Abstract

We present a state-of-the-art algorithm for measuring the semantic similarity of word pairs using novel combinations of word embeddings, WordNet, and the concept dictionary 4lang. We evaluate our system on the SimLex-999 benchmark data. Our top score of 0.76 is higher than any published system that we are aware of, well beyond the average inter-annotator agreement of 0.67, and close to the 0.78 average correlation between a human rater and the average of all other ratings, suggesting that our system has achieved near-human performance on this benchmark.

0 Introduction

We present a hybrid system for measuring the semantic similarity of word pairs. The system relies both on standard word embeddings, the WordNet database, and features derived from the 4lang concept dictionary, a set of concept graphs built from entries in monolingual dictionaries of English. 4lang-based features improve the performance of systems using only word embeddings and/or WordNet, our top configurations achieve state-of-the-art results on the SimLex-999 data, which has recently become a popular benchmark of word similarity metrics.

In Section 1 we summarize earlier work on measuring word similarity and review the latest results achieved on the SimLex-999 data. Section 2 describes our experimental setup, Sections 2.1 and 2.2 documents the features obtained using word embeddings and WordNet. In Section 3 we briefly introduce the 4lang resources and the formalism it uses for encoding the meaning of words as directed graphs of concepts, then document our efforts to develop novel 4lang-based similarity features. Besides improving the performance of existing systems for measuring word similarity, the goal of the present project is to examine the potential of 4lang representations in representing non-trivial lexical relationships that are beyond the scope of word embeddings and standard linguistic ontologies.

Section 4 presents our results and provides rough error analysis. Section 5 offers some conclusions and plans for future work. All software presented in this paper is available for download under an MIT license at http://github.com/recski/wordsim.

1 Background

Measuring the semantic similarity of words is a fundamental task in various natural language processing applications. The ability to judge the similarity in meaning of any two linguistic structures reflects on the quality of the representations used. Vector representations (word embeddings) are commonly used as the component encoding (lexical) semantics in virtually all NLP applications. The similarity of word vectors is by far the most common source of information for semantic similarity in state-of-the-art systems, e.g. nearly all top-scoring systems at the 2015 SemEval Task on measuring semantic similarity (Agirre et al., 2015) rely on word embeddings to score sentence pairs (see e.g. (Sultan et al., 2015; Han et al.,

Proceedings of the 1st Workshop on Representation Learning for NLP, pages 193–200,
Berlin, Germany, August 11th, 2016.

2015)).

Hill et al. (2015) proposed the SimLex-999 dataset as a benchmark for word similarity, arguing that pre-existing gold standards measure *association*, not similarity, of word pairs; e.g. the words *cup* and *coffee* receive a high score by annotators in the widely used wordsim353 data (Finkelstein et al., 2002). SimLex has since been used to evaluate various algorithms for measuring word similarity. Hill et al. (2015) reports a Spearman correlation of 0.414 achieved by an embedding trained on Wikipedia using word2vec (Mikolov et al., 2013). Schwartz et al. (2015) achieves a score of 0.56 using a combination of a standard word2vec-based embedding and the SP model, which encodes the cooccurrence of words in *symmetric patterns* such as *X and Y* or *X as well as Y*.

Banjade et al. (2015) combined multiple word embeddings with the word similarity algorithm of (Han et al., 2015) used in a top-scoring SemEval system, and simple features derived from WordNet (Miller, 1995) indicating whether word pairs are synonymous or antonymous. Their top system achieved a correlation of 0.64 on SimLex. The highest score we are aware of is achieved using the Paragram embedding (Wieting et al., 2015), a set of vectors obtained by training preexisting embeddings on word pairs from the Paraphrase Database (Ganitkevitch et al., 2013). The top correlation of 0.69 is measured when using 300-dimension embedding created from the same GloVe-vectors that have been introduced in this section (trained on 840 billion tokens). Hyperparameters of this database have been tuned for maximum performance on SimLex, another version tuned for the WS-353 dataset achieves a correlation of 0.667.

2 Setup

Our system is trained on a variety of real-valued and binary features generated using word embeddings, WordNet, and 4lang definition graphs. Each class of features will be presented in detail below. We perform support vector regression (with RBF kernel) over all features using the numpy library, the model is trained on 900 pairs of the SimLex data and used to obtain scores for the remaining 99 pairs. We compute the Spearman correlation of the output with SimLex scores. We evaluate each of our models using tenfold cross-validation and by averaging the ten correlation figures. The changes in performance caused by previously used feature classes are described next, the performance of all major configurations are summarized in Section 4.

2.1 Word embeddings

Features in the first group are based on word vector similarity. For each word pair the cosine similarity of the corresponding two vectors is calculated for all embeddings used. Three sets of word vectors in our experiments were built using the neural models compared by Hill et al. (2015): the SENNA[1] (Collobert and Weston, 2008), and Huang[2] (Huang et al., 2012) embeddings contain 50-dimension vectors and were downloaded from the authors' webpages. The word2vec (Mikolov et al., 2013) vectors are of 300 dimensions and were trained on the Google News dataset[3].

We extend this set of models with GloVe vectors[4] (Pennington et al., 2014), trained on 840 billion tokens of Common Crawl data[5], and the two word embeddings mentioned in Section 1 that have recently been evaluated on the SimLex dataset: the 500-dimension SP model[6] (Schwartz et al., 2015) (see Section 1) and the 300-dimension Paragram vectors[7] (Wieting et al., 2015). The model trained on 6 features corresponding to the 6 embeddings mentioned achieves a Spearman correlation of 0.72, the performance of individual embeddings is listed in Table 1.

2.2 Wordnet

Another group of features are derived using WordNet (Miller, 1995). WordNet-based metrics proved to be useful in the Semeval-system of Han et al. (2013), who used these metrics for calculating a boost of word similarity scores. The top system of Banjade et al. (2015) also includes a subset of these features. We chose to use four of these metrics as binary features in our system;

System	Spearman's ρ
Huang	0.14
SENNA	0.27
GloVe	0.40
Word2Vec	0.44
SP	0.50
Paragram	0.68
6 embeddings	**0.72**

Table 1: Performance of word embeddings on SimLex

these indicate whether one word is a direct or two-link hypernym of the other, whether the two are derivationally related, and whether one word appears frequently in the glosses of the other (and its direct hypernym and its direct hyponyms). Each of these features improved our system independently, adding all of them brought the system's performance to 0.73. A model trained on the 4 WordNet-based features alone achieves a correlation of 0.33.

3 4lang

The 4lang theory of semantics was introduced and motivated in Kornai (2010) and Kornai (2012). The name refers to the initial concept dictionary, which had bindings in four languages, representative samples of the major language families spoken in Europe; Germanic (English), Slavic (Polish), Romance (Latin), and Finno-Ugric (Hungarian). Today, bindings exist in over 40 languages (Ács et al., 2013). We only present a bird's-eye view here, and refer the reader to the book-length presentation (Kornai, in preparation) for details. In brief, 4lang is an algebraic (symbolic) system that puts the emphasis on lexical definitions at the word and sub-word level, and on valency (slot-filling) on the phrase and sentence level. Paragraphs and yet higher (discourse) units are not well worked out, but these play no role in any of the approaches to analogy and similarity that we are aware of.

Historically, 4lang falls in the AI/KR tradition, following on the work of Quillian (1969), Schank (1975), and more recently Banarescu et al. (2013). Linguistically, it is closest to Wierzbicka (1972), Goddard (2002) and to modern theories of case grammar and linking theory (see Butt (2006) for a summary). Computationally, 4lang is in the finite state tradition (Koskenniemi, 1983), except it relies on an extension of finite state automata (FSA) introduced by Eilenberg (1974) to *machines*.

In addition to the usual state machine (where letters of the alphabet correspond to directed edges running between the states), an Eilenberg machine will also have a *base set X*, with each letter of the alphabet corresponding to a binary relation over X. As the machine consumes letters one by one, the corresponding relations are composed. How this mechanism can be used to account for slot-filling in a variable-free setting is described in Kornai (2010).

Central to the goals of the current paper is the structure of X. As a first approximation, X can be thought of as a hypergraph, where each hypernode is a lexeme (for a total of about 10^5 such hypernodes), and hyperedges run from (hyper)node a to b if b appears in the definition of a. Since the definition of fox includes the word clever, we have a link from fox to clever, but not conversely, since the definition of clever does not refer to fox. Edges are of three types: 0, corresponding both to attribution and IS_A relations; 1, corresponding to grammatical subjects; and 2, corresponding to grammatical objects. Indirect objects are handled by the decomposition methods pioneered in generative semantics, without recourse to a '3' link type (Kornai, 2012).

Each lexeme is a small Eilenberg machine, with only a few states in its FSA, so the state space X of the entire lexicon is best viewed as a large graph with about 10^6 states (assuming 10 states per hypernode). This base set is shared across the individual machines and functions analogously to the *blackboard* long familiar from AI (Nii, 1986). The primary purpose of the machine apparatus is to formalize the classical distributed model of semantic interpretation, spreading activation (Collins and Loftus, 1975; Nemeskey et al., 2013), by a series of changes in the hypernode activation levels, described by the relations on X. Manual grammar writing in this style can lead to very high precision high recall grammars (Karlsson et al., 1995; Tapanainen and Järvinen, 1997), but for now we rely on the Stanford Parser (Chen and Manning, 2014) to produce the dependency structures that we process into simplified

4lang representations (ordinary edge-colored directed graphs rather than hypergraphs) we call definition graphs and describe briefly in Section 3.1.

We derive several similarity features from pairs of definition graphs built using the 4lang library[8]. Words that are not part of the manually built 4lang dictionary[9] are defined by graphs built from entries in monolingual dictionaries of English using the Stanford Dependency Parser and a small hand-written mapping from dependency relations to 4lang connections (see Recski (2016) for details). The set of all words used in definitions of the Longman Dictionary of Contemporary English (Bullon, 2003), also known as the Longman Defining Vocabulary (LDV), is included in the ca. 3000 words that are defined manually in the 4lang dictionary. Recski and Ács (2015) used a word similarity metric based on 4lang graphs in their best STS submission, their findings served as our starting point when defining features over pairs of 4lang graphs.

3.1 The formalism

For the purposes of word similarity calculations we find it expedient to abstract away from some of the hypergraph/machine aspects of 4lang discussed above and represent the meaning of both words and utterances as directed graphs, similarly to the Abstract Meaning Representations (AMRs) of Banarescu et al. (2013). Nodes correspond to language-independent concepts, edges may have one of three labels (0, 1, 2). 0-edges represent attribution (dog $\xrightarrow{0}$ friendly), the IS_A relation (hypernymy) (dog $\xrightarrow{0}$ animal), and unary predication (dog $\xrightarrow{0}$ bark). Since concepts do not have grammatical categories, phrases like *water freezes* and *frozen water* would both be represented as water $\xrightarrow{0}$ freeze. 1- and 2-edges connect binary predicates to their arguments, e.g. cat $\xleftarrow{1}$ catch $\xrightarrow{2}$ mouse). The meaning of each 4lang concept is represented as a 4lang graph over other concepts, e.g. the concept bird is defined by the graph in Figure 1.

3.2 Graph-based features

We experimented with various features over pairs of 4lang graphs as a source of word similarity. The simple metric defined by Recski and Ács (2015) is based on the intuition that similar concepts will overlap in the elementary configurations they take part in: they might share a 0-neighbor, e.g. train $\xrightarrow{0}$ vehicle $\xleftarrow{0}$ car, or they might be on the same path of 1- and 2-edges, e.g. park $\xleftarrow{1}$ IN $\xrightarrow{2}$ town and street $\xleftarrow{1}$ IN $\xrightarrow{2}$ town. The metric used by Recski and Ács (2015) defines the sets of *predicates* of each concept based on this intuition: given the example definition of *bird* in Figure 1, predicates of the concept bird (P(bird)) are {vertebrate; (HAS, feather); (HAS, wing); (MAKE, egg)}. Predicates are also inherited via paths of 0-edges, e.g. (HAS, wing) will be a predicate of all concepts for which $\xrightarrow{0}$ bird holds.

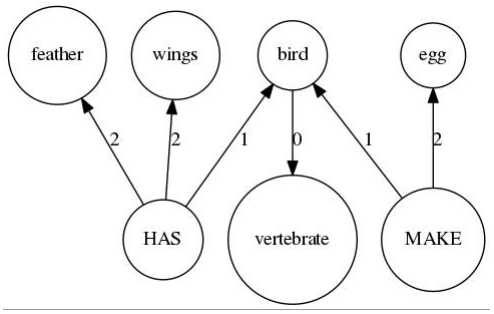

Figure 1: 4lang definition of bird.

Our first feature extracted for each word pair is the Jaccard similarity of the sets of predicates of each concept, i.e.

$$S(w_1, w_2) = \frac{|P(w_1) \cap P(w_2)|}{|P(w_1) \cup P(w_2)|}$$

A second similar feature takes into account all nodes accessible from each concept in its definition graph. Recski and Ács (2015) observe that this allows us to capture minor similarities between concepts, e.g. the definitions of casualty and army do not share predicates but do have a common node war (see Figure 2).

Based on boosting factors in the original metric we also generated three binary features. The links_contain feature is true iff either concept is contained in a predicate of the other, nodes_contain holds iff either concept is included in the other's definition graph, and 0_connected is true if the two nodes are connected by a path of 0-edges in either definition

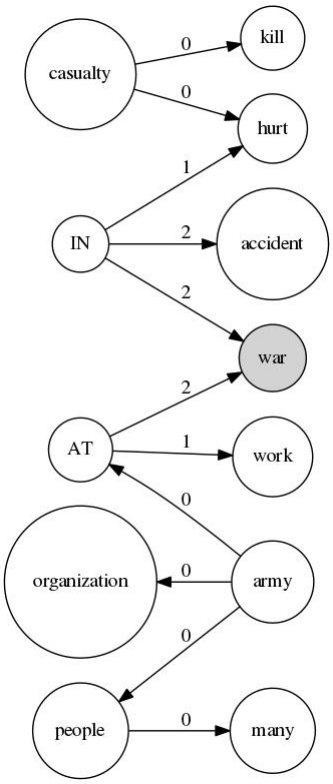

Figure 2: Overlap in the definitions of `casualty` (built from LDOCE) and `army` (defined in `4lang`)

feature	definition
`links_jaccard`	$J(P(w_1), P(w_2))$
`nodes_jaccard`	$J(N(w_1), N(w_2))$
`links_contain`	iff $w_1 \in P(w_2)$ or $w_2 \in P(w_1)$
`nodes_contain`	iff $w_1 \in N(w_2)$ or $w_2 \in N(w_1)$
`0_connected`	iff w_1 and w_2 are on a path of 0-edges

Table 2: `4lang` word similarity features

graph. All features are listed in Table 2.

The `dict_to_4lang` module used to build graphs from dictionary definitions allowed us to perform *expansion* on each graph, which involves adjoining the definition graphs of all words to the initial graph; an example is show in Figure 3.

Using only these features in initial experiments resulted in many "false positives": pairs of antonyms in SimLex were often assigned high similarity scores because this feature set is not sensitive to the `4lang` nodes `LACK`, representing negation (`dumb` $\xrightarrow{0}$ `intelligent` $\xrightarrow{0}$ `LACK`), and `BEFORE`, indicating that something was only true in the past (`forget` $\xrightarrow{0}$ `know` $\xrightarrow{0}$ `before`),

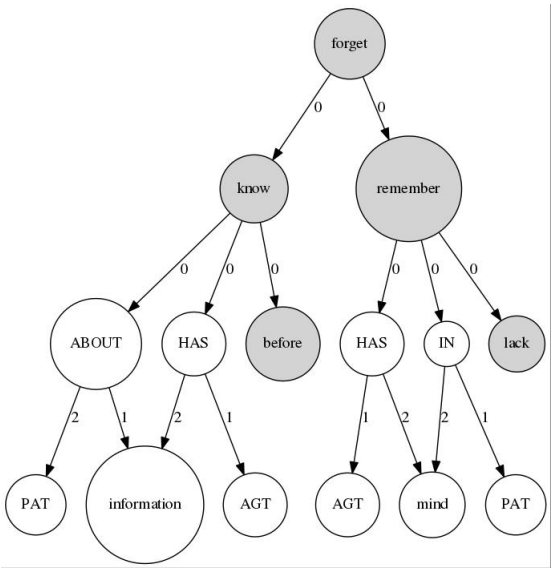

Figure 3: Expanded `4lang` definition of `forget`. Nodes of the unexpanded graph are shown in gray.

We attempt to model the effect of these nodes in two ways. First, we implement the `is_antonym` feature, a binary set to true if one word is within the scope (i.e. 0-connected to) an instance of either `lack` or `before` in the other word's graph. Next, we transform the input graphs of remaining features so that all nodes within the scope of `lack` or `before` are prefixed by `lack_` and are not considered identical with their non-negated counterparts when computing each of the features in Table 2. An example of such a transformation is shown in Figure 4.

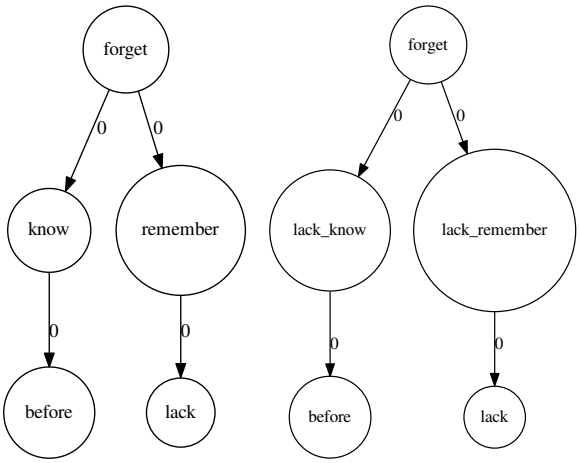

Figure 4: `4lang` definition of *forget* and its modified version

Early experiments show that a system trained on 4lang-based features only can achieve a Pearson correlation in the range of $0.32 - 0.34$ on the SimLex data, this was increased to 0.38 by the handling of LACK and BEFORE described above. This score is competitive with some word embeddings, but well below the $0.58 - 0.68$ range achieved by the state-of-the-art vector-based systems cited in Section 1 and reproduced in Section 2.1.

After testing 4lang features' impact on purely vector-based configurations we came to the conclusion that the only 4lang-based features that improve their performance significantly are 0-connected and is_antonym. Adding these two features to the vector-based system brings correlation to 0.76.

4 Results

Performance of our main configurations is presented in Table 3. The system relying on word embeddings achieves a Spearman correlation of 0.72. WordNet and 4lang features both improve the vector-based system, combining all three feature classes yields our top correlation of 0.76, higher than any previously published results. Since the average correlation between a human rater and the average of all other raters is 0.78, this figure suggests that our system has achieved near-human performance on this benchmark.

System	Spearman's ρ
embeddings	0.72
embeddings+wordnet	0.73
embeddings+4lang	0.75
embeddings+wordnet+4lang	**0.76**

Table 3: Performance of major configurations on SimLex

For the purposes of error analysis we sorted word pairs by the difference between gold similarity values from SimLex and the output of our top-scoring model. The top of this list is clearly dominated by two error classes. The largest group consists of (near-)synonyms that have not been identified as related by our model, Table 4 shows the top 5 word pairs from this category. The second error group contains word pairs that have been falsely rewarded for being associated, but not similar by the definition used when creating the SimLex data. Table 5 shows the top 5 word pairs of this error class. This second error class is an indication of a well-known shortcoming of word similarity models: (Hill et al., 2015) observes that similarity of vectors in word embeddings tend to encode association (or *relatedness*) rather than the similarity of concepts.

word1	word2	output	gold	diff
bubble	*suds*	2.97	8.57	5.59
dense	*dumb*	1.71	7.27	5.56
cop	*sheriff*	3.50	9.05	5.55
alcohol	*gin*	3.43	8.65	5.22
rationalize	*think*	3.50	8.25	4.75

Table 4: Top 5 "false negative" errors

word1	word2	output	gold	diff
girl	*maid*	7.72	2.93	-4.79
happiness	*luck*	6.59	2.38	-4.21
crazy	*sick*	7.49	3.57	-3.92
arm	*leg*	6.74	2.88	-3.86
breakfast	*supper*	8.01	4.40	-3.61

Table 5: Top 5 "false positive" errors

Since our main purpose was to experiment with 4lang representations and identify its shortcomings, we examined 4lang graphs of top erroneous word pairs. As expected, the value of the 0-connected feature was -1 for each "false negative" pair, i.e. word pairs such as those in Table 4 were not on the same path of 0-edges. In most cases this is due to the current lack of simple inferencing on 4lang representations. For example, suds are defined in LDOCE as *the mass of bubbles formed on the top of water with soap in it*, yet the resulting 4lang subgraph $\texttt{bubble} \overset{1}{\leftarrow} \texttt{HAS} \overset{2}{\rightarrow} \texttt{mass} \overset{0}{\leftarrow} \texttt{suds}$ will not trigger any mechanism that would derive $\texttt{suds} \overset{0}{\rightarrow} \texttt{bubble}$. Inference will also be responsible for deriving all uses of polysemous words, the 4lang representation of dense is therefore built from its first definition in LDOCE: *made of or containing a lot of things or people that are very close together*. A method of inference that will relate this definition with that of dumb is clearly out of reach. Better short-term results could be

obtained by using all definitions in a dictionary to build 4lang representations, for dense this would include its third definition: *not able to understand things easily*.

Other shortcomings of 4lang representations are of a more technical nature, e.g. the lemmatizer used to map words of definitions to concepts failed to map *alcoholic* to alcohol in the definition of gin: *a strong alcoholic drink made mainly from grain*. Yet other errors could be addressed by rewarding the overlap between two representations, e.g. that the graphs for cop and sheriff both contain $\xrightarrow{0}$ officer.

5 Conclusions, future work

The purpose of experimenting with 4lang-based features was to gain a better understanding of how 4lang may implicitly encode semantic relations that are difficult to model with standard tools such as word embeddings or WordNet. We found that simple features describing the relation between two concepts in 4lang improve vector-based systems significantly. Since less explicit relationships may be encoded by more distant relationships in the network of 4lang concepts, in the future we plan to examine portions of this network larger than the union of two (expanded) definition graphs. Errors made by 4lang-based systems also indicate that a more sophisticated form of lexical inference on 4lang graphs may be necessary to establish the more distant connections between pairs of concepts. In the near future we plan to experiment with features defined on larger 4lang networks. We also plan to extend our system to include the task of measuring phrase similarity, which can also be pursued using supervised learning given new resources such as the Annotated-PPDB and ML-Paraphrase datasets introduced by (Wieting et al., 2015).
