Xin Tan, Liangzhi Kou, Hassan A. Tahini & Sean C. Smith

Good electrical conductivity and high electron mobility of the sorbent materials are prerequisite for electrocatalytically switchable CO<sub>2</sub> capture. However, no conductive and easily synthetic sorbent materials are available until now. Here, we examined the possibility of conductive graphitic carbon nitride (g-C<sub>4</sub>N<sub>3</sub>) nanosheets as sorbent materials for electrocatalytically switchable CO<sub>2</sub> capture. Using first-principle calculations, we found that the adsorption energy of CO<sub>2</sub> molecules on g-C<sub>4</sub>N<sub>3</sub> nanosheets can be dramatically enhanced by injecting extra electrons into the adsorbent. At saturation CO<sub>2</sub> capture coverage, the negatively charged g-C<sub>4</sub>N<sub>3</sub> nanosheets achieve CO<sub>2</sub> capture capacities up to  $73.9 \times 10^{13} \text{ cm}^{-2}$  or 42.3 wt%. In contrast to other CO<sub>2</sub> capture approaches, the process of CO<sub>2</sub> capture/release occurs spontaneously without any energy barriers once extra electrons are introduced or removed, and these processes can be simply controlled and reversed by switching on/off the charging voltage. In addition, these negatively charged g-C<sub>4</sub>N<sub>3</sub> nanosheets are highly selective for separating CO<sub>2</sub> from mixtures with CH<sub>4</sub>, H<sub>2</sub> and/or N<sub>2</sub>. These predictions may prove to be instrumental in searching for a new class of experimentally feasible high-capacity CO<sub>2</sub> capture materials with ideal thermodynamics and reversibility.

At the current rate of emissions of greenhouse gases, for which carbon dioxide (CO<sub>2</sub>) is the main component, global warming and climate change will continue to rise<sup>1–3</sup>. One crucial issue facing efficiently separating, capturing, storing and/or converting CO<sub>2</sub> is the development of a practical sorbent material<sup>4–6</sup>. Liquid-amine, which is the most common adsorbent for current industrial process for CO<sub>2</sub> capture, suffers from relatively low efficiency, equipment corrosion, solvent loss, and toxicity<sup>7–10</sup>. Alternatively, various solid materials have been proposed as attractive adsorbents for CO<sub>2</sub> capture, including metal-organic frameworks (MOFs)<sup>11–15</sup>, aluminum nitride (AlN)<sup>16</sup>, carbon<sup>17–19</sup>, hexagonal boron nitride (*h*-BN)<sup>20</sup>, and silicon carbide (SiC)<sup>21,22</sup> nanostructures. However, the difficult regeneration processes due to the large adsorption energy, which generally demands high temperatures to release captured CO<sub>2</sub>, significantly hinders their practical applications.

Recently, electrocatalytically switchable CO<sub>2</sub> capture scheme has been proposed as a controllable, high selective, and reversible CO<sub>2</sub> capture strategy for bare *h*-BN nanomaterials<sup>23</sup>. Specifically, CO<sub>2</sub> molecules are weakly adsorbed (i.e. physisorbed) on neutral *h*-BN. By injecting extra electrons into *h*-BN adsorbent, density functional theory (DFT) calculations reveal that CO<sub>2</sub> adsorption can be dramatically enhanced via a charge-induced chemisorption interaction. The chemically adsorbed CO<sub>2</sub> can in principle be released when the extra electrons are removed. In contrast to previous methods, the CO<sub>2</sub> capture/release occurs spontaneously once extra electrons are introduced or removed, and the process of CO<sub>2</sub> capture/release can be simply controlled and reversed by switching on/off the charges carried by *h*-BN

**Figure 1.** Top (upper) and side (lower) views of (a) a  $(2 \times 2)$  reconstructed  $g\text{-C}_4\text{N}_3$  supercell. The blue and grey balls represent N and C atoms, respectively, and the unit cell of  $g\text{-C}_4\text{N}_3$  is indicated by red dot lines.  $C_1$  and  $C_2$  denote different C atoms in  $g\text{-C}_4\text{N}_3$  unit cell. The calculated band structures of (b) a  $(2 \times 2)$  reconstructed  $g\text{-C}_4\text{N}_3$ . The blue dashed line denotes the Fermi level. The red and black lines in (b) denote the spin-up and spin-down states, respectively.

nanomaterials. However,  $h\text{-BN}$  is wide-gap semiconductor with band gap around  $5.8\text{ eV}^{24,25}$  and it is not clear how to charge up bare  $h\text{-BN}$  due to its insulating character.

To overcome the above disadvantage, Jiao *et al.*<sup>26</sup> have investigated carbon nanotubes with pyridinic-nitrogen as an alternative absorbent to electrocatalytically switchable  $\text{CO}_2$  capture because of their good electron conductivity. On the other hand, we have proposed layered  $h\text{-BN}$  and graphene (hybrid BN/G) nanosheets, consisting of a single or double-layer  $h\text{-BN}$  and a substrate graphene layer, as an experimentally feasible approach to induce the requisite charge on  $h\text{-BN}$  for electrocatalytically switchable  $\text{CO}_2$  capture<sup>27</sup>. However, the synthesis of carbon nanomaterials with pyridinic nitrogen doping and hybrid BN/G are difficult to control in experiment. One natural question arise: can we find a conductive sorbent material for electrocatalytically switchable  $\text{CO}_2$  capture, which avoids complicated synthesis route?

Very recently, intense attention has been attracted by a new class of two-dimensional conjugated polymer, graphitic carbon nitride, due to the anisotropic two-dimensional geometric morphology and the aromatic  $\pi$ -conjugated framework. This endows carbon nitride nanosheets with attractive bandgap- and surface-engineered applications in both energy- and environment-related topics, such as photocatalysis for water splitting<sup>28,29</sup>, hydrogen evolution<sup>30</sup>,  $\text{CO}_2$  reduction<sup>31</sup>, organosynthesis<sup>32</sup>, amongst others<sup>33</sup>.  $g\text{-C}_3\text{N}_4$  and  $g\text{-C}_4\text{N}_3$  are two kinds of two-dimensional conjugated nanosheets, which have been recently synthesized by using cross-linking nitride-containing anions in ionic liquid<sup>34,35</sup>. Different from each other,  $g\text{-C}_3\text{N}_4$  is semiconductor<sup>34</sup>, while  $g\text{-C}_4\text{N}_3$  shows half-metallic property<sup>36</sup>.

Here we show that electrocatalytically switchable  $\text{CO}_2$  capture is indeed possible by considering conductive  $g\text{-C}_4\text{N}_3$  nanosheets, of which the charge states can be easily modified experimentally because of the good electrical conductivity and high electron mobility. Using first-principle calculations, we found that the adsorption energy of  $\text{CO}_2$  molecules on  $g\text{-C}_4\text{N}_3$  nanosheets can be dramatically enhanced from  $0.24$  to  $2.52\text{ eV}$  by injecting extra electrons into the adsorbent. At saturation  $\text{CO}_2$  capture coverage, the negatively charged  $g\text{-C}_4\text{N}_3$  nanosheets achieve  $\text{CO}_2$  capture capacities up to  $73.9 \times 10^{13}\text{ cm}^{-2}$  or  $42.3\text{ wt}\%$ . Once the extra electrons are removed, the captured  $\text{CO}_2$  molecules can easily desorb from the adsorbent. In contrast to other  $\text{CO}_2$  capture approaches, the process of  $\text{CO}_2$  capture/release occurs spontaneously without any energy barriers once extra electrons are introduced or removed, and these processes can be simply controlled and reversed by switching on/off the charging voltage. In addition, these negatively charged  $g\text{-C}_4\text{N}_3$  nanosheets are highly selective for separating  $\text{CO}_2$  from mixtures with  $\text{CH}_4$ ,  $\text{H}_2$  and/or  $\text{N}_2$ . These predictions might pave the way in searching for a new class of experimentally feasible high-capacity  $\text{CO}_2$  capture materials with ideal thermodynamics and reversibility.

## Results

Since good electrical conductivity and high electron mobility are prerequisite for injecting extra electrons into electrocatalytically switchable  $\text{CO}_2$  capture materials, we first studied the electronic structures of isolated  $g\text{-C}_4\text{N}_3$ . The lowest-energy configurations and the calculated band structures of  $g\text{-C}_4\text{N}_3$  are shown in Fig. 1. Consistent with previous studies<sup>36</sup>,  $g\text{-C}_4\text{N}_3$  is a  $(2 \times 2)$  reconstructed structure with half-metallic state. This indicates that  $g\text{-C}_4\text{N}_3$  has good electrical conductivity and high electron mobility, which should readily facilitate electron injection/release for electrocatalytically switchable  $\text{CO}_2$  capture.

**Figure 2.** Top and side views of the lowest-energy configurations of a single CO<sub>2</sub> molecule absorbed on the (a) neutral and (b) 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub>. The blue, grey and red balls represent N, C and O atoms, respectively, and the adsorption energies of the CO<sub>2</sub> molecule on neutral and 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub> are listed.

**Single CO<sub>2</sub> Adsorption on Neutral and 2 e<sup>-</sup> Negatively Charged g-C<sub>4</sub>N<sub>3</sub> Nanosheets.** We next shift our attention to a single CO<sub>2</sub> adsorption on neutral and negatively charged g-C<sub>4</sub>N<sub>3</sub>. Since g-C<sub>4</sub>N<sub>3</sub> is a (2 × 2) reconstructed structure, there are many different adsorption sites for a CO<sub>2</sub> molecule. Here, we considered all the adsorption sites: directly on top of a C or N atom, above the midpoint of a bond linking the C and N atoms, and above the center of a honeycomb-like hexagon. Figure 2 shows the lowest-energy configurations of a CO<sub>2</sub> adsorbed on neutral and 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub>. On neutral g-C<sub>4</sub>N<sub>3</sub> (Fig. 2(a)), the linear CO<sub>2</sub> molecule is parallel to g-C<sub>4</sub>N<sub>3</sub> and locates on top of three nitrogen atoms. The distance between the C atom of CO<sub>2</sub> and closest N atom is 2.966 Å, and the linear CO<sub>2</sub> molecule shows little structural change compared to a free CO<sub>2</sub> molecule with the O-C-O angle and two double C=O bonds being 178.2° and 1.176 Å, respectively. Mulliken population analysis suggests that the amount of transferred electron from the absorbed CO<sub>2</sub> molecule to g-C<sub>4</sub>N<sub>3</sub> is negligible (about 0.004 e<sup>-</sup>). For the neutral case, the CO<sub>2</sub> molecule is weakly adsorbed (i.e. physisorbed) onto neutral g-C<sub>4</sub>N<sub>3</sub> with small adsorption energy of 0.24 eV.

After injecting two extra electrons into the g-C<sub>4</sub>N<sub>3</sub> supercell (Fig. 2(b)), the CO<sub>2</sub> is strongly adsorbed at surface N atom, and changes from physisorption into chemisorption on 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub>. The distance between the C atom of CO<sub>2</sub> and surface N atom of g-C<sub>4</sub>N<sub>3</sub> is shortened to 1.569 Å, the O-C-O angle is bent from 178.2° to 131.8°, the two double C=O bonds are elongated from 1.176 to 1.246 Å, and the charge transfer from g-C<sub>4</sub>N<sub>3</sub> to CO<sub>2</sub> increase to 0.56e<sup>-</sup>. In this case, the adsorption energy of a CO<sub>2</sub> remarkably increases to 1.20 eV, which is much larger than the adsorption energies of CO<sub>2</sub> on other high-performance adsorbents (0.4–0.8 eV)<sup>6</sup>, indicating that the negatively charged g-C<sub>4</sub>N<sub>3</sub> is an excellent adsorbent for CO<sub>2</sub> capture.

To understand the underlying mechanism of CO<sub>2</sub> capture on negatively charged g-C<sub>4</sub>N<sub>3</sub>, we plotted the deformation electronic density of neutral and 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub> by subtracting the electronic density of isolated N and C atoms from the sheet in Fig. 3. Obviously, for the neutral case (Fig. 3(a)), some electrons are extracted from the C atoms and delocalized over the N atoms, as implied by the green regions. Mulliken population analysis indicated that the electrons distribute at N, C<sub>1</sub> and C<sub>2</sub> are -0.302, 0.294 and -0.036 |e|, respectively. When two extra electrons are introduced (Fig. 3(b)), the extra electrons are almost evenly distributed on N and C atoms. Mulliken population analysis suggest that each atom gains -0.07 ~ -0.09 |e|, and the electrons distribute at N, C<sub>1</sub> and C<sub>2</sub> are -0.383, 0.222 and -0.122 |e|, respectively. Compared with the neutral case, more electrons are distributed and delocalized at N atoms, as implied by the green regions in Fig. 3(b). As CO<sub>2</sub> is a Lewis acid and it prefers to accept, rather than donate, electrons during reaction, the N atom of negatively charged g-C<sub>4</sub>N<sub>3</sub> can donate electrons to CO<sub>2</sub>, and form a new bond between the C atom of CO<sub>2</sub> and surface N atom of g-C<sub>4</sub>N<sub>3</sub> (Fig. 3(d)), which is significantly different from the case that CO<sub>2</sub> on neutral g-C<sub>4</sub>N<sub>3</sub> (Fig. 3(c)). This is the reason why the CO<sub>2</sub> molecule has a strong interaction with negatively charged g-C<sub>4</sub>N<sub>3</sub>.

In order to investigate the kinetic process of CO<sub>2</sub> capture/release on 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub>, we next studied the energy change of a CO<sub>2</sub> molecule adsorbed on g-C<sub>4</sub>N<sub>3</sub> after the introduction or removal of the two extra electrons. In Fig. 4(a), we started with the lowest-energy configuration of neutral g-C<sub>4</sub>N<sub>3</sub> with a physisorbed CO<sub>2</sub> molecule. Two electrons are then added to the neutral g-C<sub>4</sub>N<sub>3</sub>, and we examined the energy changes as the system relaxes to the 2 e<sup>-</sup> negatively charged optimized state. In Fig. 4(b), we started with the lowest-energy configuration of the 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub> with a chemisorbed CO<sub>2</sub> molecule. Two electrons are removed, and then the system is allowed to relax, forming a physisorbed CO<sub>2</sub> molecule. When two extra electrons are introduced into g-C<sub>4</sub>N<sub>3</sub>, the interactions between the CO<sub>2</sub> molecule and the 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub> are significantly larger than that with neutral g-C<sub>4</sub>N<sub>3</sub>, and the CO<sub>2</sub> molecule spontaneously relaxes to chemisorption configuration. This

**Figure 3.** The deformation electronic density of (a) neutral and (b)  $2e^-$  negatively charged  $g\text{-C}_4\text{N}_3$ . Green and yellow refer to electron-rich and -deficient area, respectively. The isosurface value is  $0.02 e/\text{au}$ . (c) The total charge density distribution of a single  $\text{CO}_2$  molecule on (c) neutral and (d)  $2e^-$  negatively charged  $g\text{-C}_4\text{N}_3$ . The isosurface value is  $0.8 e/\text{au}$ . The overlap of the electron densities of the C atom of  $\text{CO}_2$  and surface N atom of  $g\text{-C}_4\text{N}_3$  in (d) indicates the formation of a new bond.

**Figure 4.** The energy change of (a) the relaxation (capture) of a  $\text{CO}_2$  molecule on  $g\text{-C}_4\text{N}_3$  after two extra electrons are introduced, and (b) the reverse relaxation (release) process of a captured  $\text{CO}_2$  molecule from  $g\text{-C}_4\text{N}_3$  after two extra electrons are removed from the adsorbent.

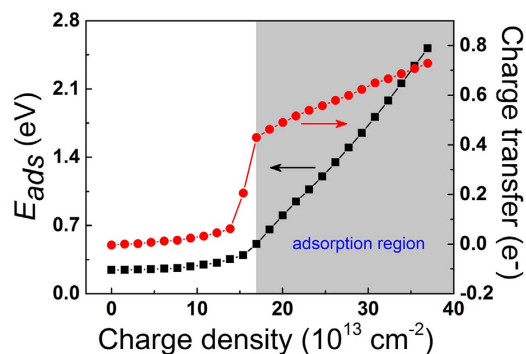

process is exothermic by  $1.08\text{ eV}$  without any energy barrier. On the other hand, when two extra electrons are removed from the  $2e^-$  negatively charged  $g\text{-C}_4\text{N}_3$ , the  $\text{CO}_2$  molecule spontaneously returns to the weakly bound state and desorbs from  $g\text{-C}_4\text{N}_3$ . This process is also exothermic by  $1.39\text{ eV}$  without any energy barrier. Therefore, the  $\text{CO}_2$  storage/release processes on negatively charged  $g\text{-C}_4\text{N}_3$  are reversible with fast kinetics, and can be easily controlled via adding/removing the extra electrons.

**The Effects of Charge Density on Single  $\text{CO}_2$  Capture on Negatively Charged  $g\text{-C}_4\text{N}_3$  Nanosheets.** To investigate the effects of charge density on  $\text{CO}_2$  capture on negatively charged  $g\text{-C}_4\text{N}_3$ , we investigated a  $\text{CO}_2$  adsorption on negatively charged  $g\text{-C}_4\text{N}_3$  with different charge densities. Here, we defined the charge densities of  $g\text{-C}_4\text{N}_3$  as follows

$$\rho = \frac{Q}{S}$$

where  $\rho$ ,  $Q$  and  $S$  are the charge densities of  $g\text{-C}_4\text{N}_3$ , the total charge and the surface area in  $2 \times 2$  supercell, respectively. For  $g\text{-C}_4\text{N}_3$ , the surface area in  $2 \times 2$  supercell can be calculated as  $S = \frac{\sqrt{3}}{2} a^2$ , where  $a$  is the lattice constant of  $2 \times 2$  supercell.

Figure 5 shows the adsorption energies of a  $\text{CO}_2$  on negatively charged  $g\text{-C}_4\text{N}_3$  and the charge transfer between  $\text{CO}_2$  and  $g\text{-C}_4\text{N}_3$  as functions of charge densities. For small charge density case ( $< 13.9 \times 10^{13} \text{ cm}^{-2}$ ), the adsorption energy of  $\text{CO}_2$  is small ( $0.24 \sim 0.35\text{ eV}$ ), and charge transfer between

**Figure 5.** The adsorption energies of a CO<sub>2</sub> on negatively charged g-C<sub>4</sub>N<sub>3</sub> and the charge transfer between CO<sub>2</sub> and g-C<sub>4</sub>N<sub>3</sub> as functions of charge densities. The gray area indicates the adsorption region.

**Figure 6.** (a) The maximum number and the average adsorption energies of captured CO<sub>2</sub> molecules on negatively charged g-C<sub>4</sub>N<sub>3</sub> with different charge densities. (b) Top and (c) side views of the lowest-energy configuration of six CO<sub>2</sub> molecules adsorbed on negatively charged g-C<sub>4</sub>N<sub>3</sub> with charge density  $61.7 \times 10^{13} \text{ cm}^{-2}$ .

CO<sub>2</sub> and g-C<sub>4</sub>N<sub>3</sub> is less than  $0.06 \text{ e}^-$ . When charge density is larger than  $13.9 \times 10^{13} \text{ cm}^{-2}$ , the adsorption energy of CO<sub>2</sub> and the charge transfer from g-C<sub>4</sub>N<sub>3</sub> to CO<sub>2</sub> increase dramatically with increasing charge density, indicating the CO<sub>2</sub> molecule can only adsorb on negatively charged g-C<sub>4</sub>N<sub>3</sub> with large charge density. Considering the adsorption energies of CO<sub>2</sub> on other high-performance adsorbents is  $0.4\text{--}0.8 \text{ eV}$ <sup>6</sup>, we define the minimum charging density for CO<sub>2</sub> capture on negatively charged g-C<sub>4</sub>N<sub>3</sub> is about  $17.0 \times 10^{13} \text{ cm}^{-2}$ .

**CO<sub>2</sub> Capture Capacity on Negatively Charged g-C<sub>4</sub>N<sub>3</sub> Nanosheets.** To estimate CO<sub>2</sub> capture capacity on negatively charged g-C<sub>4</sub>N<sub>3</sub>, we studied the maximum number and the average adsorption energy of captured CO<sub>2</sub> molecules on negatively charged g-C<sub>4</sub>N<sub>3</sub> with different charge densities (Fig. 6(a)). Here, we determine the maximum number of captured CO<sub>2</sub> for each negatively charged g-C<sub>4</sub>N<sub>3</sub> with different charge density by gradually increasing the number of CO<sub>2</sub> molecules on negatively charged g-C<sub>4</sub>N<sub>3</sub> until no more CO<sub>2</sub> can be adsorbed. The average adsorption energy of captured CO<sub>2</sub> is calculated as the total adsorption energy divided by the maximum number of captured CO<sub>2</sub>. The results show that no CO<sub>2</sub> molecules can be captured by negatively charged g-C<sub>4</sub>N<sub>3</sub> with small charge density ( $\leq 12.3 \times 10^{13} \text{ cm}^{-2}$ ). As the charge density increase from  $18.5 \times 10^{13}$  to  $61.6 \times 10^{13} \text{ cm}^{-2}$ , the negatively charged g-C<sub>4</sub>N<sub>3</sub> can capture two, four and six CO<sub>2</sub> molecules with the average adsorption energy of captured CO<sub>2</sub> molecules ranging from 0.72 to 3.58 eV. We note that a further increase in the number of CO<sub>2</sub> molecules leads to some CO<sub>2</sub> molecules moving far away from the adsorbent during the geometry optimization even if we further increase the charge density of g-C<sub>4</sub>N<sub>3</sub>. Therefore, we define six CO<sub>2</sub>

**Figure 7.** The adsorption energies of CO<sub>2</sub>, CH<sub>4</sub>, H<sub>2</sub>, N<sub>2</sub> and H<sub>2</sub>O on neutral, 1 e<sup>-</sup> and 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub>.

molecules in each  $2 \times 2$  supercell (i.e. CO<sub>2</sub> capture capacity  $73.9 \times 10^{13} \text{ cm}^{-2}$  or 42.3 wt%) as the likely saturation CO<sub>2</sub> capture coverage (Fig. 6(b,c)). It should be noted that surface defective sites such as N vacancies or un-condensed amino group could lower CO<sub>2</sub> capture capacity. However, considering the high CO<sub>2</sub> capture capacity of negatively charged g-C<sub>4</sub>N<sub>3</sub>, we believe this may nevertheless represent a feasible high-capacity CO<sub>2</sub> capture material.

Interestingly, we note that the CO<sub>2</sub> molecules do not all bind equally but the capture process occurs discretely two at a time. To further confirm this phenomenon, we put four CO<sub>2</sub> molecules on neutral g-C<sub>4</sub>N<sub>3</sub> and gradually increase the charge density of negatively charged g-C<sub>4</sub>N<sub>3</sub> until four CO<sub>2</sub> are all captured (corresponding lowest-energy configurations are shown in Figure S1 of the Supporting Information). Clearly, four CO<sub>2</sub> are physically adsorbed on neutral and 1 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub> (Figure S1(a,b), Supporting Information). On 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub>, two CO<sub>2</sub> are chemisorbed while other two CO<sub>2</sub> are physisorbed on adsorbent (Figure S1(c), Supporting Information). When three electrons are introduced, all the CO<sub>2</sub> are captured on 3 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub> (Figure S1(d), Supporting Information).

**CH<sub>4</sub>, H<sub>2</sub> and N<sub>2</sub> Adsorption on g-C<sub>4</sub>N<sub>3</sub> Nanosheets.** CH<sub>4</sub>, H<sub>2</sub>, N<sub>2</sub> are three types of gas mixtures that are currently most interesting for CO<sub>2</sub> capture technologies, namely, postcombustion (predominantly CO<sub>2</sub>/N<sub>2</sub> separation), natural gas sweetening (CO<sub>2</sub>/CH<sub>4</sub>), and precombustion (CO<sub>2</sub>/H<sub>2</sub>) capture<sup>37</sup>. In order to demonstrate the high selectivity of negatively charged g-C<sub>4</sub>N<sub>3</sub> nanosheets for CO<sub>2</sub> capture, we calculated the adsorption energies of CH<sub>4</sub>, H<sub>2</sub> and N<sub>2</sub> on neutral and negatively charged g-C<sub>4</sub>N<sub>3</sub> and compared with those of CO<sub>2</sub>. In Fig. 7 we list the comparative adsorption energies of CO<sub>2</sub>, CH<sub>4</sub>, H<sub>2</sub>, and N<sub>2</sub> on neutral, 1 e<sup>-</sup> and 2 e<sup>-</sup> negatively charged g-C<sub>4</sub>N<sub>3</sub> (corresponding lowest-energy configurations are shown in Figure S2 of the Supporting Information). Clearly, the adsorptions of CH<sub>4</sub>, H<sub>2</sub> and N<sub>2</sub> on neutral, 1 e<sup>-</sup> and 2 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub> are all physical rather than chemical. The distance between the carbon atom of CH<sub>4</sub> (the hydrogen atom of H<sub>2</sub>, the nitrogen atom of N<sub>2</sub>) and g-C<sub>4</sub>N<sub>3</sub> is 3.157–3.159 (2.111–2.539, 2.865–3.236) Å, respectively. The adsorption energies of CH<sub>4</sub>, H<sub>2</sub> and N<sub>2</sub> on neutral, 1 e<sup>-</sup> and 2 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub> range from 0.06 to 0.39 eV. In contrast, although CO<sub>2</sub> is physically adsorbed at neutral and 1 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub> with small adsorption energy in the range from 0.24 to 0.32 eV, CO<sub>2</sub> is tightly chemisorbed on 2 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub> with large adsorption energy of 1.20 eV. The above comparisons demonstrate that negatively charged g-C<sub>4</sub>N<sub>3</sub> has very high selectivity for capturing CO<sub>2</sub> from CH<sub>4</sub>, H<sub>2</sub> and/or N<sub>2</sub> mixtures.

**Water Adsorption on g-C<sub>4</sub>N<sub>3</sub> Nanosheets.** Since water saturates most industrial gas streams, including flue gas, we also studied the adsorption energies of H<sub>2</sub>O on neutral and negatively charged g-C<sub>4</sub>N<sub>3</sub> and compared with those of CO<sub>2</sub>, as shown in Fig. 7 (corresponding lowest-energy configurations are shown in Figure S2 of the Supporting Information). On neutral g-C<sub>4</sub>N<sub>3</sub>, both CO<sub>2</sub> and H<sub>2</sub>O are physically adsorbed on adsorbents with small adsorption energies of 0.24 and 0.38 eV, respectively. On 1 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub>, the adsorption energy of CO<sub>2</sub> slightly increases to 0.32 eV, while the adsorption energy of H<sub>2</sub>O significantly increases to 0.60 eV, which is twice as much as that of CO<sub>2</sub>. On 2 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub>, both CO<sub>2</sub> and H<sub>2</sub>O are chemically adsorbed on adsorbents with large adsorption energies of 1.20 and 1.18 eV, respectively. These results indicate that the negatively charged g-C<sub>4</sub>N<sub>3</sub> cannot selectively capture CO<sub>2</sub> from a gas mixture with H<sub>2</sub>O present, and we should utilize some absorbent to eliminate water prior to CO<sub>2</sub> adsorption. In fact, since the adsorption energy of H<sub>2</sub>O is twice as much as that of CO<sub>2</sub> on 1 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub>, utilization of 1 e<sup>-</sup> g-C<sub>4</sub>N<sub>3</sub> to eliminate water prior to CO<sub>2</sub> adsorption is one potentially viable approach. In this scenario, we could utilize g-C<sub>4</sub>N<sub>3</sub> at lower voltage to eliminate water prior to a second stage of CO<sub>2</sub> adsorption at slightly higher voltage.

## Discussion

In summary, we have shown that modification of the charge state of conductive g-C<sub>4</sub>N<sub>3</sub> nanosheets provides an experimentally feasible approach for electrocatalytically switchable CO<sub>2</sub> capture. Compared with other CO<sub>2</sub> capture approaches, the process of CO<sub>2</sub> capture/release occurs spontaneously without any energy barriers once extra electrons are introduced or removed, and these processes can be simply controlled and reversed by switching on/off the charging voltage. In addition, these negatively charged g-C<sub>4</sub>N<sub>3</sub> nanosheets are highly selective for separating CO<sub>2</sub> from mixtures with CH<sub>4</sub>, H<sub>2</sub> and/or N<sub>2</sub>.

Good electrical conductivity and high electron mobility of the sorbent materials are prerequisite for electrocatalytically switchable CO<sub>2</sub> capture. The aim of the present paper is to explore conductive and easily synthetic sorbent material as an experimentally feasible adsorbent for electrocatalytically switchable CO<sub>2</sub> capture. These predictions may prove to be instrumental in searching for a new class of high-capacity CO<sub>2</sub> capture materials with ideal thermodynamics and reversibility, and we hope that this work will stimulate further theoretical and experimental research in this direction.

## Methods

Our DFT calculations employed the linear combination of atomic orbital and spin-unrestricted method implemented in Dmol<sup>3</sup> package<sup>38</sup>. The generalized gradient approximation (GGA) in Perdew–Burke–Ernzerhof (PBE) functional form<sup>39</sup> together with an all-electron double numerical basis set with polarization function (DNP) were adopted. Since the standard PBE functional is incapable of giving an accurate description of weak interactions, we adopted a DFT+D (D stands for dispersion) approach with the Grimme's vdW correction in our computations<sup>40</sup>. The real-space global cutoff radius was set to be 4.1 Å.

To study CO<sub>2</sub> capture/release on g-C<sub>4</sub>N<sub>3</sub> nanosheets, we employed 2 × 2 supercell with periodic boundary conditions in the *x*-*y* plane (Fig. 1(a)). The vacuum space was set to larger than 20 Å in the *z* direction to avoid interactions between periodic images. In geometry optimizations, all the atomic coordinates were fully relaxed up to the residual atomic forces smaller than 0.001 Ha/Å, and the total energy was converged to 10<sup>-5</sup> Ha. The Brillouin zone integration was performed on a (6 × 6 × 1) Monkhorst-Pack k-point mesh<sup>41</sup>.

In order to investigate the gas adsorption on adsorbent, we defined the adsorption energy  $E_{ads}$  of CO<sub>2</sub>, CH<sub>4</sub>, H<sub>2</sub> and N<sub>2</sub> molecules on g-C<sub>4</sub>N<sub>3</sub> as follows

$$E_{ads} = (E_{C_4N_3} + nE_{gas} - E_{C_4N_3-gas})/n \quad (1)$$

where  $E_{C_4N_3}$ ,  $E_{gas}$ ,  $E_{C_4N_3-gas}$ , and  $n$  are the total energy of isolated g-C<sub>4</sub>N<sub>3</sub> nanosheets, isolated gas molecule, g-C<sub>4</sub>N<sub>3</sub> with the adsorbed gas, and number of gas molecules adsorbed on g-C<sub>4</sub>N<sub>3</sub>. According to this definition, a more positive adsorption energy indicates a stronger binding of the gas molecule to g-C<sub>4</sub>N<sub>3</sub>. The electron distribution and transfer mechanism are determined using the Mulliken method<sup>42</sup>.
