[1] Determination of the relative inputs of aquatic autochthonous and terrestrial allochthonous organic matter into marine and lacustrine environments is essential to understanding the global carbon budget. A variety of proxies are used for this purpose, including the Branched and Isoprenoid Tetraether (BIT) index. This is calculated from the concentrations of branched glycerol dialkyl glycerol tetraethers (GDGTs), derived from unidentified terrestrial bacteria, and crenarchaeol, a marker for aquatic mesophile Thaumarchaeota (Crenarchaeota group I). As the index is a ratio, its value depends on both the crenarchaeol aquatic in situ production and the soil-derived branched GDGT input. Therefore, the BIT index reflects not only changes in the input of terrestrial or soil organic matter but also relative variations in aquatic Thaumarchaeota abundance in the water column. In fact, we show that in oceanic and lacustrine settings, the BIT index can be dominated by the aquatic end-member of the ratio. Consequently, the BIT index by itself can be an unreliable proxy to compare the input of terrestrial matter between sites and over time, and we propose that the quantification of branched GDGT fluxes or concentrations may instead be a better indicator of soil terrestrial inputs.

### 1. Introduction

[2] The fate of terrestrial organic matter in marine and lacustrine sediments and its influence on sediment carbon burial and preservation need to be established for a better understanding of the global carbon cycle. Different proxies are currently used to trace the origin of organic matter in sediments, e.g., carbon to nitrogen (C:N) ratio, organic carbon isotopic composition ( $\delta^{13}\text{C}_{\text{org}}$ ), n-alkane and lignin phenol abundances [e.g., Gordon and Goñi, 2003; Weijers *et al.*, 2009a]. However, as they are influenced by more than one parameter, a multiproxy approach is generally recommended [e.g., Hedges and Oades, 1997; Meyers, 1997; Pancost and Boot, 2004; Birks and Birks, 2006]. One of the most novel proxies to trace terrestrial organic carbon inputs was introduced by Hopmans *et al.* [2004] as the Branched and Isoprenoid Tetraether (BIT) index, based on the measurement of glycerol dialkyl glycerol tetraethers (GDGTs).

[3] Branched GDGTs were first identified in soils and peat bogs and present branched alkyl chains. By analogy with the

structures of bacterial lipids, their source organisms were postulated to be soil bacteria, but so far their exact provenance has not been conclusively ascertained [Weijers *et al.*, 2006a, 2009b]. Acidobacteria were proposed as likely candidates [Weijers *et al.*, 2009b] and recently a branched GDGT was indeed identified in two acidobacteria cultures [Sinninghe Damsté *et al.*, 2011]. Marine bacteria do not seem to synthesize branched GDGTs because those lipids have not been detected or are present only in low abundances in open ocean samples [Hopmans *et al.*, 2004]. Recently, however, in situ production of branched GDGTs in marine and lacustrine sediments has been suggested since core branched GDGTs were found at sites with low direct runoff or fluvial inputs, and because their distributions did not match those in nearby soils [Peterse *et al.*, 2009; Sinninghe Damsté *et al.*, 2009; Tierney *et al.*, 2010].

[4] Isoprenoid GDGTs instead are derived from Archaea, and crenarchaeol has been proposed as a marker for pelagic Thaumarchaeota (mesophile Archaea, formerly Crenarchaeota group I [Brochier-Armanet *et al.*, 2008; Sinninghe Damsté *et al.*, 2002]). Low abundances of crenarchaeol have also been found in isolates and samples from terrestrial environments such as soils and peats [Leininger *et al.*, 2006; Weijers *et al.*, 2006b; Walsh *et al.*, 2008], as well as in hot springs [Pearson *et al.*, 2004; de la Torre *et al.*, 2008; Pitcher *et al.*, 2009], and rivers [Herfort *et al.*, 2006; Kim *et al.*, 2007], indicating that the producing organisms are more widespread than initially thought.

[5] The BIT index describes the ratio between the branched and the isoprenoid tetraether crenarchaeol [Hopmans *et al.*, 2004]. It was proposed as a proxy for the relative input of soil organic matter to coastal marine sediments [Hopmans *et al.*, 2004]. Indeed, BIT values have been shown to track a plume from the mouth of the Congo River into the open ocean [Hopmans *et al.*, 2004], the fluvial input of terrestrial matter into the North Sea [Hopmans *et al.*, 2004; Herfort *et al.*, 2006], as well as storm-flood events in a river dominated continental margin [Kim *et al.*, 2007, 2009]. The BIT is also increasingly used as a proxy to estimate modern and trace past changes in “terrestrial organic matter (or soil organic matter) input” [e.g., Ménot *et al.*, 2006; Sluijs *et al.*, 2006; Huguet *et al.*, 2007; Donders *et al.*, 2009; Weijers *et al.*, 2009a].

[6] However, several constraints in the use of the BIT have been reported. These include concerns about the inter-laboratory comparability of the BIT as it is very sensitive to analytical instrumental conditions and therefore their relative responses vary between laboratories [Escala *et al.*, 2009; Schouten *et al.*, 2009]. It has also been argued that the BIT is a specific proxy for soil input rather than for bulk terrestrial matter, and is thus sensitive to the lack of well developed soils in the potential source regions [Walsh *et al.*, 2008; Belicka and Harvey, 2009]. Weijers *et al.* [2009a] attempted to quantify the relative soil organic carbon input in a downcore record from the Congo Fan, but as the authors pointed out, this required assuming similar and constant concentrations of the terrestrial and marine biomarkers versus bulk terrestrial and marine organic carbon, respectively. Furthermore, Huguet *et al.* [2008] found that the BIT index was affected by diagenesis, as degradation rates of crenarchaeol were twofold higher than those of soil-derived branched GDGTs. Variability in terrestrial organic matter sources, transport, and degradation was also suggested to explain a weak correlation found between BIT and lignin phenol, while the BIT was correlated to bulk sedimentary organic matter proxies [Smith *et al.*, 2010]. Herfort *et al.* [2006], Walsh *et al.* [2008], and Belicka and Harvey [2009] furthermore have reported low BIT indices at sites with high terrestrial organic carbon inputs and pointed out that apart from variations in the sources of the terrestrial material, large crenarchaeol concentration changes may also drive the BIT changes. Here we show that indeed the BIT is often driven by the variability of crenarchaeol concentration rather than that of branched GDGTs.

## 2. Methods

### 2.1. Core Locations

#### 2.1.1. Lake Baikal Record

[7] Lake Baikal is located in Siberia, Russia, in one of the most continental regions of the world. It is the deepest and one of the largest freshwater lakes of the world. The lake surface freezes for 4–6 months each year, but the water column remains oxygenated throughout [Schmid *et al.*, 2008]. Diatoms are the dominant phytoplankton group, occasionally forming extensive blooms [Kozhova and Izmet'eva, 1998], and Lake Baikal sediments consist of alternating layers of organic, diatom-rich, and inorganic diatom-poor sediments indicative of changing productivity linked to climate (see Mackay [2007] for a review). The two core intervals used in this

study cover a time span from ~107 to ~130 kyr B.P. (last interglacial period and transitions) and approximately the past 50 kyr (part of last glacial period, including interstadial MIS3, and Holocene [Escala, 2009]). Sediment core CON01-603-3 was retrieved from the North Basin (53°57'N, 108°55'E) at 386 m water depth. The overall age model was based on magnetostratigraphic correlation [Démory *et al.*, 2005], while the determination of the last interglacial section was based on the core lithology and correlation of high-resolution pollen and diatom records [Fietz *et al.*, 2007].

#### 2.1.2. Southern Ocean Record

[8] Core PS2489-2 (42°52'S, 8°58'E) was recovered from the Atlantic Southern Ocean at 3794 m water depth. This site is located in the present-day subantarctic zone and is particularly influential for the marine carbon reservoir through changes in westerly winds position and iron fertilization of marine biota [Martínez-García *et al.*, 2009, 2011]. It is characterized by relatively low phytoplankton export production during interglacial periods and high export production during glacial stages essentially stimulated by atmospheric supply of iron [Martínez-García *et al.*, 2009, 2011]. The record studied covers from the mid-Pleistocene to the Holocene, encompassing several glacial and interglacial cycles (MIS 1 to MIS 12, ~500 kyr B.P.). The age model used in this study is published by Martínez-García *et al.* [2009].

#### 2.1.3. Fram Strait Record

[9] Core MSM05/05-712-1 was retrieved from the eastern Fram Strait at 1490 m water depth (78°54'N, 6°46'E). This site is strategically situated in the path of Atlantic water inflow to the Arctic Ocean [Spielhagen *et al.*, 2011]. Most of the recent organic matter in this region is autochthonous with terrestrial organic matter supply being likely a result of long-range sea ice transport from the Svalbard archipelago and from the northern Barents Sea [Hebbeln, 2000]. The core spans approximately the last 2000 years [Spielhagen *et al.*, 2011].

#### 2.1.4. NE Atlantic Record

[10] Core MD01-2461 was collected from the Northeast (NE) Atlantic (51°45'N, 12°55'W) at 1153 m water depth. The site is located in the northwestern flank of the Porcupine Seabight, close to a principal outlet glacier draining the British Ice Sheet and also received ice rafted debris derived from other North Atlantic margins [Peck *et al.*, 2006]. The analyzed section spans from 24.5 to 14.5 kyr B.P., across the last glacial maximum and Heinrich events 1 and 2 [Peck *et al.*, 2006].

#### 2.1.5. Alboran Sea Record

[11] Core ODP-977A was retrieved from the eastern sub-basin of the Alboran Sea (36°02'N, 1°57'W), in a transitional area between the Atlantic and the Mediterranean. The region has a complex water column structure with deep Mediterranean and surface Atlantic water masses. The analyzed section spans 145–245 kyr B.P. [Huguet *et al.*, 2011] and comprises characteristic sequences of rapid warming and cooling events [Martrat *et al.*, 2004].

## 2.2. Sample Processing and Analyses

### 2.2.1. Extraction

[12] One to 5 g homogenized freeze-dried sediment from Lake Baikal, Southern Ocean, NE Atlantic, and Fram

Strait were extracted by microwave using a mixture of dichloromethane/methanol (3/1 vol/vol). The temperature of the vessel containing the sample was increased to 70°C over 5 min, held at 70°C for 5 min and then decreased to 30°C. One to 2 g freeze-dried sediment from the Alboran Sea were extracted using an Accelerated Solvent Extractor 200 (ASE 200, DIONEX) with a mixture of dichloromethane/methanol (9/1 vol/vol) at 100°C and 7.6 10<sup>6</sup> Pa. Extracts were filtered through a Pasteur pipette filled with sodium sulfate to remove water and then taken to dryness by centrifugal vacuum concentration (miVac, Genevac) or under gentle nitrogen stream.

### 2.2.2. Fractionation

[13] Lake Baikal, NE Atlantic and Alboran Sea extracts were manually fractionated with activated alumina in a Pasteur pipette using mixtures of hexane/dichloromethane (9/1 vol/vol) and dichloromethane/methanol (1/1 vol/vol) as eluents [Sinninghe Damsté et al., 2002; Escala et al., 2009]. Southern Ocean extracts were analyzed without further fractionation. Fram Strait extracts were redissolved in 100 µL hexane/dichloromethane (50/50 vol/vol) prior to manual injection in a Thermo Surveyor HPLC system equipped with a Lichrosphere Silicon dioxide column (4.6 × 250 mm, 5 µm; Teknokroma) and a stainless steel inline filter (2 µm pore size). Compound class fractionation was achieved running n-hexane (0–2.7 min), dichloromethane (2.7–5.7 min), acetone (5.7–9.2 min) and n-hexane (9.2–13.5 min) with a 2 mL min<sup>-1</sup> flow.

### 2.2.3. Instrumental Analysis

[14] The dry polar fractions were redissolved in hexane/n-propanol (99/1 vol/vol) and filtered through 0.50 µm PTFE filters (Advantec). A Dionex P680 HPLC system coupled to a Thermo Finnigan TSQ Quantum Discovery Max quadrupole mass spectrometer with an APCI interface was used. The target compounds were separated with a Tracer Excel CN column (0.4 × 20 cm, 3 µm; Teknokroma) equipped with a precolumn filter and a guard column. The solvent program was modified from Schouten et al. [2007] and Escala et al. [2007]. Samples were eluted with hexane/n-propanol at 0.6 mL min<sup>-1</sup>. The amount of n-propanol was held at 1.5% for 4 min, increased gradually to 5.0% during 11 min, then increased to 10% during 1 min and held at 10% for 4 min, then decreased to 1.5% during 1 min and held at 1.5% for 9 min until the end of the run. The parameters of the APCI were set as follows to generate positive ion spectra: corona discharge 3 µA, vaporizer temperature 400°C, sheath gas pressure 49 mTorr, auxiliary gas (N<sub>2</sub>) pressure 5 mTorr and capillary temperature 200°C. GDGTs were monitored in selected ion monitoring (SIM) mode at mass-to-charge ratio (*m/z*) 1292 (crenarchaeol), 1022 (brGDGT I), 1036 (brGDGT II), and 1050 (brGDGT III). The synthetic tetraether lipid GR was used as external standard. Compound GR has a *m/z* of 1208, a structure typical of neutral archaeal membrane lipids and presumably does not occur in the environment [Réthoré et al., 2007; Escala, 2009]. It is characterized by a hemicyclic lipid core composed of two phytanyl chains and a 31-atom-long bridging chain containing a cyclopentane ring linked together by two glycerol moieties to which they are attached via ether bonds; it furthermore has two neutral hydroxyl groups [Réthoré et al., 2007]. The HPLC-MS system was checked for TEX<sub>86</sub> and BIT index accuracy with a

standard sediment sample before and between sample sets [Escala, 2009]. External curves were measured before each sample series. The reproducibility of the quantification is estimated to be ±10%. The BIT index was calculated as

$$\text{BIT} = \frac{[\text{brGDGT I} + \text{brGDGT II} + \text{brGDGT III}]}{[\text{crenarchaeol} + \text{brGDGT I} + \text{brGDGT II} + \text{brGDGT III}]} \quad (1)$$

(codes correspond to structures shown by, e.g., Hopmans et al. [2004]).

## 3. Results and Discussion

[15] Crenarchaeol and branched GDGT concentrations in the sediment are both influenced by their respective production, transport and deposition processes. All those factors depend on the environmental conditions of any investigated site. Hence, the BIT index variability can be due to a wide range of environmental conditions. This considerably hampers the interpretation of the relative terrestrial organic matter input over time or when comparing sites. Here we first compare average BIT indices between several sites and then discuss what affects the BIT index variability over time in Lake Baikal and the site from the Southern Ocean.

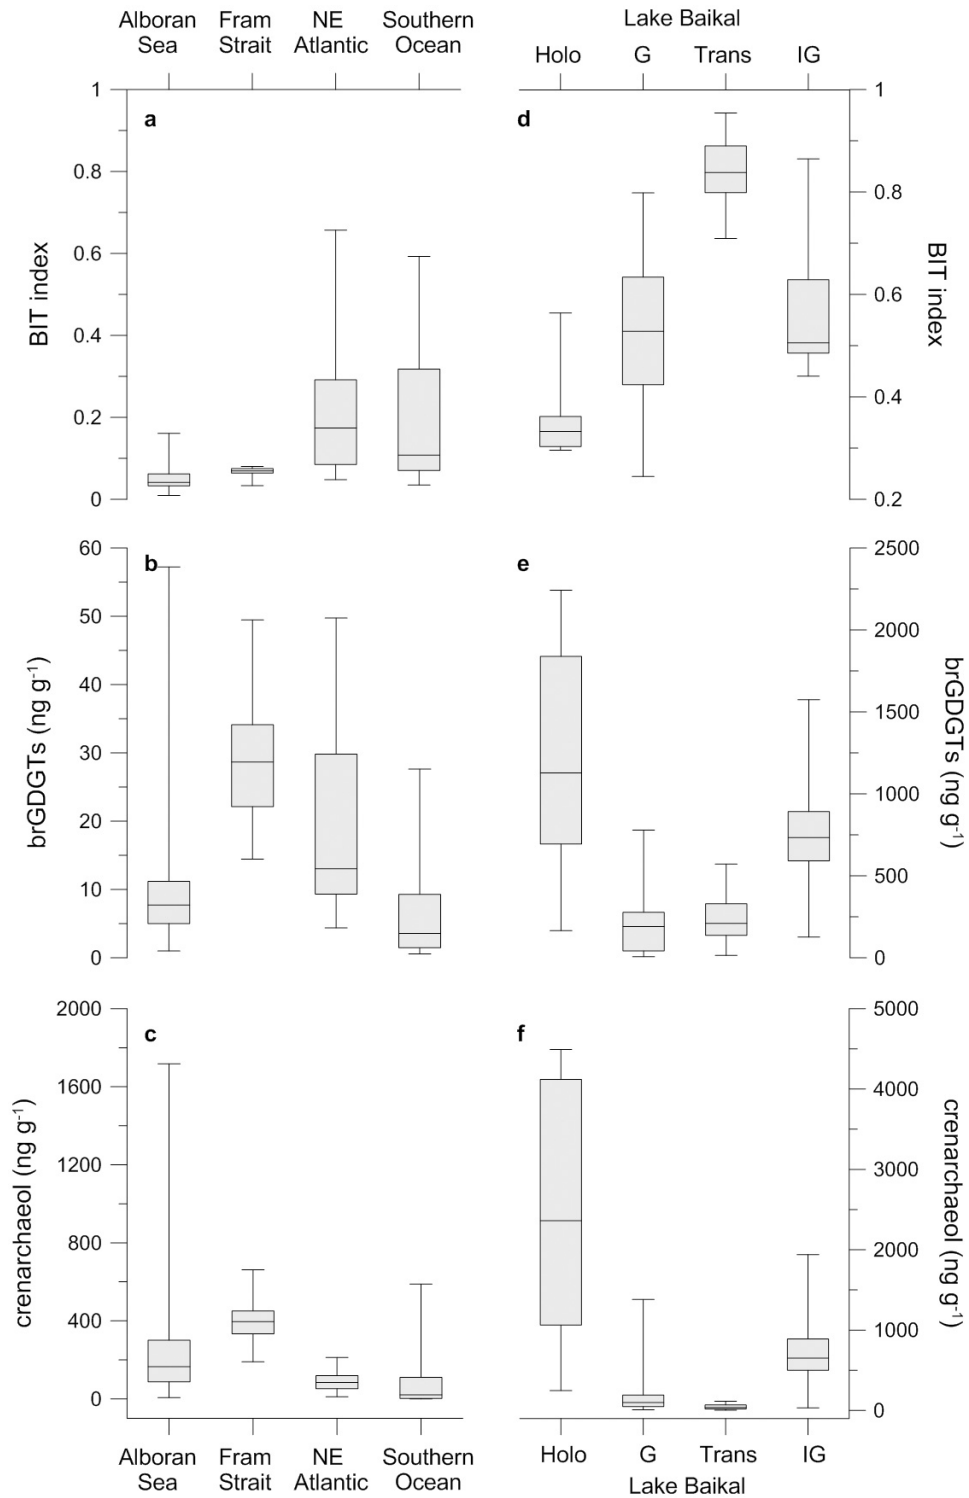

### 3.1. Comparison of BIT Indices Between Sites

[16] Low BIT values do not necessarily correspond to sites with the lowest concentrations of branched GDGTs. The lowest BIT values are measured in samples from the Alboran Sea, where indeed the concentration of branched GDGTs is relatively low, but equally low BIT values are found in the Fram Strait (Figure 1a), even though the branched GDGT abundances are 1 order of magnitude higher (Figure 1b). The low BIT at the Fram Strait is due to the relatively high crenarchaeol abundances (Figure 1c). In the NE Atlantic and Southern Ocean records we also observe higher median BIT values but lower median branched GDGT concentrations, which is due to the greater difference in the crenarchaeol concentration (Figures 1a–1c).

[17] It is obvious then, from the site comparison, that variations in crenarchaeol concentrations can determine the BIT value, rather than branched GDGTs concentration changes. This is in agreement with previous work that reported low BIT values in fjords and coastal areas with high terrestrial organic carbon inputs [Herfort et al., 2006; Huguet et al., 2007; Walsh et al., 2008; Belicka and Harvey, 2009]. Furthermore, in various African lakes, the BIT index was significantly correlated with the crenarchaeol concentration but not with branched GDGTs, again indicating the greater importance of the archaeal aquatic end-member on the BIT index comparing various sites [Tierney et al., 2010].

### 3.2. BIT Index Downcore Variability

[18] In the record from the subantarctic Southern Ocean the BIT index is always high during the interglacial periods (Figure 2a), which are however characterized by very low inputs of branched GDGTs (Figure 2b). The higher BIT results from the much more pronounced decrease of crenarchaeol concentrations during the unproductive interglacial

**Figure 1.** Branched and Isoprenoid Tetraether (BIT) index values and concentrations of crenarchaeol ( $\text{ng g}^{-1}$ ) and branched glycerol dialkyl glycerol tetraethers (GDGTs) ( $\text{ng g}^{-1}$ ) in (a–c) marine records and in (d–f) Lake Baikal over various time spans. Time spans for the Baikal records are shown in Figures 3 and 4; briefly, they are Holocene (Holo),  $\sim 0$ –12 kyr B.P.; last glacial (G),  $\sim 12$ –55 kyr B.P.; transitions (trans),  $\sim 96$ –113 and  $\sim 127$ –139 kyr B.P.; and last interglacial (IG),  $\sim 113$ –127 kyr B.P. Box-whisker plots indicate medians (bar), 75%–25% percentiles (boxes), and minima and maxima (vertical bars).

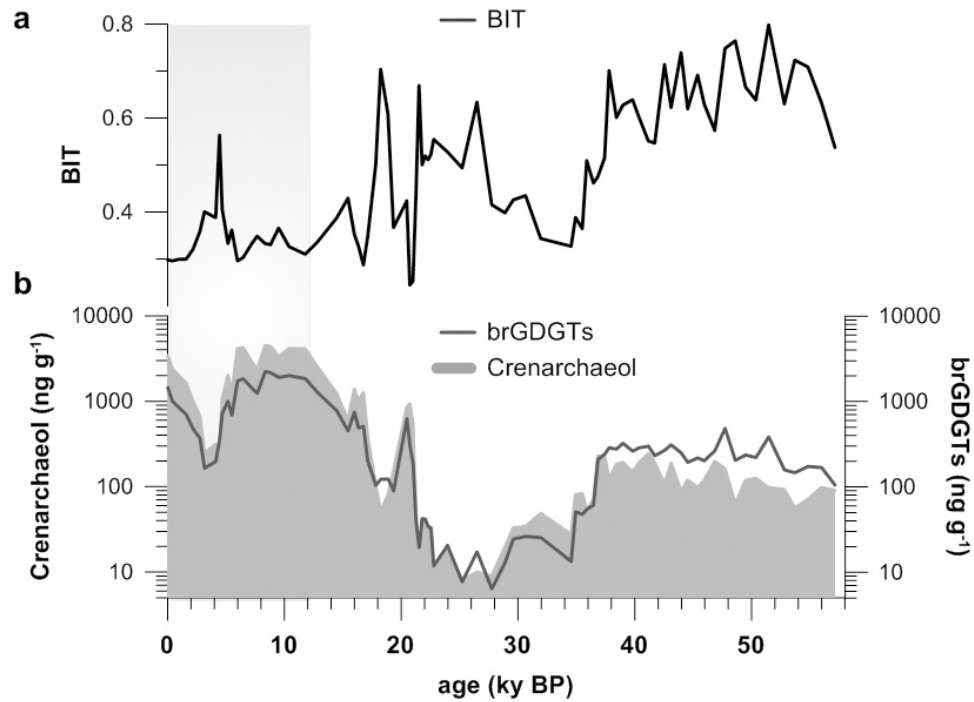

**Figure 2.** Subantarctic Southern Ocean record: (a) BIT index and (b) branched GDGTs and crenarchaeol. Shaded areas highlight approximately the productive glacial periods.

periods (Figure 2b). The low input of terrestrial material during interglacial periods is supported by the analysis of  $^{230}\text{Th}$ -normalized fluxes, mass accumulation rates and concentrations of several inorganic (Fe, Al, Ti, and  $^{232}\text{Th}$ ) and organic tracers (long-chain odd-carbon-numbered n-alkanes) of lithogenic material [Martínez-García *et al.*, 2009, 2011]. All these tracers show the same evolution over the glacial-interglacial cycles than the branched GDGTs, and the opposite than the BIT index, i.e., high fluxes/concentrations of terrigenous material during glacial stages and low fluxes/concentrations during the interglacial periods.

[19] In Lake Baikal, the BIT index should be primarily affected by the input of branched GDGTs since the input of terrestrial organic matter should be much higher than in the open ocean systems. The sources of this terrestrial TOC are presumably humic substances delivered by the inflowing water from the surrounding land [Heim *et al.*, 2005]. However, in Lake Baikal, the median BIT index for the Holocene is the lowest compared to the other periods (Figure 1d), while the branched GDGT concentrations are the highest (Figure 1e). This is due to the much more pronounced differences in crenarchaeol (Figure 1f). In fact the BIT index steadily diminishes since the last glacial toward the present (Figure 3a), while the branched GDGTs vary strongly over time (Figure 3b) [Escala, 2009]. The BIT is highest during the transitional periods at the onset and termination of the last interglacial (Figure 1a), although again, this is not due to high branched GDGT but low crenarchaeol concentrations (Figures 1e and 1f). During the last Interglacial, the BIT index decreases strongly compared to the transitional periods (Figure 4a), while the branched GDGT

concentration increases (Figure 4b). Higher terrestrial input during the interglacial, contrasting with the low BIT index, was also previously suggested based on higher TOC% and C:N values [Fietz *et al.*, 2007]. Crenarchaeol, in contrast, shows much stronger variability (Figure 4b) explaining the strong changes in the BIT index (Figure 4a).

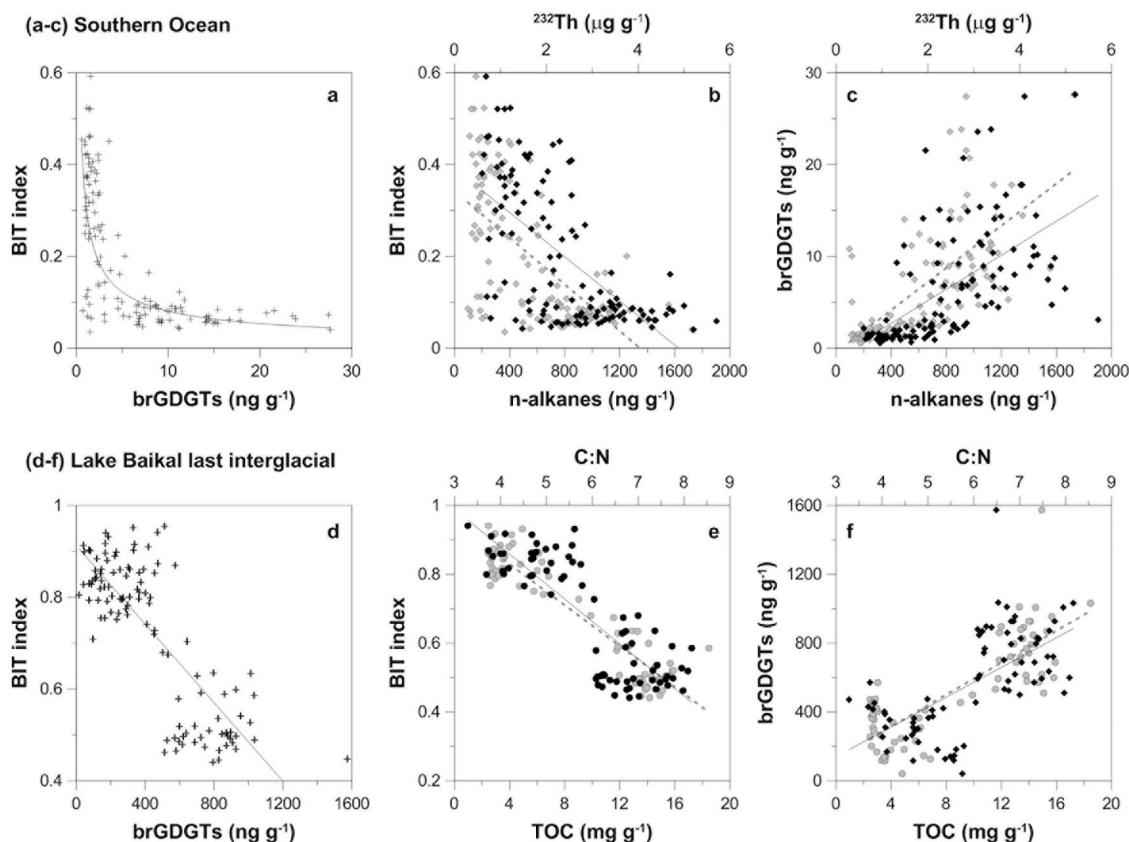

[20] In both the Southern Ocean and Lake Baikal, degradation might partly explain the higher BIT values during the less productive periods (interglacials for the Southern Ocean and glacial for Lake Baikal), since prolonged exposure to oxic conditions may selectively degrade crenarchaeol and artificially raise BIT values [Huguet *et al.*, 2008]. However, the BIT is not only negatively correlated to the branched GDGT concentrations (Figures 5a and 5d) but also to other potential terrestrial input proxies (Figures 5b and 5e). The branched GDGT concentrations, in contrast, show positive correlations with those other terrestrial input proxies (Figures 5c and 5f), which is in agreement with previous observations [Herfort *et al.*, 2006; Huguet *et al.*, 2007; Walsh *et al.*, 2008; Weijers *et al.*, 2009a]. One possibility to explain the parallel, stronger increase in crenarchaeol, and consequent low BIT, is the fertilization effect of terrestrial input on phytoplankton production which, in turn, triggered an increase in archaeal abundance [Fietz *et al.*, 2011]. The n-alkanes and  $^{232}\text{Th}$  records indeed indicated an increase in glacial dust (and iron) deposition over the Southern Ocean, which stimulated marine export production during glacial stages [Martínez-García *et al.*, 2009, 2011]. The close coupling between crenarchaeol, phytoplankton productivity and dust can be explained, for example, if aquatic Thaumarchaeota are hetero- [e.g., Ouverney and Fuhrman, 2000]

**Figure 3.** Lake Baikal Holocene and last glacial record [cf. *Escala*, 2009]: (a) BIT index and (b) branched GDGTs and crenarchaeol. The shaded area highlights approximately the Holocene period.

**Figure 4.** Lake Baikal last interglacial and transitional periods: (a) BIT index and (b) branched GDGTs and crenarchaeol. The shaded area highlights approximately the last interglacial period.

**Figure 5.** Relationship of branched GDGT concentrations with BIT index as well as both with other potential terrestrial matter input proxies, respectively: (a–c) in the Southern Ocean record (see Figure 2) [cf. Martínez-García *et al.*, 2009] and (d–f) in the record of Lake Baikal Interglacial and transitional periods (see Figure 4) [cf. Fietz *et al.*, 2007]. In Figures 5a and 5d, BIT is negatively related to branched GDGTs (crosses,  $r^2 = 0.58$  and  $0.65$ , respectively). In Figure 5b, BIT is negatively related to n-alkanes (grey diamonds,  $r^2 = 0.42$ ) and  $^{232}\text{Th}$  (black diamonds,  $r^2 = 0.41$ ). In Figure 5c, branched GDGTs are positively related to n-alkanes (grey diamonds,  $r^2 = 0.5$ ) and  $^{232}\text{Th}$  (black diamonds,  $r^2 = 0.35$ ). In Figure 5e, BIT is negatively related to total organic carbon (TOC, which includes both aquatic and terrestrial sources; grey circles,  $r^2 = 0.87$ ) and the C:N ratio (black circles,  $r^2 = 0.69$ ). In Figure 5f, branched GDGTs are positively related to TOC (grey circles,  $r^2 = 0.65$ ) and the C:N ratio (black circles,  $r^2 = 0.4$ ).

or mixotrophic [e.g., Ingalls *et al.*, 2006] and depend on phytoplankton-derived carbon, or if they are chemoautotrophic nitrifiers [e.g., Herndl *et al.*, 2005; Könneke *et al.*, 2005] through the increase in the supply of ammonium produced by phytoplankton degradation.

#### 4. Conclusions

[21] The BIT index was defined as the relative abundance of terrestrially derived branched GDGTs versus crenarchaeol, therefore, its variability is driven by changes in both components [Hopmans *et al.*, 2004]. In agreement with earlier studies [Herfort *et al.*, 2006; Walsh *et al.*, 2008; Belicka and Harvey, 2009], our results illustrate further that the BIT index may be controlled largely by the aquatic GDGT abundance rather than by inputs of terrestrial GDGTs. A change in the BIT therefore does not necessarily reflect a change in the flux of terrestrial carbon. The quantification of branched GDGT concentrations or fluxes might give a better estimate of the soil-derived organic matter input, as long as aquatic

in situ production of the branched GDGTs can be excluded at the study site.
