Summary

1. Epibiosis in the marine environment is a stressor that may determine invasion success in introduced species. Previous comparisons showed resistance to epibionts can be higher in non-native than in resident seaweed species, but we do not know whether it is an intrinsic trait of the non-natives or it has been acquired during the invasion process. To elucidate this question, a comparison between native and non-native populations of the same species is needed.

2. Resistance against two groups of epiphytes was assessed in living thalli and in artificial substrata coated with surface extracts, both gained from four Asian (native) and four European (non-native) populations of the red alga *Gracilaria vermiculophylla*. Two diatom species and two filamentous macroalgae were used as micro- and macro-epiphytes, and one of each type was collected in Asia, while the other came from Europe. Laboratory assays were done in both distributional ranges of *G. vermiculophylla* and in different seasons. We used *G. vermiculophylla* from four populations in each range and used a fully-crossed design with the factors a) 'Origin of *Gracilaria*', b) 'Origin of epiphytes', c) 'Season' and d) 'Solvent used for extraction'.

3. Both groups of epiphytes, regardless of their origin, attached less to living thalli and to surface extracts from non-native *G. vermiculophylla*. Fewer diatoms attached to hexane-based extracts, while fewer *Ceramium* filaments settled on extracts gained with dichloromethane.

4. *Synthesis.* Our results show for the first time that non-native individuals of a marine organism are better defended against epiphytes than native conspecifics. Furthermore, we found evidence that at least a part of the defense is based on extractable secondary metabolites. We discuss several mechanisms that could explain the increased resistance to epiphytes in non-native individuals, including the release from enemies in the non-native range, which could lead to an

41 increase in algal performance during the invasion process. We suggest that an enhanced defense

42 against epiphytes after introduction is one reason for *G. vermiculophylla*'s invasion success. Our

43 observation may also apply to other basibiont-epibiont and host-enemy systems, including plant-

44 plant, plant-animal and animal-animal interactions, in aquatic environments and could be a key

45 feature of bioinvasions.

Introduction

Biological invasions are an important component of global change (Mack *et al.* 2000; Ricciardi 2007) and can cause severe ecological or economic problems by altering local biodiversity and affecting the services of ecosystems (Pimentel, Zuniga & Morrison 2005; Williams & Smith 2007; Vilà *et al.* 2011; Newton *et al.* 2013; Paini *et al.* 2016). Therefore, bioinvasions in the aquatic and terrestrial realm are receiving attention by scientists, authorities and environmental managers worldwide (Torchin & Mitchell 2004; Olenin *et al.* 2014). This growing awareness is needful, since the number of successful invasions is rising rapidly. In the marine environment, for instance, it increases exponentially and about 20% of the invasions are due to the spread of macroalgae (Schaffelke, Smith & Hewitt 2006).

To manage invasive species and to alleviate their negative effects, it is necessary to understand the mechanisms that determine the success or failure of invasions: Why do certain species invade new habitats successfully while others fail? Which factors allow the establishment and spread of introduced species? Currently, several hypotheses suggest explanatory concepts for these questions. Among them, the Enemy Release Hypothesis (ERH) is one of the most well-known (Keane & Crawley 2002). It states that when species are introduced into new habitats they are confronted with an abiotic and biotic environment that can be substantially different from the one they adapted to over evolutionary time scales. If co-evolved antagonists are absent in the new habitat and resident predators or parasites cannot recognise the newly introduced species as a resource, a release of the introduced species results from enemy control (Vermeij *et al.* 2009; Cacabelos *et al.* 2010). Furthermore, the Evolution of Increased Competitive Ability Hypothesis (EICA), which is an extension of the ERH, argues that non-native species that are released from their native enemies do not need to defend at all or, at least, less than in their home range. This

92   release would allow them to invest more energy into growth, reproduction or into tolerating

93   environmental stress (Hierro, Maron & Callaway 2005; Joshi & Vrieling 2005; Lenz *et al.* 2011),

94   what, in turn, should make them competitively superior to native species (Blossey & Nötzold

95   1995; Müller-Schärer, Schaffner & Steinger 2004). Finally, the "Novel Weapons"-hypothesis by

96   Callaway and Ridenour (2004) suggests that non-native species should be less susceptible to

97   resident enemies than native ones, because they possess biochemical defense mechanisms to

98   which native antagonists have not adapted to so far.

99   Most if not all marine organisms are prone to colonization by sessile life forms (epibionts),

100   including bacteria, protists, microalgae, macroalgae and invertebrates. This phenomenon is

101   known as epibiosis and it can severely impair the performance of the host organisms (basibionts)

102   (Wahl 2008; Thomsen *et al.* 2012). It has been reported that epibionts can affect the growth and

103   survival of macroalgal hosts by a) limiting the uptake of oxygen, carbon dioxide and nutrients

104   through the thallus surface, b) reducing the amount of light available for photosynthesis, c)

105   physically inhibiting sporulation, d) decreasing thallus flexibility, and/or e) increasing the

106   palatability of the thallus (Wahl, Hay & Enderlein 1997; Hemmi *et al.* 2005). Macroalgae

107   therefore need physical or chemical defenses to minimize colonization of their surfaces.

108   All the hypotheses described above should also hold true for host-epibiont interactions, but have

109   so far been widely neglected as a factor determining invasion success. So far, studies that tried to

110   elucidate the relevance of host-enemy interactions for biological invasions mainly focused on

111   non-native spermatophytes and their antagonists as well as their competitors in terrestrial

112   systems (Keane & Crawley 2002; Verhoeven *et al.* 2009), while less research has been done on

113   marine species (Wikström *et al.* 2006). Furthermore, most studies on non-native species -

114   resident enemy interactions in marine systems considered herbivory (Wikström *et al.* 2006;

Forslund, Wikström & Pavia 2010; Engelen *et al.* 2011; Hammann *et al.* 2013), while little is known about the interactions between non-native basibionts and resident epibionts (Strong, Maggs & Johnson 2009; Baer & Stengel 2014). A comparison between the non-native brown alga *Fucus evanescens* and the native *Fucus vesiculosus* in Swedish waters revealed that resistance to epibiosis was higher in the non-native species (Wikström & Kautsky 2004; Wikström & Pavia 2004). However, we lack knowledge whether this difference is based on species-specific traits or whether resistance to epibiosis can be gained during the invasion process. This could, for instance, be due to the release from other enemies that would allow the allocation of energy to defenses against epibionts.

To elucidate whether non-native seaweed species are better defended against epibionts than their native conspecifics, we compared the susceptibility to epiphytism by microalgae and macroalgae between native and non-native populations of the red macroalga *Gracilaria vermiculophylla*. This perennial seaweed originates from the Northwest Pacific but during the last four decades it invaded many coastal habitats in the eastern Pacific (Bellorin, Oliveira & Oliveira 2004), the eastern Atlantic (Rueness 2005) and the western Atlantic (Freshwater *et al.* 2006; Thomsen *et al.* 2006) and the Mediterranean Sea (Sfriso *et al.* 2012). *Gracilaria vermiculophylla* has proven to be a particularly suitable marine model organism for the testing of theoretical concepts that predict the causes or consequences of biological invasions. It has, for example, been demonstrated that non-native populations of this species have a much lower genetic diversity than native populations (Kim, Weinberger & Boo 2010), while, nonetheless, the former proved to be more resistant towards herbivory (Weinberger *et al.* 2008; Rempt *et al.* 2012; Hammann *et al.* 2013; Hammann *et al.* 2016) and heat stress (Hammann 2014). These findings shed light on

137   potential reasons for the invasion success of *G. vermiculophylla* and stimulated curiosity about

138   how this seaweed interacts with epibionts in its non-native range.

139   Putative differences in the resistance against micro-epiphytes between native and non-native

140   populations of *G. vermiculophylla* have been studied for bacteria (Saha *et al.* 2016), while we are

141   not aware of studies that were done with eukaryote micro-epiphytes and macro-epiphytes. We

142   conducted common garden experiments, i.e. individuals of *G. vermiculophylla* from different

143   geographic ranges were transplanted into a common environment, with *G. vermiculophylla* from

144   Asia and Europe and with micro- and macro-epiphytes coming from the macroalga's native and

145   non-native range.

Materials and methods

Collection of *Gracilaria vermiculophylla* and of epiphytes

Algal individuals were collected from four native and four non-native populations (Table 1). Sampling was conducted three times: from May to June and again from August to September 2014 as well as from June to July 2015. Laboratory experiments were conducted in June (summer) and in October (autumn) 2014 at the Helmholtz Centre for Ocean Research at Kiel, Germany, and in September (autumn) 2014 at the Xunshan Group Co., Ltd, Rongcheng, China, as well as in July (summer) 2015 at the Akkeshi Marine Station, Akkeshi, Japan (Table 2). Prior to experiments, living algal specimens from all sampling sites were transferred to the respective laboratory and kept under laboratory conditions for at least one week to allow them to recover from the transport (see Appendix S1 in Supporting Information for details).

Two pennate diatom species of the genus *Stauroneis* were isolated from individuals of *G. vermiculophylla* that were collected in Rongcheng and in the Kiel Fjord, respectively. Individuals of *Ceramium tenerrimum* were collected in Rongcheng, while specimens of *Ceramium virgatum* stem from Kiel Fjord (see Appendix S2 for details).

Algal surface extraction

Before the extraction procedure, adherent water was removed from the algal thalli in a centrifuge (Eppendorf 5810 R) with 200 rpm for 30 s. Surface associated metabolites were extracted from 80 g algal wet mass using the 'dipping technique' (de Nys, Dworjanyn & Steinberg 1998; Nylund *et al.* 2007), by dipping the algal individuals into a stirred mixture of dichloromethane (DCM) and hexane 1:4 (v/v) for 5 s. This procedure was benign and was chosen after different mixtures of solvents and dipping times were tested with regard to their effects on the survival of

182   epidermal cells which was verified with Evan's blue (Figure S1). This was done to make sure

183   that any damaging of cell walls, which could have led to the leaching of non-surface compounds,

184   was avoided. The resulting solution was immediately filtered through a paper filter (Macherey

185   Nagel, 185 mm in diameter) to remove particles and the solvents were then evaporated under

186   vacuum at 30 °C. The residue was re-dissolved in hexane to exclude non-polar compounds and

187   this step was repeated until the hexane appeared colourless. The residue that remained after this

188   first extraction step was then re-dissolved in DCM to extract existing polar components. Finally,

189   4 ml of both extracts were collected and stored at -20 °C.

190   **Extracted surface area**

191   To identify the extracted surface area, the relationship between algal surface area and algal wet

192   weight was determined. Ten algal fragments, taken haphazardly across all populations, were

193   carefully dried with paper and then scanned and weighed. The imaging software Image J

194   (National Institute of Health, Bethesda, Maryland, USA) was used to analyze the surface area of

195   each fragment. The algal thallus was viewed as a cylinder, so the projection area = thallus

196   diameter × thallus length. The surface would then be $= \pi \times$ thallus diameter × thallus length $= \pi \times$

197   projection area. We identified the average surface area per g algal material across all ten

198   fragments as 46.06 ± 2.8 cm^2 g^{-1} (mean ± SD). The total extracted surface area was 80 g * 46.06

199   ± 2.8 cm^2 g^{-1} = 3684.8 ± 224 cm^2.

200   **Defense capacity against diatoms in living *Gracilaria vermiculophylla* thalli**

201   We combined living thalli of *G. vermiculophylla* from both ranges (native and non-native) with

202   diatoms from Kiel as well as Rongcheng, respectively. For each basibiont-epibiont combination,

203   six fragments of 2 cm were cut from six randomly chosen algal individuals (n = 6) and were

204 placed separately into the wells of a 6-well plate (Standard, Sarstedt AG & Co.) together with 3

205 ml of a homogenized diatom suspension per well. The covered plate was then incubated for 3 h.

206 A pilot study was done with different incubation periods (3 h, 5 h and 6 h), but diatom

207 attachment did not increase any further after 3 h (Table S1). During incubation the plates were

208 placed on a rotary shaker (100 rpm) that served to gently homogenize the suspension.

209 Afterwards, each algal fragment was rinsed with 3 ml of sterile seawater. Algal pieces were then

210 transferred to tubes containing 50 ml of sterile seawater and all attached diatoms were extricated

211 by shaking the tube with a vortex shaker for 3 min. The shaken-off diatoms were collected on

212 polycarbonate filters (0.2 µm pore size, 25 mm in diameter), which were then inspected under a

213 fluorescence microscope and photographed. The photos were later used to assess the number of

214 diatoms per algal fragment. The tested algal area was determined by scanning the fragments

215 afterwards and quantifying their surface area with Image J.

216 **Defense capacity against *Ceramium* sp. in living *Gracilaria vermiculophylla* thalli**

217 The majority of studies about the attachment of epiphytes or epizoans to hosts focused on

218 colonization by microscopic propagules and spores, which are the mobile stages of the otherwise

219 sessile epibionts. However, vegetative thalli of *Ceramium* sp. can directly attach or penetrate into

220 the host by the formation of hapteria (Leonardi *et al.* 2006; Lion *et al.* 2006; Michetti *et al.*

221 2016). We therefore conducted assays with *C. tenerrimum* and *C. virgatum* with filaments of

222 these algae and organized them in the same way as the diatom trials described in the previous

223 paragraph. For this, ten algal individuals per population of *G. vermiculophylla* were used (i.e. n =

224 10 per basibiont-epibiont combination). From each of these ten replicates we cut a fragment of 2

225 cm, while a *Ceramium* filament of the same length was then bound to *G. vermiculophylla* using

226 colored paper clips. This was done to shorten the distance between the fragments and by this to

227 increase the likelihood of attachment. These pairs were put into Petri dishes containing 30 ml of

228 the modified culture medium of Provasoli's enriched seawater (PES) (Bold & Wynne 1978). The

229 covered Petri dishes were incubated for two weeks and attachment rates were quantified after

230 this time.

231 **Chemical defense capacity against diatoms in *Gracilaria vermiculophylla* surface extracts**

232 These assays were organized in the same way as the ones with living thalli. For the assays with

233 extracts we used an extract concentration that was five times higher than the natural surface

234 concentration. This was done to compensate for the possible degradation and incomplete

235 extraction of active compounds. In one cylindrical well of a 96-well plate (flat bottom, Greiner

236 bio-one), 100 µl of both, DCM and hexane, cover a total surface area of 94 mm². Thus, 5.1 µl of

237 surface extracts and 94.9 µl of pure solvent were then pipetted into each well to cover the aspired

238 wall area. Wells loaded with pure DCM and hexane were later used as controls. Solvents were

239 then evaporated overnight in a freeze-dryer. After this, 100 µl of the homogenized diatom

240 suspension were transferred into the wells. Four wells of each experimental group received

241 extracts and diatoms, while four wells received extracts only to check for extract background

242 fluorescence. Control wells were treated in the same way. Afterwards, the covered 96-well plate

243 was incubated for 3 h and then each well was rinsed with 200 µl of sterile seawater. Finally,

244 fluorescence intensity per well was measured and the number of diatoms per well was calculated

245 from fluorescence intensity by using the linear function that was established in a pilot study

246 (Appendix S3, Figure S2).

247 **Chemical defense capacity against *Ceramium* sp. in *Gracilaria vermiculophylla* surface**

248 **extracts**

249   These assays were organized in the same way as the ones with living thalli. In a 6-well plate, 120

250   µl of solvent can cover the total surface area of the bottom of one well. A paper filter (Carl Roth,

251   3.5 cm in diameter) was put into each well to avoid erosion by solvents. For applying a fivefold

252   natural surface concentration, 52 µl of surface extracts and 68 µl of pure solvent were then

253   pipetted into each well, while we had five wells per population. Some wells received pure DCM

254   or hexane and served as controls. The solvent was then evaporated overnight in a freeze-dryer.

255   After that, 5 ml of PES medium and ten *Ceramium* filaments (1 cm) were transferred to each

256   well. The covered 6-well plate was then incubated for two weeks. Afterwards, the proportion of

257   *Ceramium* filaments that attached to the paper filter was quantified.

258   **Statistical analyses**

259   All statistical and graphical analyses were done using the free statistical computing software R

260   (R Development Core Team 2014). We used mixed effect-modelling to analyze the data from

261   our multifactorial experimental approach. In case of the assays with living thalli, our

262   experimental design included three fixed factors: 1) 'Origin' with the levels 'Native' and 'Non-

263   native' (i.e. origin of *Gracilaria*), 2) 'Diatom' / '*Ceramium*' with the levels 'China' and

264   'Germany' (i.e. origin of epiphytes), and 3) 'Season' with the levels 'Summer' and 'Autumn'

265   (i.e. the time of the experiment). In the assays with surface extracts we had one more fixed

266   factor: 'Solvent' with the levels 'DCM' and 'hexane'. In all analyses, the algal sampling sites

267   were included as a random factor, while the two types of epiphytes (diatoms/*Ceramium*) were

268   analyzed separately. To achieve homogeneity of variances and normality of errors, data from the

269   assays with diatoms and living thalli were square root transformed and data from the assays with

270   diatoms and surface extracts were log-transformed. However, homogeneity of variances could

271   not be achieved for all factors. We therefore included weights for 'Season' and 'Diatom' to

272   account for the differences in the variance structures between their factor levels in the modelling.

273   For this we used the varIdent function of the nlme package in R (Zuur *et al.* 2009). Test

274   assumptions were checked graphically with residual plots (Zuur, Ieno & Elphick 2010). In

275   addition, a mixed effect-modelling, with the factors 'Origin', 'Diatom' / '*Ceramium*', 'Season'

276   and 'Material'(i.e. thalli and surface extracts), was used to analyze the data from the two assays

277   with diatoms and from the two assays with *Ceramium* sp., respectively, in a common approach

278   (see results in Table S2, S3). To achieve homogeneity of variances and normality of errors, data

279   from the two assays with diatoms were square root transformed.

Results

Defense capacity against diatoms in living *Gracilaria vermiculophylla* thalli

After 3 h of exposure to colonization by diatoms, a three-way-interaction among the factors 'Diatom', 'Origin' and 'Season' was observed: Fewer diatoms from Rongcheng attached to non-native than to native *G. vermiculophylla* in autumn and this difference was less pronounced in Summer and less observed with diatoms from Kiel in both seasons (Fig. 1, Table 3). For both diatom species fewer cells (by 60% less) attached to non-native than to native *G. vermiculophylla* individuals (Fig. 1, Table 3) and only 4% of the unexplained variation was found to be covered by the random factor 'Site'. Furthermore, for both diatom species, settlement rates were on average by 66% lower in summer than in autumn. Averaged across the two seasons, diatoms from Kiel settled by 21% less often on *G. vermiculophylla* thalli than their congeners from Rongcheng (Fig. 1, Table 3).

Defense capacity against *Ceramium* sp. in living *Gracilaria vermiculophylla* thalli

After two weeks of colonization by *Ceramium* filaments there was an interaction between '*Ceramium*' and 'Origin' (Fig. 2, Table 4). *Ceramium virgatum* (from Kiel, Germany) attached less to non-native than to native *G. vermiculophylla*, while this difference was less pronounced in *C. tenerrimum* (from Rongcheng, China). An interaction between '*Ceramium*' and 'Season' also emerged since attachment rates of *C. tenerrimum* differed between autumn and summer, while this was not the case for *C. virgatum* (Fig. 2, Table 4). Filaments of both *Ceramium* species attached, on average, by 33% less often to non-native than to native *G. vermiculophylla* specimens (Fig. 2, Table 4). In this case, 37% of the unexplained variation was covered by 'Site'. Furthermore, attachment rates, averaged across both *Ceramium* species, were by 10% lower in

312   autumn than in summer, while they, when averaged across both seasons, did not differ between

313   the two *Ceramium* species (Fig. 2, Table 4).

Chemical defense capacity against diatoms in *Gracilaria vermiculophylla* surface extracts

315   The results from this assay are generally in accordance with those of the diatom trials with living

316   thalli. After exposing the surface extracts to diatom settlement for 3 h, an interaction among the

317   factors 'Solvent', 'Diatom' and 'Season' was observed: Attachment rates of diatoms from Kiel

318   on surfaces coated with DCM-based extracts were lower in summer than in autumn, but no such

319   difference was observed on surfaces coated with hexane-based extracts or with diatoms from

320   Rongcheng on any coated surfaces (Table 5). Additionally, fewer diatoms attached (by 9% less)

321   to surfaces coated with extracts from non-native than from native *G. vermiculophylla* (Figs 3 and

322   4, Table 5) and only 2% of the unexplained variation was covered by 'Site'. In general, diatom

323   settlement rates were again by 22% lower in summer than in autumn (Figs 3 and 4, Table 5).

324   Interestingly, different from the assays with living thalli, diatoms from Kiel settled two times

325   more often than diatoms from Rongcheng (Fig. 3, Table 5). Moreover, we found fewer diatoms

326   (by 4% less) attached to surfaces covered with non-polar compounds (extracted with hexane)

327   than to those coated with polar compounds (extracted with DCM) (Fig. 4, Table 5).

Chemical defense capacity against *Ceramium* sp. in *Gracilaria vermiculophylla* surface extracts

330   In autumn we found, after two weeks of exposing surface extracts to colonization by *Ceramium*

331   filaments that fewer (by 13% less) *Ceramium* filaments attached to surfaces coated with

332   moderately polar compounds than on such covered with non-polar compounds. This was not the

333   case in summer and this difference led to an interaction between 'Solvent' and 'Season' (Fig. 6,

334   Table 6). In addition, there was an interaction between '*Ceramium*' and 'Season': Attachment

335   rates of *C. virgatum* were lower in autumn than in summer, while this difference was less

336   pronounced in *C. tenerrimum* (Fig. 5, Table 6). Furthermore, fewer *Ceramium* filaments (by 10%

337   less) attached to surfaces coated with extracts gained from non-native than to surfaces with

338   extracts from native *G. vermiculophylla* (Figs 5 and 6, Table 6) and only 0.5% of the

339   unexplained variation was covered by 'Site'. In general, *Ceramium* filaments attached 22% less

340   often in autumn than in summer (Figs 5 and 6, Table 6), but attachment rates never differed

341   between the two *Ceramium* species (Fig. 5, Table 6).

Discussion

For this intra-specific comparison, we sampled individuals of *G. vermiculophylla* at different sampling locations in either the native or the non-native range of the species. Within the respective ranges, the different sampling sites were located in nearly the same biogeographical region according to the Marine Ecoregions of the World (MEOW) system suggested by Spalding *et al*. (2007). The sites in the native range were located in the Cold Temperate Northwest Pacific/Yellow Sea (China) and in Northeastern Honshu (Japan) as well as in the Warm Temperate Northwest Pacific/Central Kuroshio Current (Japan), which is adjacent to Northeastern Honshu. The sites in the non-native range were located in the Northern European Sea/Baltic & North Sea (Germany) and in the Celtic Sea as well as the Lusitanian/South European Atlantic Shelf (France), which is adjacent to the Celtic Sea. Furthermore, we took care that the distances between the various sampling sites in the native as well as in the non-native range were similar, in order to have the same degree of between-site variability within the ranges. We therefore assumed that the within-range variability, which could be attributed to potential differences in the diversity and composition of the resident flora and fauna as well as to climate conditions, would be low. This assumption was confirmed by the low amount of unexplained variation (0.5% to 4%) that was actually covered by the random factor 'Site' in most of our statistical modellings. This was true for diatom attachment rates on both living thalli and on extracts and for *Ceramium* attachment to extracts. In contrast to this, *Ceramium* attachment rates on living thalli varied considerably (37% of the unexplained variation) among sites within both ranges and we cannot plausibly explain this deviation from the otherwise consistent picture.

In our study we used two types of epiphytes to test for inter-population differences in *G. vermiculophylla* with regard to its susceptibility to epiphytes: Diatoms as a common type of

376   micro-epiphytes and *Ceramium* filaments as a macro-epiphyte. We found that both of them,

377   independent of their actual origin, attached by 60% and 33%, respectively, less to the living thalli

378   of European *G. vermiculophylla* than to those of Asian conspecifics. In general, such a difference

379   could either due to the fact that non-native *G. vermiculophylla* individuals are better defended

380   and therefore attract fewer/repel more epiphytes or it could be due to lower settlement rates of

381   native colonizers on the non-native macroalga. However, our experimental design excluded the

382   latter option, since we exposed non-native macroalgae to epiphytes from the native as well as

383   from the non-native range and both combinations showed the same trend. This finding indicates

384   that non-native *G. vermiculophylla* are better defended against epiphytes than those that stem

385   from the native range.

386   In macroalgae, resistance to epibiosis can be mediated by a) the thallus surface structure

387   (Schumacher *et al.* 2007; Chapman *et al.* 2014), b) surface associated bacterial communities that

388   repel epibionts (Boyd, Adams & Burgess 1999; Dobretsov, Dahms & Qian 2006), and c)

389   surface-bound secondary metabolites that have anti-epibiont activities (Nylund *et al.* 2007; Saha

390   *et al.* 2011; Thabard *et al.* 2011). The question is now whether one or more of these mechanisms

391   changed with regard to their mode of action or with regard to their efficiency during the invasion

392   process. Such a change could, *inter alia*, be caused by a directional selection of genotypes that

393   exhibit a low susceptibility to epibionts during transport or after release into the new habitat.

394   However, we cannot think of a scenario during these phases that would specifically select for

395   resistance to epibiosis. Furthermore, since the non-native gene pool is a reduced subset of the

396   gene pool in the donor region, it is possible, although presumably not very likely, that by chance

397   an epibiosis-resistant genotype was highly frequent among the introduced individuals. Finally, a

398   change in the quality of anti-epiphyte defenses could be attributed to increased energy resources,

399   which are a consequence of the release from abiotic and biotic pressures in the new environment

400   (Joshi & Vrieling 2005). Under such conditions, non-native seaweeds may reduce specific

401   defenses they developed against enemies in their native range and shift energy resources towards

402   more general anti-enemy defenses. An observation made at our study site in the native range

403   hints at the potential relevance of the last mechanism: In Rongcheng, China, an amphipod

404   species, *Caprella* sp., is the main grazer of *G. vermiculophylla* in many habitats and it can

405   consume substantial parts of this local alga during summer (S. Wang, pers. obs.). In Kiel,

406   Germany, so far no herbivore makes use of this alga to such an extent and it seems that the

407   grazing pressure on *G. vermiculophylla* is generally lower than in Rongcheng (Hammann *et al.*

408   2013). However, we do not have information whether the picture is the same in the other non-

409   native habitats that we sampled in Europe. If *G. vermiculophylla* is mostly ungrazed in coastal

410   habitats in Europe, this could have allowed the non-native *G. vermiculophylla* to allocate a larger

411   part of their energy budget to anti-epibiont defenses and this possibly caused their lower

412   attractiveness for colonizers.

413   An important aspect of our study was to identify properties of *G. vermiculophylla* that mediate

414   its anti-epiphyte defenses. For this we compared epiphyte attachment rates on living thalli to

415   those on extract coated surfaces. Here we observed that the general trend in epiphyte attachment

416   was the same for living thalli and extract coated substrata. However, the effect size, i.e. the

417   difference in the susceptibility to epiphytes in native and non-native *G. vermiculophylla*, was

418   consistently smaller in the latter assays: Fewer diatoms (on average 9% for extracts, 60% for

419   living thalli) and fewer *Ceramium* filaments (on average 10% for extracts, 33% for living thalli)

420   attached to substrata that were covered with extracts from European *G. vermiculophylla* than to

421   those with extracts from Asian specimens. This, first of all, confirms that resistance to epiphytes

422   in *G. vermiculophylla* has, at least partly, a chemical component. If the lower susceptibility in

423   non-native *G. vermiculophylla* is due to this chemical component, it could either be based on an

424   increased synthesis of active compounds (Forslund, Wikström & Pavia 2010) or due to the

425   presence of some chemical compounds that are novel to resident enemies in these individuals

426   (Enge *et al.* 2012). Overall, extracts exhibited a lower inhibitory activity against diatom and

427   *Ceramium* settlement than living algae. This difference could be due to the fact that active

428   metabolites were insufficiently captured by the extraction process or degraded after extraction.

429   Alternatively, other non-chemical components such as surface properties - which were of course

430   excluded in the assays with extracts - could also have contributed to the overall deterrence.

431   Finally, the compounds which were responsible for the anti-epiphyte activity we observed in

432   living *G. vermiculophylla* may not only have stemmed from the thallus surface but also from the

433   inside of algal cells. This reason could have been relevant since some epibionts, including

434   species of the genus *Ceramium*, penetrate into algal thalli and therefore also get in contact with

435   their interior (e.g. Leonardi *et al.* 2006). We have no data that could elucidate which of the three

436   scenarios was responsible for the picture we observed. However, since we used only two

437   solvents for the extractions (i.e. hexane and DCM) that cover a limited part of the polarity

438   spectrum, it is at least likely that we missed relevant compounds and thereby underestimated the

439   potential of chemical defenses in *G. vermiculophylla*.

440   So far, no tests have been made to investigate whether the surface texture, microtopography or

441   consistency of *G. vermiculophylla* thalli mediates a defense against epibionts. Such effects are

442   known from *Saccharina* species (Chapman *et al.* 2014; da Gama, Plouguerné & Pereira 2014)

443   that belong to the brown macroalgae and possess an outer cell wall with a mucilage consisting of

444   alginic acid with traces of sulphated fucoidan that could, theoretically, act as a low-adhesion,

445   gelatinous covering.

446   Whatever the mechanism is, a low susceptibility to epiphytes in non-native populations of *G.*

447   *vermiculophylla* can, at least partly, explain the invasion success of the species. It has been

448   proposed that marine algal invaders have more effective anti-epibiont defenses than comparable

449   resident species, e.g. in its non-native habitats in northern Europe the brown alga *Fucus*

450   *evanescens* is known to get less colonized by filamentous algae and sessile invertebrates than its

451   native congener *Fucus vesiculosus* (Wikström & Pavia 2004). When their surface is free of

452   epibionts, macroalgae can take up more oxygen, carbon dioxide and nutrients. Furthermore, they

453   receive more light for photosynthesis and are less prone to dislodgement caused by

454   biomechanical drag. Furthermore, they may be less attractive to grazers (Wahl, Hay & Enderlein

455   1997). Therefore, algae, which are free of epibionts or show low degrees of epiphyte or epizoan

456   cover, should have more energy available for reproduction and growth, as well as for tolerating

457   adverse environmental conditions – what in turn should increase their potential to establish and

458   spread in new environments.

459   The Enemy Release Hypothesis proposes that non-indigenous species are commonly released

460   from biotic pressures, e.g. grazing, in their recipient habitat, because they leave their co-evolved

461   antagonists behind while, at the same time, resident enemies fail to recognize the new species as

462   a food source (Keane & Crawley 2002). In this context, Hammann *et al.* (2013) found that the

463   periwinkle species *Littorina brevicula,* which lives in the native range of *G. vermiculophylla,*

464   consumes more of this seaweed, regardless from which distributional range the algal material

465   stems, than *Littorina littorea*, which is from its non-native range. This finding is presumably due

466   to the fact that *L. brevicula* coevolved with *G. vermiculophylla* and can make better use of it as a

467   food source. A somewhat comparable preference of native over non-native *G. vermiculophylla*

468   was also shown by the diatoms we used in the assays with living thalli: diatoms from Rongcheng

469   generally attached in higher numbers to *G. vermiculophylla* from both distributional ranges than

470   diatoms from Kiel. This finding may also be due to the fact that these diatoms recognize *G.*

471   *vermiculophylla* more readily as a suitable settlement substratum than diatoms from the non-

472   native range. Surprisingly, we observed the opposite picture when we tested the surface extracts.

473   This mismatch suggests that, besides a chemical defense, other properties of the thallus surface,

474   such as its structure or the presence of biofilms, play a role in the anti-diatom defense in living

475   thalli. However, we did not find a difference between the attachment rates exhibited by the two

476   *Ceramium* species for both substrata. However, it is not clear why this epiphyte did not show a

477   preference. It is possible that *C. virgatum* – with regard to *G. vermiculophylla* as a settlement

478   substratum - generally has the same settlement capacity as *C. tenerrimum*. The absence of a

479   difference is somewhat surprising, because the way the *Ceramium* filaments attach to algal

480   surfaces constitutes a very intimate connection of the two organisms. It is most often

481   characterized as an infection of the basibiont, because it is mediated by the formation of hapteria

482   that first attach to the thalli of the host and then penetrate into its tissue (Lion *et al.* 2006). Lion

483   *et al*. (2006) found that after wounding *Gracilaria chilensis* released oxylipins, which suppressed

484   the development of hapteria in *Ceramium rubrum*. This fact indicates that co-evolution occurs

485   between *Ceramium* species and their hosts and hence a difference in settlement rates between *C.*

486   *tenerrimum* and *C. virgatum* would be likely.

487   Previous studies have suggested that season (Culioli *et al.* 2002; Hellio *et al.* 2004) can influence

488   the capacity of a seaweed to defend itself against epibionts. In accordance with this finding, we

489   found differences in epiphyte settlement rates between summer and autumn of the same year of

490   which we assume that they are attributed to differences in the anti-epiphyte activity of *G.*

491   *vermiculophylla*. Fewer diatoms attached to both living fragments and extract-coated surfaces in

492   summer, while fewer *Ceramium* filaments attached to those substrates in autumn. Such inter-

493   seasonal differences in anti-epiphyte defenses presumably correlate with natural fluctuations in

494   the overall propagule abundance in the colonizer pool (Steinberg & Vanaltena 1992; Amade &

495   Lemée 1998; Wahl *et al.* 2010; Rickert *et al.* 2015), which means that marine macroalgae can

496   adjust their anti-epibiont activities to quantitative or qualitative changes in colonization pressure.

497   In both regions where we collected algae, diatoms are more abundant from April to June than

498   from August to October (Trimonis, Vaikutiene & Gulbinskas 2010; Wang *et al.* 2014), while

499   *Ceramium* is more abundant during the latter time span (Weinberger *et al.* 2014; S. Wang, pers.

500   obs.). However, we collected our data only during the course of one year and we therefore do not

501   have robust evidence for seasonality in the defense capacity of *G. vermiculophylla*. To establish

502   such a pattern, assays would need to be repeated over several years.

503   A further interesting observation that we made was that fewer diatoms attached to surfaces

504   covered with non-polar compounds than to those coated with polar compounds, while the

505   opposite was true for *Ceramium* filaments. This indicates that the defenses against these two

506   epiphytes are mediated by compounds that differ in polarity. A similar observation has been

507   reported earlier: surface compounds extracted with a mixture of hexane and DCM from

508   *Caulerpa filiformis* significantly inhibited spore settlement of *Polysiphonia* sp., while more polar

509   compounds, which were extracted with DCM from surfaces of the same species, inhibited

510   settlement and germling development of gametes of *Ulva australis* (Nylund *et al.* 2007).

511   Our study is the second biogeographical comparison of defense capacities against epibionts

512   between native and non-native populations of *G. vermiculophylla* (Saha *et al.* 2016), which is

513   now invasive in many coastal areas worldwide. However, it gives the first evidence that the

514   capacity to defend against epibionts is higher in non-native individuals than in native –

515   regardless of whether the epibionts originate from the native of the non-native range of *G.*

516   *vermiculophylla*. Our findings therefore seemingly contradict the observations made by Saha *et*

517   *al*. (2016), who focused on seaweed-bacteria interactions and showed that non-native *G.*

518   *vermiculophylla* are better defended against bacterial epibionts from the non-native range but, at

519   the same time, have reduced their capacity to defend themselves against epibionts from their

520   home range. The contradiction may be due to the use of different micro-epibionts. Bacteria are

521   the first colonizers of bare substrata in the marine environment (Wahl 1989) and can regulate the

522   production of bioactive compounds, motility, and biofilm formation by Quorum Sensing (QS),

523   which is a density-dependent cell-cell signaling communication among bacteria (da Gama,

524   Plouguerné & Pereira 2014). Furthermore, it is known that bacterial biofilm formation can

525   mediate further colonization by eukaryote micro- and macro-epibionts. The differences between

526   epibacteria and other epibionts could have led to the evolution of different defense strategies

527   against them in seaweeds. Unlike compounds that function against eukaryote micro- and macro-

528   epibionts through growth inhibition or lethality, most antimicrobial settlement and attachment

529   defenses impact the behavior of bacteria, such as swarming (Rasmussen & Givskov 2006).

530   Even though our study focused on macrophyte-epiphyte interactions in the marine environment,

531   our findings should be applicable to all basibiont-epibiont interactions in aquatic systems,

532   including plant-plant, plant-animal and animal-animal combinations, since epibionts are

533   widespread and most of them are generalists (Wahl & Mark 1999). Additionally, our findings

534   may also be applicable to host-herbivore interactions in aquatic systems, since, similar to

535   epibionts, many herbivores are generalists and an increased chemical resistance to herbivory has

536 already been documented in non-native plants and seaweeds (Forslund, Wikström & Pavia

537 2010).

538 We conclude that the lower susceptibility to epiphytes that we observed in non-native *G.*

539 *vermiculophylla* cannot be explained by a lower epibiont pressure experienced by the non-native

540 individuals, but is due to an elevated resistance to epibiosis that, at least partly, is linked to an

541 enhanced chemical defense capacity. Our study therefore provides the first evidence of an

542 increased resistance to epibiosis in introduced populations of a widely distributed marine species.

543 This change in its performance during the invasion process may be critical for the invasion

544 success of the macroalga.
