Tests***

225 After reporting to the laboratory on days 6 and 7 of the supplementation interventions,
226 subjects were required to rest in a seated position for 10 min in an isolated room.
227 Thereafter, blood pressure of the brachial artery was measured whilst the subject was
228 seated using an automated sphygmomanometer (Dinamap Pro, GE Medical Systems,
229 Tampa, USA). Four measurements were taken and the mean of the measurements
230 was calculated. A venous blood sample was then drawn into a lithium-heparin tube

231 and centrifuged at 4000 rpm and 4°C for 10 min, within 3 min of collection. Plasma
232 was subsequently extracted and immediately frozen at -80°C for later analysis of
233 [NO₂⁻] in duplicate via chemiluminescence (6) and [ARG], [CIT] and [L-ornithine]
234 ([ORN]) using high-performance liquid chromatography (HPLC; see below for
235 details).

236

237 Thirty minutes after arriving at the laboratory (90 minutes after the ingestion of the
238 supplement), subjects completed a series of cycle exercise tests. We elected to
239 commence exercise testing 90 minutes after supplement consumption since published
240 pharmacokinetic data has shown that this time frame should coincide with peak
241 plasma [ARG] after orally ingesting 6 g CIT (53) or 6 g ARG (10). The exercise
242 protocol consisted of three ‘step’ exercise tests including two moderate-intensity step
243 tests followed by one severe-intensity exercise bout. Moderate-intensity step tests
244 were completed to assess \dot{V}_{O_2} kinetics and cycling economy in the absence of a \dot{V}_{O_2}
245 slow component, while severe-intensity step tests were completed to assess \dot{V}_{O_2}
246 kinetics in the presence of a \dot{V}_{O_2} slow component where $\dot{V}_{O_{2max}}$ is attained and the
247 tolerable duration of exercise is <20 min (49, 66). We conducted repeated step tests
248 on the same laboratory visit since a prior moderate-intensity step exercise bout does
249 not impact on \dot{V}_{O_2} kinetics during subsequent moderate- or severe-intensity cycle
250 exercise (12, 16). Therefore, all subjects performed a total of four bouts of moderate-
251 intensity exercise and two bouts of severe-intensity exercise for each experimental
252 condition.

253

254 Each transition began with 3 min of baseline cycling at 20 W before an abrupt
255 transition to the target work rate. A passive recovery of 5 min separated the
256 transitions. The moderate-intensity steps were each of 6 min duration. On day 6 of
257 each supplementation condition, subjects cycled for 6 min at a severe-intensity
258 constant-work-rate (70% Δ) followed immediately by a 60 s all-out sprint. The
259 resistance on the pedals during the 60 s all-out effort was set using the linear mode of
260 the Lode ergometer so that the subject would attain the power output calculated to be
261 50% Δ if they attained their preferred cadence (linear factor = power/preferred
262 cadence²). Subjects were provided with a 5 s countdown prior to the sprint and were
263 instructed to attain the peak power as quickly as possible and to continue exercising
264 maximally for the duration of the sprint. No time feedback was given to the subjects

265 at any point during the sprint. On day 7 of the supplementation period, the severe-
266 intensity constant-work-rate bout was continued to the limit of tolerance. The time to
267 task failure was used as a measure of exercise tolerance and was recorded when the
268 pedal rate fell by > 10 rpm below the required pedal rate.

269

270 ***Measurements***

271 During all tests, pulmonary gas exchange and ventilation were measured breath-by-
272 breath with subjects wearing a nose clip and breathing through a low-dead-space,
273 low-resistance mouthpiece and impeller turbine assembly (Jaeger Triple V). The
274 inspired and expired gas volume and gas concentration signals were continuously
275 sampled at 100 Hz, the latter using paramagnetic (O₂) and infrared (CO₂) analyzers
276 (Jaeger Oxycon Pro, Hoechberg, Germany) via a capillary line connected to the
277 mouthpiece. The gas analyzers were calibrated before each test with gases of known
278 concentration and the turbine volume transducer was calibrated with a 3-liter syringe
279 (Hans Rudolph, Kansas City, MO). The volume and concentration signals were time-
280 aligned by accounting for the delay in the capillary gas transit and the analyzer rise
281 time relative to the volume signal. Pulmonary gas exchange and ventilation were
282 calculated and displayed breath-by-breath.

283

284 During the exercise trials, a blood sample was collected from a fingertip into a
285 capillary tube over the 20 s preceding the step transition in work rate, the 20 s
286 preceding the completion of 360 s of moderate and severe cycling exercise, and also
287 immediately following the all-out sprint and immediately after exhaustion during the
288 severe-intensity constant-work-rate trial. These whole blood samples were
289 subsequently analyzed to determine blood [lactate] (YSI 1500, Yellow Springs
290 Instruments, Yellow Springs, OH, United States) within 30 s of collection.

291

292 The oxygenation status of the *m. vastus lateralis* of the right leg was monitored using
293 a commercially available near-infrared spectroscopy (NIRS) system (model NIRO
294 300, Hamamatsu Photonics KK, Hiugashi-ku, Japan). The system consisted of an
295 emission probe that irradiates laser beams and a detection probe. Four different
296 wavelength laser diodes provided the light source (776, 826, 845, and 905 nm) and
297 the light returning from the tissue was detected by a photomultiplier tube in the
298 spectrometer. The intensity of incident and transmitted light was recorded

299 continuously at 2 Hz and used to estimate concentration changes from the resting
300 baseline for oxygenated, deoxygenated, and total tissue hemoglobin/myoglobin.
301 Therefore, the NIRS data represent a relative change based on the optical density
302 measured in the first datum collected. The deoxygenated hemoglobin/myoglobin
303 concentration ([HHb]) signal was assumed to provide an estimate of changes in
304 fractional O₂ extraction in the field of interrogation (e.g., 21). It should be noted here
305 that the contribution of deoxygenated myoglobin to the NIRS signal is presently
306 unclear, and, as such, the terms [HbO₂], and [HHb] used in this paper should be
307 considered to refer to the combined concentrations of oxygenated and deoxygenated
308 hemoglobin and myoglobin, respectively. The tissue oxygenation index (TOI) was
309 calculated using the following equation:

310

$$311 \quad \text{TOI} = \frac{[\text{HbO}_2]}{[\text{HbO}_2] + [\text{HHb}]} \times 100 \quad (\text{Eqn 1})$$

312

313 The leg was initially cleaned and shaved around the belly of the muscle, and the
314 optodes were placed in the holder, which was secured to the skin with adhesive at 20
315 cm above the fibular head. To secure the holder and wires in place, an elastic
316 bandage was wrapped around the subject's leg. The wrap helped to minimize the
317 possibility that extraneous light could influence the signal and also ensured that the
318 optodes did not move during exercise. Indelible pen marks were made around the
319 holder to enable precise reproduction of the placement in subsequent tests. The probe
320 gain was set with the subject at rest in a seated position with the leg extended at down
321 stroke on the cycle ergometer before the first exercise bout, and NIRS data were
322 collected continuously throughout the exercise protocols. The data were subsequently
323 downloaded onto a personal computer, and the resulting text files were stored on disk
324 for later analysis.

325

326 Plasma [ARG], [CIT] and [ORN] were determined by *o*-phthaldialdehyde (OPA)
327 derivatised, fluorescence-detection HPLC, using methods adapted from Jones and
328 Gilligan (27). The HPLC apparatus was a Perkin Elmer Flexar LC system with
329 Chromera software (Perkin Elmer, MASS, USA). In brief, plasma was de-proteinised
330 in 1.5N perchloric acid, neutralised in 2N potassium hydrogen carbonate, and
331 centrifuged. 100µL of supernatant, 100µL of 1.2% benzoic acid, and 1.4mL H₂O

332 were added to HPLC vials. 50 μ L of unknowns/standards were mixed with 50 μ L of an
 333 OPA solution containing 2-mercaptoethanol (Fluoraldehyde OPA reagent solution,
 334 Thermo Scientific, IL, USA), enabling the pre-column derivatization of amino acids
 335 with a highly fluorescent OPA adduct. 25 μ L of derivatised sample was mixed in
 336 mobile phase and eluted at 0.8 ml.min⁻¹ through a 4.6 x 150mm, 2.7 μ m Brownlee
 337 SPP C18 reverse-phase analytical column with 5mm guard column with matching
 338 specification. A gradient protocol of aqueous mobile phase A (0.05M potassium
 339 phosphate buffer, pH 7.2) with organic mobile phase B (acetonitrile/methanol/water,
 340 40/40/20) was performed: 0 – 1.5 min, 80% Mobile A; 1.5 – 18.5, 80 – 65%; 23.5,
 341 50%; 32.5, 40%; 36.5, 30%; 43.5, 0%; 51.5, 80%. Fluorescence was monitored at
 342 excitation and emission wavelengths of 340 and 455 nm, respectively. Amino acid
 343 concentrations were determined against standards calibration curves between 0 and
 344 500 μ M (nmol.mL⁻¹).

345

346 ***Data Analysis Procedures***

347 The breath-by-breath \dot{V}_{O_2} data from each test were initially examined to exclude errant
 348 breaths caused by coughing, swallowing, sighing, etc., and those values lying more
 349 than four standard deviations from the local mean were removed. The breath-by-
 350 breath data were subsequently linearly interpolated to provide second-by-second
 351 values and, for each individual, identical repetitions were time-aligned to the start of
 352 exercise and ensemble-averaged. The first 20 s of data after the onset of exercise (i.e.,
 353 the phase I response) were deleted and a nonlinear least-square algorithm was used to
 354 fit the data thereafter. A single-exponential model was used to characterize the \dot{V}_{O_2}
 355 responses to moderate exercise and a bi-exponential model was used for severe
 356 exercise, as described in the following equations:

357

$$358 \quad \dot{V}_{O_2}(t) = \dot{V}_{O_2 \text{ baseline}} + A_p(1 - e^{-(t - TD_p)/\tau_p}) \quad (\text{moderate}) \quad (\text{Eqn. 2})$$

$$359 \quad \dot{V}_{O_2}(t) = \dot{V}_{O_2 \text{ baseline}} + A_p(1 - e^{-(t - TD_p)/\tau_p}) + A_s(1 - e^{-(t - TD_s)/\tau_s}) \quad (\text{severe}) \quad (\text{Eqn. 3})$$

360

361 where $\dot{V}_{O_2}(t)$ represents the absolute \dot{V}_{O_2} at a given time t ; $\dot{V}_{O_2 \text{ baseline}}$ represents the
 362 mean \dot{V}_{O_2} in the baseline period; A_p , TD_p , and τ_p represent the amplitude, time delay,
 363 and time constant, respectively, describing the phase II increase in \dot{V}_{O_2} above baseline;
 364 and A_s , TD_s , and τ_s represent the amplitude of, time delay before the onset of, and
 365 time constant describing the development of, the \dot{V}_{O_2} slow component, respectively.

366 An iterative process was used to minimize the sum of the squared errors between the
367 fitted function and the observed values. $\dot{V}_{O_2\text{baseline}}$ was defined as the mean \dot{V}_{O_2}
368 measured over the final 90 s of the resting baseline period. The \dot{V}_{O_2} at 360 s was taken
369 as the mean \dot{V}_{O_2} between 330 and 360 s, while the \dot{V}_{O_2} at the limit of tolerance (T_{lim})
370 was defined as the mean \dot{V}_{O_2} measured over the final 30 s of the exhaustive exercise
371 bout. Because the asymptotic value (A_s) of the exponential term describing the \dot{V}_{O_2}
372 slow component may represent a higher value than is actually reached at the end of the
373 exercise, the actual amplitude of the \dot{V}_{O_2} slow component at the end of exercise was
374 defined as A_s' . The A_s' parameter was compared at the same iso-time (360-s) for all
375 dietary interventions. The amplitude of the slow component was also described
376 relative to the entire \dot{V}_{O_2} response. In addition, the functional 'gain' (G) of the
377 fundamental \dot{V}_{O_2} response was computed by dividing A_p by the Δ work rate. To
378 determine the overall kinetics of the \dot{V}_{O_2} response to both moderate- and severe-
379 intensity exercise, the data were also fit with a mono-exponential model from 0-s to
380 end-exercise without time delay. This mean response time (MRT) was used to
381 calculate the O_2 deficit using the following equation:

382

$$O_2 \text{ Deficit (L)} = \text{MRT}(\text{min}) \times \Delta \dot{V}_{O_2} \text{ (L)} \quad (\text{Eqn 4})$$

383

384 where $\Delta \dot{V}_{O_2}$ was the difference in \dot{V}_{O_2} at 360 s and baseline.

385

386 To provide information on muscle oxygenation, we also modelled the [HHb] response
387 to exercise. Mono- and bi-exponential models, similar to those described above, were
388 applied to the ensemble averaged data with the exception that the fitting window
389 commenced at the time at which the [HHb] signal increased 1 SD above the baseline
390 mean. The [HHb] kinetics for moderate exercise were determined by constraining the
391 fitting window to the point at which mono-exponentiality became distorted,
392 consequent to a gradual fall in [HHb], as determined by visual inspection of the
393 residual plots. The [HHb] kinetics for severe exercise were determined by fitting a bi-
394 exponential model from the first data point, which was 1 SD above the baseline mean
395 through the entire response. The [HHb] TD and τ values were summed to provide
396 information on the overall [HHb] response dynamics in the fundamental phase of the
397 response. The [HbO₂] response does not approximate an exponential and was,
398 therefore, not modelled. Rather, we assessed this by determining the [HbO₂] at

399 baseline (90-s preceding step transition), 120 s (30 s mean surrounding 120 s) and end
400 exercise (mean response over the final 30 s of exercise). The TOI responses were
401 assessed using the same data analysis procedures.

402

403 **Statistics**

404 A one-way repeated-measures ANOVA was employed to assess between-supplement
405 differences in blood pressure; plasma [ARG], [CIT], [ORN] and [NO₂⁻]; \dot{V}_{O_2} ; NIRS-
406 derived [HHb], [HbO₂] and TOI; and exercise performance. Significant effects were
407 further explored using simple contrasts with the alpha level adjusted via a Fisher's
408 LSD correction. Data are presented as mean \pm SD, unless otherwise stated. Statistical
409 significance was accepted when $P < 0.05$.

410

411 **Results**

412

413 The PLA, ARG and CIT supplements administered in this study were well tolerated
414 by all subjects with no negative side effects reported. Subjects consumed all doses of
415 the supplement for each experimental condition and their diet was consistent across
416 all the dietary interventions. The $\dot{V}_{O_{2peak}}$ attained in the ramp incremental test was
417 $3.94 \pm 0.51 \text{ L} \cdot \text{min}^{-1}$ which equated to a relative $\dot{V}_{O_{2peak}}$ of $50 \pm 9 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. The
418 work rates which corresponded to 90% GET and 70% Δ were $120 \pm 23 \text{ W}$ and $284 \pm$
419 40 W , respectively.

420

421 *Plasma [NO₂⁻], [ARG], [CIT] and [ORN]*

422 The plasma [NO₂⁻], [ARG], [CIT] and [ORN] data for the PLA, ARG and CIT
423 conditions are reported in Table 1. The ANOVA revealed a significant main effect
424 for supplement on plasma [ARG], [CIT] and [ORN] (all $P < 0.001$). Plasma [ARG]
425 was increased above PLA ($57 \pm 14 \mu\text{M}$) in ARG ($151 \pm 31 \mu\text{M}$) and CIT (135 ± 22
426 μM ; both $P < 0.001$), with no differences between ARG and CIT ($P > 0.05$; Table 1).
427 Plasma [CIT] was not significantly different between PLA ($23 \pm 5 \mu\text{M}$) and ARG (26
428 $\pm 6 \mu\text{M}$; $P > 0.05$), but was significantly greater than both these conditions with CIT
429 ($665 \pm 205 \mu\text{M}$; $P < 0.001$; Table 1). Plasma [ORN] was significantly greater in CIT
430 ($50 \pm 6 \mu\text{M}$) than PLA ($26 \pm 8 \mu\text{M}$; $P < 0.001$) and significantly greater in ARG ($62 \pm$
431 14) than both PLA and CIT ($P > 0.05$; Table 1). Plasma [NO₂⁻] was significantly

432 increased in ARG (106 ± 41 nM; $P < 0.05$), but not following CIT supplementation
433 (100 ± 38 nM; $P = 0.08$), compared to PLA (83 ± 25 nM; Table 1).

434

435 *Blood Pressure*

436 The blood pressure data for the PLA, ARG and CIT conditions are reported in Table
437 2. There was a significant main effect for supplement on systolic blood pressure
438 (SBP; $P < 0.05$), with follow up analyses showing that SBP was lower after CIT ($118 \pm$
439 6 mmHg; $P < 0.05$), but not after ARG (120 ± 7 mmHg; $P > 0.05$), compared to PLA
440 (122 ± 7 mmHg; Table 2). While there was no main effect for supplement on
441 diastolic blood pressure (DBP; $P > 0.05$), there was a significant main effect for
442 supplement on mean arterial pressure (MAP; $P < 0.05$). Relative to PLA (87 ± 3
443 mmHg), MAP was lower after CIT (85 ± 2 mmHg; $P < 0.05$), but not ARG (86 ± 2
444 mmHg; $P > 0.05$; Table 2).

445

446 *Pulmonary \dot{V}_{O_2} Kinetics*

447 The pulmonary gas exchange data from the moderate- and severe-intensity cycle tests
448 are reported in Table 3. There were no significant between-supplement differences
449 for the baseline and end-exercise \dot{V}_{O_2} during the moderate-intensity step exercise tests
450 ($P > 0.05$). Accordingly, the fundamental \dot{V}_{O_2} amplitude was not significantly
451 different between the conditions (PLA: 0.87 ± 0.21 , ARG: 0.87 ± 0.22 , CIT: $0.86 \pm$
452 0.23 L·min⁻¹; $P > 0.05$; Table 3). The phase II τ was also not significantly different
453 between conditions (PLA: 24 ± 7 , ARG: 22 ± 7 , CIT: 21 ± 6 s; $P > 0.05$; Table 3).

454

455 The baseline \dot{V}_{O_2} and phase II \dot{V}_{O_2} kinetics during severe-intensity exercise were not
456 significantly impacted by the dietary interventions employed in this investigation
457 ($P > 0.05$ for all comparisons). The \dot{V}_{O_2} at exhaustion was not significantly different
458 between experimental conditions and was also not significantly different from the \dot{V}_{O_2}
459 $\dot{V}_{O_{2peak}}$ attained in the ramp incremental test ($P > 0.05$ for all comparisons). No
460 significant differences in the fundamental \dot{V}_{O_2} amplitude (PLA: 2.23 ± 0.34 , ARG:
461 2.26 ± 0.42 , CIT: 2.29 ± 0.45 L·min⁻¹) or \dot{V}_{O_2} slow component (PLA: 0.66 ± 0.09 ,
462 ARG: 0.60 ± 0.12 , CIT: 0.58 ± 0.13 L·min⁻¹; $P > 0.05$; Table 3) were observed across
463 the experimental conditions. However, there was a significant main effect for
464 supplement on the MRT ($P < 0.05$), with faster overall \dot{V}_{O_2} kinetics observed after CIT
465 compared to PLA supplementation (PLA: 60 ± 8 , CIT: 54 ± 5 s; $P < 0.05$; Figure 1).

466 There were no significant differences in \dot{V}_{CO_2} and RER between the PLA, ARG and
467 CIT conditions during moderate- or severe-intensity cycle exercise ($P>0.05$ for all
468 comparisons, data not shown). There were also no between condition differences in
469 blood [lactate] at any time comparison in this study ($P>0.05$, data not shown).

470

471 *NIRS Variables*

472 The NIRS-derived muscle [HHb], [HbO₂] and TOI data during moderate- and severe-
473 intensity cycle exercise with PLA, ARG and CIT supplementation are reported in
474 Table 4. There were no significant differences between the experimental conditions
475 for the [HbO₂] and TOI responses during moderate-intensity exercise ($P>0.05$ for all
476 comparisons). However, the [HHb] amplitude during moderate-intensity cycling
477 exercise was significantly lower after CIT supplementation (PLA: 8 ± 4 , CIT: 6 ± 4
478 A.U.; $P>0.05$; Figure 2). While there were no significant between-supplement
479 differences in [HHb] dynamics or in muscle [HbO₂] during severe-intensity cycle
480 exercise in this study, the muscle TOI was significantly elevated over the first 360 s of
481 severe-intensity exercise with CIT supplementation ($P<0.05$; Table 4; Figure 3).

482

483 *Exercise Performance*

484 The power profiles for the three experimental conditions during the 60 s all-out sprint
485 that followed the 6 min bout of severe-intensity exercise (the exercise performance
486 test) are shown in Figure 4, while the times to exhaustion during the severe-intensity
487 constant-work-rate cycle trials (the exercise tolerance test) are shown in Figure 5. A
488 significant main effect for supplement was observed for the peak power attained and
489 total work completed during the 60 s all-out sprint that concluded the exercise
490 performance test ($P<0.05$). Follow up analyses showed that, compared to PLA, CIT
491 supplementation increased the test peak power by 9% (PLA: 480 ± 98 , CIT: 524 ± 94
492 W; $P<0.05$; Figure 4) and the total work completed during the 60 s sprint by 7%
493 (PLA: 21 ± 4 , CIT: 23 ± 4 kJ; $P<0.05$; Figure 4). Neither peak power output ($482 \pm$
494 102 W) nor total sprint work completed (21 ± 5 kJ) were significantly impacted by
495 ARG supplementation ($P>0.05$). The total work completed over the entire exercise
496 performance test was greater with CIT (125 ± 19 kJ; $P<0.05$), but not ARG (124 ± 19
497 kJ; $P>0.05$), compared to PLA (123 ± 18 kJ; $P<0.05$). There was a strong trend for a
498 main effect of supplement on the time-to-exhaustion during the exercise tolerance test
499 ($P=0.07$). When between-condition analyses were conducted, there was a significant

500 12% increase in exercise tolerance time after CIT supplementation relative to PLA
501 (PLA: 589 ± 101 , CIT: 661 ± 107 s; $P < 0.05$; Figure 5). Exercise tolerance was not
502 significantly improved with ARG (612 ± 150 s) compared to PLA ($P > 0.05$). The
503 changes in exercise tolerance after CIT supplementation were not related to changes
504 in plasma $[\text{NO}_2^-]$, $\dot{V}\text{O}_2$ kinetics or muscle oxygenation ($P > 0.05$ for all comparisons).

505

506 **Discussion**

507

508 The principal novel findings from this study are that short-term supplementation with
509 pure CIT enhanced endurance exercise performance in concert with faster overall $\dot{V}\text{O}_2$
510 kinetics and a 21% increase in the sensitive NO biomarker, plasma $[\text{NO}_2^-]$. This is in
511 contrast to previous research demonstrating that acute CIT supplementation lowers
512 plasma $[\text{NOx}]$ and compromises exercise tolerance (26), but consistent with studies
513 showing that short term supplementation with L-citrulline malate can positively
514 impact on skeletal muscle power output and metabolic responses (7, 19). These
515 findings are important since they suggest that CIT might be responsible for the
516 positive effects previously reported following L-citrulline malate supplementation, and
517 offer new insights into the mechanisms by which CIT supplementation might be
518 ergogenic. Conversely, no significant differences in $\dot{V}\text{O}_2$ kinetics and exercise
519 performance were observed following short-term ARG supplementation. These
520 findings suggest that short-term CIT supplementation, but not short term ARG
521 supplementation, might be an effective dietary intervention to improve oxidative
522 metabolism and exercise performance in healthy adults.

523

524 *Influence of ARG and CIT supplementation on plasma [ARG], [CIT] and $[\text{NO}_2^-]$*

525 In an attempt to overcome the well developed inter-organ system for ARG clearance,
526 recent studies have investigated the efficacy of oral CIT supplementation as an
527 alternative method to enhance NO production via NOS. Oral CIT supplementation is
528 appealing in this regard since CIT is not significantly metabolized in the gut (68) and
529 liver (59, 65), and less than 1% of orally ingested CIT is excreted in the urine (50).
530 As such the majority of an oral CIT load passes into the systemic circulation, as
531 reflected by a significant increase in plasma [CIT] after CIT ingestion in the current
532 study and numerous previous reports (8, 16, 42, 51, 53). Thereafter the bulk of

533 plasma CIT is converted into ARG, mostly in the kidneys (15, 24, 59, 65, 70), but also
534 in several other tissues (15, 23, 70). This is compatible with the significant increase
535 in plasma [ARG] in this study, and several previous studies (32, 47, 53, 62), following
536 CIT supplementation. It is important to note that, not only does CIT increase
537 systemic [ARG] by avoiding catabolism along the intestinal-renal axis, but CIT might
538 also be expected to enhance ARG bioavailability given that CIT can function as an
539 allosteric inhibitor of arginase (54). This is supported by our finding of a lower
540 plasma [ORN], the product of ARG metabolism by arginase (70), after CIT compared
541 to ARG supplementation in this study. However, in spite of this potential for greater
542 systemic ARG bioavailability following oral CIT compared to oral ARG
543 supplementation, and in contrast to previous studies reporting a greater increase in
544 plasma [ARG] after CIT ingestion relative to ARG ingestion (32, 47, 53, 62), plasma
545 [ARG] was increased by a similar magnitude when the same dose of CIT and ARG
546 was orally administered in this study. These conflicting findings might be a function
547 of between-study differences in the experimental subjects and supplementation
548 regimes. Therefore, our results do not support the notion of a greater systemic ARG
549 availability after CIT compared to ARG supplementation, at least in healthy adult
550 males undergoing the ARG and CIT supplementation procedures employed in this
551 study.

552

553 As well as increasing NOS substrate provision, there is some evidence to suggest that
554 NO production is enhanced after CIT treatment (46, 53, 63) and that CIT can restore
555 NO production in conditions where NO production is compromised (16, 36).
556 However, there is also a suggestion that CIT ingestion tends to lower NO production,
557 as inferred from plasma [NOx] (26). Plasma [NO₂⁻] better reflects human NOS
558 activity than plasma [NOx] (34) and is likely to provide a more accurate assessment
559 of NOS-derived NO. In this study CIT supplementation increased plasma [NO₂⁻] by
560 21%, but this increase did not attain statistical significance ($P=0.08$). On the other
561 hand, ARG supplementation resulted in a statistically significant (28%) increase in
562 plasma [NO₂⁻]. Taken together, these data suggest that short-term ARG
563 supplementation might be more effective than CIT supplementation at increasing the
564 sensitive biomarker of NOS activity, plasma [NO₂⁻] (28, 34). However, the extent to
565 which plasma [NO₂⁻] reflects skeletal muscle NOS activity is unclear. In this study
566 plasma [ORN] was lower following CIT than ARG. It is known that ORN competes

567 with ARG for cellular uptake via the y^+ carrier system (70). As such, this might have
568 facilitated greater skeletal muscle ARG uptake after CIT compared to ARG
569 supplementation in this study. The finding of a greater increase in tissue [ARG] (63)
570 after CIT ingestion relative to ARG ingestion supports this postulate. Moreover, the
571 lower plasma [ORN] following CIT than ARG, despite a similar increase in plasma
572 [ARG], implies a lower arginase activity following CIT (70). Providing muscle
573 [ORN] was also lower following CIT compared to ARG supplementation in this
574 study, muscle arginase activity may have been downregulated. While there appears to
575 be some controversy regarding the levels of arginase in human skeletal muscle (20,
576 45), the potential for CIT to inhibit arginase might be important since arginase-II
577 content in human skeletal muscle can be similar to that observed in the kidney, i.e.,
578 relatively high (45). Therefore, the functional effects of CIT (described below) may
579 be muscle-specific and not detected as changes in plasma $[\text{NO}_2^-]$, which may be more
580 indicative of gross changes in NOS activity throughout the body. Likewise, the ARG-
581 induced increase in plasma $[\text{NO}_2^-]$, observed in the present study, may be due to non-
582 endothelial NOS-mediated NO production or NOS-mediated NO production at sites
583 other than skeletal muscle.

584

585 *Influence of ARG and CIT supplementation on blood pressure*

586 A hallmark of enhanced NO synthesis is a reduction in blood pressure owing to NO-
587 induced smooth muscle relaxation (22). It has also recently been demonstrated that
588 circulating NO_2^- itself can act as a *source* for NO synthesis via endogenous human
589 nitrite reductase activities, associated with proteins such as xanthine oxidase and
590 deoxyhemoglobin (see 37 for review). However, in spite of a significant increase in
591 plasma $[\text{NO}_2^-]$ after ARG supplementation, resting blood pressure was not
592 significantly lowered. This suggests that the increase in plasma $[\text{NO}_2^-]$ after short-
593 term ARG supplementation might not have been sufficient to lower resting blood
594 pressure in normotensive adults. Conversely, CIT supplementation, which did not
595 significantly increase plasma $[\text{NO}_2^-]$, significantly reduced resting blood pressure.
596 Although previous studies have shown a reduction in arterial stiffness (46), enhanced
597 endothelium-dependent vasorelaxation in response to acetylcholine (25) and an
598 association between the change in the ARG/ADMA ratio and flow mediated dilation
599 (53) with CIT, we have shown for the first time that pure CIT supplementation can
600 reduce blood pressure in healthy normotensive adults. An increase in cyclic

601 guanosine monophosphate (cGMP) has been reported after short-term CIT
602 consumption (49) which suggests that the reduction in blood pressure with CIT might
603 result from NO-cGMP-related smooth muscle relaxation. Alternatively, CIT might
604 alter vascular tone through another endothelium-derived relaxing factor such as
605 prostacyclin or endothelium-derived hyperpolarizing factors independent of, or
606 alongside, an increase in NO. Further research is required to investigate the
607 mechanisms by which CIT might positively impact on vascular and other
608 physiological responses.

609

610 *Influence of ARG and CIT supplementation on \dot{V}_{O_2} kinetics*

611 Giannesini et al. (19) reported that short-term L-citrulline malate supplementation
612 lowered both the oxidative and phosphocreatine cost of skeletal muscle force
613 production in the rat gastrocnemius muscle *in situ*. We have previously shown that
614 short-term dietary nitrate supplementation can also lower skeletal muscle ATP
615 turnover by attenuating ATP flux through oxidative phosphorylation and
616 phosphocreatine (PCr) hydrolysis in association with lower \dot{V}_{O_2} in humans
617 completing knee-extensor exercise (2). Therefore, we hypothesized that short term
618 CIT supplementation might lower \dot{V}_{O_2} in humans completing cycle exercise.
619 However, in contrast to our previous findings with dietary nitrate supplementation (6)
620 and our experimental hypothesis, short term CIT supplementation did not
621 significantly lower \dot{V}_{O_2} during moderate-intensity cycle ergometry exercise. Our
622 findings in this study might differ with those reported by Giannesini et al. (19) as a
623 consequence of differences in the experimental model (human skeletal muscle
624 contraction *in vivo* vs. isolated rat skeletal muscle *in situ*) or differences in the L-
625 citrulline supplementation procedures (pure L-citrulline supplementation vs. L-
626 citrulline malate supplementation).

627

628 In the present study short term CIT supplementation did not significantly increase
629 plasma $[\text{NO}_2^-]$ and moderate exercise \dot{V}_{O_2} was not significantly altered. We have
630 recently shown that acute ARG ingestion did not increase plasma $[\text{NO}_2^-]$ or lower
631 moderate exercise \dot{V}_{O_2} (60). However, plasma $[\text{NO}_2^-]$ was increased by 28%
632 following short term ARG in the present study without impacting on moderate
633 exercise \dot{V}_{O_2} . Importantly neither ARG nor CIT increased plasma $[\text{NO}_2^-]$ to the extent
634 observed when moderate exercise \dot{V}_{O_2} is lowered by dietary nitrate supplementation

635 (2, 5-6, 33) and this likely accounts for the similar moderate exercise \dot{V}_{O_2} across PLA,
636 ARG and CIT in the present study. While neither the steady-state \dot{V}_{O_2} nor the rate at
637 which \dot{V}_{O_2} increased following the onset of moderate-intensity exercise were
638 significantly impacted by ARG or CIT supplementation, the NIRS-derived muscle
639 [HHb] amplitude was lower with CIT. Since the NIRS-derived muscle [HHb] signal
640 is considered a non-invasive proxy for muscle fractional O_2 extraction (e.g., 21), the
641 lower muscle [HHb] amplitude with CIT in the absence of a change in \dot{V}_{O_2} suggests
642 that CIT may have improved O_2 availability/distribution within the muscle
643 microvasculature.

644

645 During severe-intensity exercise, the overall \dot{V}_{O_2} kinetics was faster following CIT
646 supplementation compared to PLA. These data support the findings of Bendahan *et*
647 *al.* (7) who reported that L-citrulline malate supplementation elevated muscle
648 oxidative ATP production determined *in vivo* using ^{31}P -MRS. The faster overall \dot{V}_{O_2}
649 kinetics after CIT supplementation was accompanied by an increased NIRS-derived
650 TOI throughout the exercise bout. This suggests that CIT supplementation improved
651 the distribution of O_2 within the muscle microvasculature which, in turn, permitted a
652 greater \dot{V}_{O_2} over the initial stages of severe-intensity cycle exercise. Previous studies
653 have also reported that overall \dot{V}_{O_2} kinetics during severe-intensity exercise is speeded
654 by interventions that enhance muscle O_2 availability (e.g., 3, 64). However, it is
655 known that muscle NIRS measures manifest significant spatial heterogeneities across
656 the contracting quadriceps (29) so it is unclear whether a lower [HHb] amplitude
657 during moderate-intensity exercise, and the increased TOI during severe-intensity
658 exercise, at a discrete site of the *vastus lateralis* is reflective of an improved matching
659 between muscle O_2 delivery and muscle O_2 consumption across the contracting
660 quadriceps. Indeed, some studies report good agreement between NIRS markers of
661 muscle oxygenation and mixed venous P_{O_2} or oxygenation (e.g., 39), while other
662 studies do not (e.g., 38). It has also been suggested that the interpretation of NIRS
663 data may be complicated by increased skin blood flow (30, 40), as develops during
664 exercise. However, the NIRS-derived [HHb] (30) and TOI (40) that were used to
665 draw inferences on muscle oxygenation in this study are not altered by increased skin
666 blood flow. Alternatively, since short-term L-citrulline malate supplementation has
667 been shown to speed the rate of muscle phosphocreatine resynthesis following
668 exercise (7, 18), a process coupled to the maximal rate of ATP derived from

669 mitochondrial oxidative phosphorylation (41), it is also possible that CIT speeded
670 overall \dot{V}_{O_2} kinetics through enhancing muscle oxidative metabolism independent of
671 enhanced muscle O_2 delivery. There was no improvement in NIRS-derived TOI or \dot{V}
672 o_2 dynamics during severe exercise in this study after ARG supplementation.

673

674 *Influence of ARG and CIT supplementation on exercise performance*

675 Severe exercise tolerance was increased by 12% and subjects completed 7% more
676 sprint work during an exercise performance test with CIT supplementation. While L-
677 citrulline malate supplementation has been shown to increase muscle force production
678 (7, 19), to improve muscle contractile efficiency (19) and to prevent the decline in
679 muscle force production with endotoxemia (18), studies investigating the effects of
680 CIT on exercise performance or muscle fatigue resistance are limited and equivocal.
681 Of the two studies investigating the influence of CIT supplementation on exercise
682 performance to date, one has reported improved exercise tolerance in mice performing
683 swimming exercise (56), while the other showed that CIT compromised incremental
684 exercise performance in humans (26). It is unclear why our findings contrast with
685 those of Hickner et al. (26). While Hickner et al. (26) designed an experiment to
686 assess the influence of acute ingestion of either 3 or 9 g of CIT on incremental
687 treadmill exercise performance, we investigated the effects of 7 days of 6 g·day⁻¹
688 supplementation with CIT on cycling exercise tolerance and performance. These
689 conflicting findings might therefore be a consequence of different exercise
690 performance tests and dosing procedures, with 6-7 days of supplementation being
691 more effective than acute CIT ingestion. Moreover, an important difference between
692 these studies is the influence of CIT supplementation on NO biomarkers.
693 Specifically, we have shown that short term CIT tended ($P=0.08$) to increase plasma
694 $[NO_2^-]$ and improved exercise performance, whereas Hickner et al. (26) reported a
695 surprising tendency for acute CIT to lower plasma $[NO_x]$ (plasma [nitrite] + [nitrate])
696 and to compromise exercise performance. Therefore, the extent to which CIT
697 influences exercise performance appears to be linked to the duration of the
698 supplementation period and its impact on NO bioavailability.

699

700 The improved exercise performance after CIT supplementation was accompanied by
701 faster overall \dot{V}_{O_2} kinetics although there was no significant correlation between the
702 two. An increase in muscle oxidative ATP turnover in concert with a lower pH/power

703 ratio after L-citrulline malate supplementation has also been reported previously (7).
704 While we observed no change in blood [lactate] during and after severe-intensity
705 exercise with CIT supplementation in this study, previous studies have reported lower
706 end-exercise blood [lactate] and [ammonia] (56), as well as a lower rate of muscle
707 phosphocreatine degradation (19) with CIT. Taken together, these findings suggest
708 that CIT supplementation might increase the proportional energy contribution from
709 oxidative metabolism thereby limiting the utilization of the finite anaerobic energy
710 reserves and reducing the accumulation of metabolites linked to the process of muscle
711 fatigue.

712

713 The findings presented in this study suggest that short-term supplementation with L-
714 citrulline powder might lower blood pressure, speed \dot{V}_{O_2} kinetics and improve
715 exercise tolerance/performance. An alternative, natural, method to increase dietary L-
716 citrulline intake is via the consumption of watermelon (*Citrullus lanatus*), which
717 contains ~2.33 g of L-citrulline/L of unpasteurized watermelon juice (58).
718 Accordingly, subjects would be required to consume a daily watermelon dose of ~2.5
719 L in order to ingest the same dose of L-citrulline administered in this study. Further
720 research is required to determine whether the effects reported following short term
721 CIT supplementation in this study can be reproduced using watermelon juice
722 supplementation.

723

724 In conclusion, this study has shown that short-term CIT supplementation can reduce
725 blood pressure, speed \dot{V}_{O_2} kinetics and enhance endurance exercise performance.
726 Supplementation with ARG, on the other hand, did not significantly impact on these
727 parameters. Therefore, the results of this study suggest that chronic supplementation
728 with CIT might represent a practical, dietary intervention to reduce blood pressure,
729 and enhance oxidative metabolism and exercise performance in young, healthy adults.

730

731

732

733 **Acknowledgment**

734 The authors are grateful to NOW Sports Nutrition for providing the placebo, L-
735 arginine and L-citrulline supplements that were used in this study. We received no
736 funding from NOW Sports Nutrition for this work.

997 **Figure 1:** The pulmonary \dot{V}_{O_2} mean response time (MRT) during severe-intensity
998 constant-work-rate cycle exercise after placebo (PLA), L-arginine (ARG) and L-
999 citrulline (CIT) supplementation. The *upper panel* compares the \dot{V}_{O_2} MRT following
1000 placebo (PLA) and L-arginine (ARG) supplementation. The *lower panel* compares
1001 the \dot{V}_{O_2} MRT following following PLA and L-citrulline (CIT) supplementation. The
1002 *filled bars* represent the group mean \pm SEM responses after ARG and CIT
1003 supplementation, while the *open bars* represent the group mean \pm SEM responses
1004 after PLA supplementation. The solid grey lines represent the individual responses to
1005 the supplements. * indicates significantly different from PLA ($P < 0.05$). Note the
1006 significant decrease in the \dot{V}_{O_2} MRT after CIT but not ARG supplementation.

1007

1008 **Figure 2:** Group mean NIRS-derived muscle [deoxyhemoglobin] ([HHb]) during a
1009 moderate-intensity step cycle test following placebo (PLA), L-arginine (ARG) and L-
1010 citrulline (CIT) supplementation. Note the significant reduction in the [HHb]
1011 amplitude during moderate-intensity cycling exercise after CIT, but not ARG
1012 supplementation, compared to PLA.

1013

1014 **Figure 3:** Group mean NIRS-derived muscle tissue oxygenation index (TOI) during a
1015 severe-intensity step cycle test following placebo (PLA), L-arginine (ARG) and L-
1016 citrulline (CIT) supplementation. Note the significant increase in muscle oxygenation
1017 during severe-intensity cycling exercise after CIT, but not ARG supplementation,
1018 compared to PLA.

1019

1020 **Figure 4:** Group mean power profiles during a 60 s all-out cycle sprint commenced
1021 immediately after 6 min of severe-intensity cycle exercise following placebo (PLA),
1022 L-arginine (ARG) and L-citrulline (CIT) supplementation. Note the significant
1023 increase in peak and mean power output during the 60 s all-out sprint after CIT, but
1024 not ARG supplementation, compared to PLA.

1025

1026 **Figure 5:** Time-to-exhaustion during severe-intensity constant-work-rate cycle
1027 exercise after placebo (PLA), L-arginine (ARG) and L-citrulline (CIT)
1028 supplementation. The *upper panel* compares time-to-exhaustion following placebo

1029 (PLA) and L-arginine (ARG) supplementation. The *lower panel* compares time-to-
1030 exhaustion following PLA and L-citrulline (CIT) supplementation. The *filled bars*
1031 represent the group mean \pm SEM responses after ARG and CIT supplementation,
1032 while the *open bars* represent the group mean \pm SEM responses after PLA
1033 supplementation. The solid grey lines represent the individual responses to the
1034 supplements. * indicates significantly different from PLA ($P<0.05$). Note the
1035 significant increase in exercise tolerance after CIT but not ARG supplementation.

1074 **Table 1. Resting plasma [nitrite] and blood pressure measures following placebo**
 1075 **(PLA), L-arginine (ARG) and L-citrulline (CIT) supplementation.**
 1076

	PLA	ARG	CIT
Plasma [nitrite] (nM)	83 ± 25	106 ± 41*	100 ± 38
Plasma [L-arginine] (μM)	57 ± 14	151 ± 31*	135 ± 22*
Plasma [L-citrulline] (μM)	23 ± 5	26 ± 6	665 ± 205*#
Plasma [L-ornithine] (μM)	26 ± 8	62 ± 14*	50 ± 6*#

1077 Values are presented as the mean ± SD. * = significantly different from placebo
 1078 ($P < 0.05$); # = significantly different from ARG ($P < 0.05$).
