Pre-print of: Font, X. et al. "Evolution of organic matter in a full-scale composting plant for the treatment of sewage sludge and biowaste by respiration techniques and pyrolysis-GC/MS" in Bioresource technology (Ed. Elsevier), vol. 102, issue 6 (March 2011), p. 4536-4543. The final version is available at DOI 10.1016/j.biortech.2010.12.108

Abstract

A full-scale composting plant treating, in two parallel lines, sewage sludge and the source-selected organic fraction of municipal solid waste (OFMSW or biowaste) has been completely monitored. Chemical routine analysis proved not to be suitable for an adequate plant monitoring in terms of stabilization and characterization of the process and final compost properties. However, dynamic respiration index demonstrated to be the most feasible tool to determine the progression of the degradation and stabilization of organic matter for both sewage sludge and OFMSW lines. Both lines exhibited an important degree of stabilization of organic matter using rapid and cumulative respiration indices. Pyrolysis-GC/MS was applied in the most important inputs, outputs and intermediate points of the plant. It proved to be a powerful tool for the quantitative characterization of molecular composition of organic matter present in solid samples. A full characterization of the samples considered is also presented.

Keywords: Sewage sludge; Biowaste; Composting; Respirometry; Pyrolysis-GC/MS.

According to the European legislation (Directive 99/31/EC) the total amount of organic matter contained in source-separated collection of the organic fraction of municipal solid waste (OFMSW) and the municipal solid waste (MSW) disposed in landfills must be considerably reduced. Many studies have shown that MSW contains a high proportion of organic materials, from 50 to 65% (Tchnobanoglous et al., 1993) and OFMSW from 80 to 95%. The need to reduce the biodegradable fraction allocated in landfills has favoured the development of composting as useful biotechnology for transforming organic waste into suitable agricultural products (Senesi and Brunetti, 1996). In addition to the problem associated of MSW a large volume of municipal wastewater are worldwide generated every year. Wastewater treatment requires both the management and treatment of the produced sludge that represents more than 50% of the construction and operating costs of wastewater treatment plants (Metcalf and Eddy, 2003). The application of sewage sludge to soil is a current practice for returning valuable nutrients and organic matter to reclaim degraded soils. However, sewage sludge should be stabilized and hygienized before its application on agricultural soil and composting technologies can effectively decompose organic matter into a stable end product (Gea et al., 2007). In general, the stability of these products derived from sewage sludge and OFMSW/MSW treatments plants should be considered prior to their soil applications. Stability is defined as the extent to which readily biodegradable organic matter has decomposed (Lasaridi and Stentiford, 1998). The analysis of a waste treatment plant requires a reliable measure of the biological activity of the organic matter easily degradable (Lasaridi and Stentiford, 1998). The application of respiration indices has proven to be very useful in

the monitoring of waste treatment plants and for the prediction of the stability of final

products such as compost (Adani et al., 2006; Barrena et al., 2009; Ponsá et al., 2010; Pognani et al., 2010). Among the biological methodologies suggested, aerobic respiration indices have been highlighted as the most suitable tool for the stability assessment (Barrena el al., 2009; Wagland et al., 2009). Indeed, it has been used in recent works to analyze the performance of different treatment processes (Ponsá et al., 2010), for instance Pognani et al. (2010) carried out the complete respirometric monitoring of a combined anaerobic/aerobic municipal source-separated waste treatment plant.

High levels of respiration are typical of non-stable materials, so their application may immobilize inorganic nitrogen in soil, increase the production of phytotoxic compounds (Senesi et al., 1996), reduce plant growth and produce unpleasant odours.

Composting is an aerobic thermophilic process, which requires oxygen to stabilize the organic wastes and an optimal moisture content for the microorganisms development (Haug, 1993). The common control variables at compost facilities are temperature, oxygen, moisture and porosity. The final product, the compost, is a stable, sanitized and humus-like material (Haug, 1993). Composting stages are common for all composting systems. Initially high microbial activity produces heat that causes an increase of temperature rapidly to the thermophilic range (above 45°C). Usually temperature increase up to approximately 60°C and remains there for several weeks depending on the size of the system and the composition of raw materials. After the rapidly degradable components are consumed, heat generation gradually declines during the maturation stage. At the end of this stage, the material is no longer self-heating, and the finished compost is ready for use (Haug, 1993).

Often the application of composting to some organic wastes does not result as expected because these materials do not achieve the biological requirements of C/N ratio to be successfully composted (Charest and Beauchamp, 2002; Sánchez, 2007). It is known that an optimal C/N ratio is required to perform the composting process because an insufficient

content of nitrogen causes a limitation of cellular growth (increased time of efficient composting process). Furthermore a high concentration of nitrogen causes ammonia emissions and consequently generation of offensive odours, atmospheric pollution (Pagans et al., 2006) and a loss of fertilizer value of the final compost. Haug (1993) proposed an optimum C/N ratio value between 15 to 30. Other authors reduced this range between 25 to 30 (Huang et al., 2004; Zhu, 2007). Normally the assessment of C/N ratio in solid samples has been determined on organic matter through the determination of total organic carbon (TOC) and total Kjeldahl nitrogen (NTK). In general, the C/N ratio, as an indicator of composting process, has been determined assuming that both nutrient sources are biodegradables (Huang et al., 2004; Zhu, 2007; Sánchez, 2007). However the biodegradable C/N ratio should be based on total biodegradable organic carbon (BOC) content because the main part of nitrogen, in organic samples, is present in protein-like molecules that are easily biodegradable (Haug, 1993), but a large part of non-biodegradable carbon source is present (Sánchez, 2007). BOC can be also divided into two fractions i.e., readily and slowly biodegradable (Trémier et al., 2005; Fernández et al., 2008). Organic samples with high fiber content such as lignin could have a critical influence in the composting process due to its slow biodegradation as carbon sources. The first references to the approach of a direct determination of the BOC in solid wastes using the cumulative CO₂ production were proposed by Komilis and Ham (2006) and Sánchez (2007). During composting, organic matter is transformed through the successive activities of different groups of microorganisms to more stable complex of organic compounds (Hernández et al., 2006). Pyrolysis GC/MS is a technique already used for the characterization of organic matter and its humic fraction (Genevini et al., 2002; 2003) and it could be more

revealing on chemical transformation than techniques that require sample manipulation

(Ceccanti et al., 2007). Its major advantage is that it can be applied directly to the organic

material to be analyzed with no prior extraction being necessary (Hernández et al., 2006). In addition, the technique is fast and reproducible because it does not need any chemical manipulation (Ceccant et al., 2007). Pyrolysis GC/MS has been applied to several materials like digested sewage sludge, mulched soil and agricultural soil (Hernández et al., 2006; Ceccanti et al., 2007). However, to our knowledge, it has never been applied to follow the evolution of the organic matter in a complex full-scale waste treatment plant as the one described in this work.

The aim of the study undertaken in this waste treatment plant was focused on monitoring and comparing the OFMSW and sewage sludge lines in terms of respirometic indices, biological organic carbon and changes of molecular composition of organic matter using the pyrolysis GC/MS technique in a complete composting process.

pre-print

2. Material and methods

2.1 Analytical methods

Analytical methods were carried out on a representative sample (approximately 40 kg) obtained by mixing four sub-samples (10 kg each) taken from different points of the material. Samples derived from the OFMSW line were ground to 15-20 mm particle size to reduce the dimension of the original materials. The samples were frozen at -18°C within 12 hours after sampling. Before every analysis samples were thawed during 24 hours at room temperature. These representative samples were used to carry out the entire set of analytical tests. pH, Electrical Conductivity (EC), Total Solid (TS), Volatile Solids (VS), Total Organic Carbon (TOC), Total Kjeldahl Nitrogen (NTK) and N-NH₃ (determined directly in the plant on fresh material) were determined according to the standard procedures recommended by the Test Methods for the Examination of Composting and Compost (TMECC) (USDA, 2001). All tests

were run in triplicates and the results are presented as the average followed by the standard deviation.

2.2 Plant characteristics

The composting plant studied in this work was located in the province of Girona (Catalonia, Spain) and the sampling was carried out during the summer of 2009. This facility treats around 6000 Mg y⁻¹ of OFMSW coming from a street bin collection system, 5500 Mg y⁻¹ of sewage sludge and 1200 Mg y⁻¹ of coffee roasted waste (CRW), which is used in combination with sewage sludge. The plant used also 400 Mg y⁻¹ of wood chips as a bulking agent and produced respectively 1500 Mg y⁻¹ of compost of each treatment line. The OFMSW line generated 1000 Mg y⁻¹ of refuse that was landfilled. The plant consists of an area suitable to discharge sewage sludge and OFMSW, seven composting tunnels completely closed and monitored and a maturation area (only for the OFMSW line). Composts obtained from both lines were stored in the plant before its commercialization. Compost obtained from OFMSW line was suitable for agricultural use and compost obtained from sewage sludge line was used only for civil works.

Samples were collected from the most significant points of the two lines of the facility. The samples selected for this study were: raw material (both lines), input mixture of tunnels (both lines); output materials of tunnels (both lines), output material at the end of maturation phase (OFMSW line), rejected material of refining compost process (OFMSW line), final compost (both lines) and CRW (sewage sludge line).

2.3 OFMSW line

Input material (OFMSW: TS of 400.8 ± 33.2 g kg⁻¹ wet weight (w.w.) and VS of 771.7 ± 62.4 g kg⁻¹ TS) as received at the plant was mixed with wood chips, used as bulking agent,

at volume ratio 1:2 (OFMSW: wood chips) using an industrial homogenizer. After mixing, the material was introduced in the composting tunnels. Tunnels dimension were 15x5x5 m (length, width, height) and each tunnel was filled to 80% of its maximum capacity (around 107 Mg). The decomposition phase took place in the tunnels under controlled conditions of aeration and watering (leachate produced during the decomposition of organic matter matrix was used to preserve the moisture content within the correct range: between 70 and 50%). The process parameters such a temperature, moisture content and oxygen content were controlled automatically. The residence time of the mixture in the tunnel was approximately two weeks. After the decomposition phase, the tunnels were cleared out and the resulting material was screened with a mesh trommel of 100 mm and it was sent to the maturation area. Maturation phase was performed in aerated static piles. Prior to set up the maturation pile, an absorbent layer mainly made of wood chips was placed over the perforated pavement to ensure the correct distribution of air thought the mass. Leachate produced during the maturation phase was collected and treated at the nearby wastewater treatment plant (WWTP). These piles were watered according to the evolution of moisture content during the process. During the first three days of maturation air was provided continually. Following this period, the pile aeration system was intermittent with 15 minutes of aeration followed by 15 minutes without aeration. The total maturation stage lasts for approximately eight weeks. To obtain the final compost, the matured material was screened to 10 mm by a trommel and refined using a ballistic separator. The final compost (TS of 751.4 \pm 3.0 g kg⁻¹ w.w. and VS of 637.6 \pm 3.6 g kg⁻¹ TS) produced was stored in the plant before commercialization. Wood chips not degraded during the process were separated and re-used. Refuse (TS

wood chips not degraded during the process were separated and re-used. Refuse (1S of 809.9 ± 32.2 g kg⁻¹ w.w. and VS of 460.2 ± 13.2 g kg⁻¹ TS) generated during the screening at 100 and 10 mm was landfilled. Extra production of leachate was collected and treated at the nearby WWTP. Treated water used in the composting process comes from the same WWTP.

2.4 Sewage sludge line

Fresh sewage sludge (TS of 179.8 ± 3.2 g kg⁻¹ w.w. and VS of 757.0 ± 1.1 g kg⁻¹ TS) came directly from the nearby WWTP, it was stored in a tank and successively mixed at volume ratio 3:1 (v/v) with CRW (sewage sludge : CRW) (TS of 519.9 ± 3.2 g kg⁻¹ w.w. and VS of 987.6 ± 0.9 g kg⁻¹ TS) used as a co-substrate. At the same time wood chips were added as a bulking agent at volume ratio of 1:4 (v.v., sewage sludge + CRW : wood chips). A correct homogenization was provided using an industrial homogenizer. Composting tunnels were filled with this mixture and composting process took place under controlled conditions of aeration and watering. The estimated residence time was approximately three weeks and the process parameters like temperature, moisture content and oxygen content were controlled automatically. After the tunnel phase the material resulting was screened with a mesh trommel of 10 mm to obtain the final compost (TS of 696.7 ± 3.7 g kg⁻¹ w.w. and VS of 769.0 ± 39.7 g kg⁻¹ TS). Wood chips not degraded were separated and re-used. The compost was stored into the plant until commercialization.

2.5 Respirometric tests

Respirometry can be used to determine the biological activity in a sample if the assay is performed under optimal and controlled conditions (Adani et al., 2001). A respirometric assay requires optimal moisture content, oxygen content and appropriate temperature. The procedure established in this study for the determination and calculation of dynamic respiration index (DRI), cumulative respiration activity after 4 days (AT₄) and cumulative respiration index until ultimate time (ATu) was based on previous works by Adani et al. (2006), Sánchez (2007) and Pognani et al. (2010). DRI and AT₄ were recommended in the Second Draft of the Working Document on the Biological Treatment of Biowaste as

parameters for the estimation of the stability of compost (European Union, 2001) and were already used for the monitoring of other waste treatment plants (Ponsá et al., 2010; Pognani et al., 2010). Microbial respiration was measured as O₂ consumption and CO₂ production in a self-made dynamic respirameter (Ponsá et al., 2010; Pognani et al., 2010) based on the methodology described by Adani et al. (2006).

In this paper respirometric indices were also expressed in mg of CO₂ produced per g of TS in order to calculate the Biodegradable Organic Carbon (BOC) content. During the respirometric tests the aerobic degradation of organic matter caused the production and emission of CO₂ that was measured by a system of sensors. Knowing that one mol of CO₂ equal one mol of C, the BOC can be calculated from the final cumulative CO₂ emissions and the molecular weight ratio between CO₂ and C. The time required for the ATu assay was in function of the instantaneous measure of Oxygen Uptake Rate (OUR) that must be below of the 5% of the maximum OUR achieved during the test. At the end of the assay it can be considered that all the readily and almost all the slowly biodegradable organic matter were consumed (Sánchez, 2007).

2.6 Pyrolysis-GC/MS

Pyrolysis was performed with the Pyroprobe 5100 (SRA Instrument, Cernusco sul Naviglio, Italy) directly connected to a CG/MS system Agilent 5792 equipped with a fused silica capillary column (5MS 30 m x 250 μ m x 0.25 μ m). The detector consisted of an Agilent 5975C mass selective detector (EI at 70 eV). The analyses were performed applying the method reported by Dignac et al. (2005) partially modified. Approximately 0.2 mg of sample was loaded in a quartz tube in the pyrolylis unit. The pyrolysis analysis was performed starting from 625°C for 50 seconds. The final temperature was achieved at a rate of 20°C min and the end temperature of 650°C was maintained for 1 min. The pyrolysis product was then

transferred to the GC system trough a split injector operated in splitless mode using He as carrier. The temperature program of the GC oven was set at the start temperature of 30°C with an increase of temperature at 2°C min⁻¹ from 30°C to 320°C, while the column was maintained at this temperature for 15 min. Compounds were identified based on their mass spectra, GC retention time and comparison with library mass spectra (NIST).

3.1 Chemical and respiration properties

The chemical composition of the samples studied is presented in Table 1. Regarding the OFMSW line the input samples are characterized by an acid pH (5.12) as a consequence of the anaerobic processes occurring in the plastic bags in which the material is stored before its collection (Adani et al., 2006). The addition of the bulking agent (normally recirculated) to improve the porosity does not change the value of TS and VS, only the DRI_{24h} decrease 8.3%. At the end of the tunnel phase, the DRI_{24h} and TOC of the organic material decrease respectively 48.5% and 17.5% indicating that the decomposition phase took place correctly. TS increase 22.3% and VS remained approximately the same, due to the effect of concentration of the bulking agent not degraded. Before the maturation process (aerated static pile) bulking agent and inert materials (such as plastic, glass and metals) are removed by sieving the organic matrix using a 100 mm mesh trommel. At the end of the maturation process DRI_{24h} dropped until 0.8 g O₂ kg TS⁻¹ h⁻¹ (52.9% decrease), VS decrease 17.1% and TS increase 25.5%. To obtain the final compost the organic material coming from the maturation area was sieved in a mesh trommel of 10 mm. The concentration of organic fraction in the final compost caused an increase of DRI_{24h} of 11.1% (0.8 to 0.9 g O₂ TS⁻¹ h⁻¹). However bulk and refined compost presented a low DRI_{24h}, indicating that it was a stable

material. This phenomenon has been observed in other experiences when refining compost from the OFMSW (Pognani et al., 2010). Compost refuse (Table 1) had a value of DRI_{24h} of 30.8% higher than the final compost. This increase of DRI_{24h} can be explained due to the introduction of semi-composted organic matter refuse (derived from the first sieving at 100 mm at the end of tunnel phase) in the compost reject from the refining phase.

In relation to the sewage sludge line, the raw sludge was characterized by a high moisture content (82%), high NTK content (64 g N kg TS⁻¹) and a high respirometric activity (7.1 g O_2 TS⁻¹ h⁻¹) (Table 1). Before filling the tunnels, raw sludge was mixed with CRW (3:1) as a co-substrate used to reach a more suitable C/N ratio (from 6.3 to 16.9) and wood chips (1:4) to improve porosity. This also caused a drop of: moisture content (62.9% less than fresh sewage sludge), total nitrogen (57.8%) and respirometric activity (74.7% of DRI_{24h}). Composting process caused a further drop of 30% of moisture content and a high reduction in the respirometric activity (88.9%). At the end of the composting process (tunnel phase) the bulking agent not degraded was separated from the organic matrix and reused. The compost obtained (Table 1) had a higher DRI_{24h} (50%) than before due to the effect of concentration or organic matter, a lower content of VS about 10% and an accumulation of total nitrogen of 36.7%. Final DRI_{24h} (0.4 g O_2 TS⁻¹ h⁻¹) indicated that the sewage sludge compost was very stable.

Final composts obtained from both treatment lines were particularly rich in N-NH₃ (2.8 ± 0.3 g kg TS⁻¹ and 6.9 ± 0.2 g kg TS⁻¹ from OFMSW treatment line and sewage sludge treatment line, respectively). For this reason a detailed study of biodegradable organic carbon (BOC) and nitrogen content was undertaken. To establish the real quantity of BOC of the samples, ATu were performed using the method as described before. In Table 2 the values of ATu in terms of O_2 consumed and CO_2 emitted for the samples of the main steps of both lines are presented. Respirometric indices decrease during the main phase of treatment confirming

the efficiency of both treatment lines (Pognani et al., 2010). Using the quantity of CO_2 emitted, the real value of BOC for each sample could be calculated (Table 2). Results showed that the value of BOC are always lower than TOC, since C/N and BOC/N ratios were calculated using the N_{tot} content (NTK plus N-NH₃) (Haug 1993). Given that composting is a biological process the C/N ratios calculated using the chemical methodology are not suitable for this type of biological tests, being the ratio BOC/N the one that should be used for the characterization of an organic waste.

The differences found between C/N and BOC/N ratio were very high (especially for sewage sludge treatment line); BOC/N was lower on average of three times of C/N values. The results, shown in Table 2, indicated that the samples of the OFMSW line had a BOC/N ratio between 2 to 13. The BOC/N value of sewage sludge line was within 1 to 3. The BOC/N ratio found for fresh OFMSW was 12.9 similar to that reported by Kayhanian and Tchobanoglous (1992). All the values of BOC/N were lower than 13, which could cause an important loss of nitrogen during the composting process in the form of ammonia (Pagans et al., 2006) and provoke environmental contamination and odour problems. Sewage sludge had a very low BOC/N ratio (Table 2) due to the usual high nitrogen content (fresh sewage sludge: 71 g kg TS⁻¹). Moreover, in this facility, CRW was added to the sewage sludge as a cosubstrate before starting the composting process to include an extra input of carbon source (VS: 988 g kg TS⁻¹) with a low content of nitrogen content (Ntot: 18 g kg TS⁻¹). Unfortunately, none sample of this mixture is available for technical reasons. Also a great quantity of bulking agent (1:4 v.v.) was added to the mixture before starting the composting process. As expected C/N and TOC values increased until 16.9 and 507 g kg TS⁻¹ respectively (Table 2).

In accordance with the results presented in Table 2, total BOC can be directly related with the biological stability of the material. In fact, a low respirometric activity (in terms of consumption of O_2 or CO_2 emitted) corresponds to a low BOC value.

A new process index (TOC/BOC), useful to indicate the state of biodegradation of the organic matter of the samples coming from a waste treatment plant, can be proposed (Table 2). Not biodegraded samples (fresh sewage sludge and fresh OFMSW) presented a low ratio TOC/BOC (around 2), due to that the quantity of BOC is still high. When the biological treatment took place the quantity of BOC decreases much more than TOC and the value of the ratio TOC/BOC increases. The TOC/BOC ratio increase rate will change according to the biodegradability of the material composted and the effectiveness of the process. Thus, in the sewage sludge line the ratio increased from 2.4 to 10.5 after tunnel decomposition whereas in the OFMSW line, the increase was from 1.8 to 3.8. Biodegraded material (like compost) had a low value of BOC and a respective high value of ratio TOC/BOC indicating that the remaining organic matter is composed mainly of long term biodegradable organic matter or by recalcitrant organic molecules.

To reduce the time of analysis and find a rapid method to calculate the values of BOC, a potential function between TOC/BOC index versus DRI_{24h} and AT₄ values was found (Figure 1). Curve equations showed a good R square for each respirometric test (0.88 and 0.87 using AT₄ and DRI_{24h} respectively). In Figure 1 only six points were used to calculate the curve equations so, in order to obtain a more representative curve, other different samples would need to be processed in the future. Also, from the BOC analysis of a broad number of different wastes, it should be interesting to evaluate the BOC value at different test times to determine if it is possible to report a valid BOC value in a shorter period.

Further research should be performed on this ratio (TOC/BOC), as it could be used as an indicator of the waste biodegradability, similarly to the Chemical Oxygen Demand/Biochemical Oxygen Demand (COD/BOD) ratio used in water characterization. Furthermore, the increasing rate TOC/BOC during the process should be used as an indicator to compare different technologies.

3.2 Pyrolysis GC/MS

3.2.1 OFMSW line

From the pyrograms of the samples studied a large number of molecules can be identified (278-199 molecules) (Table S1-supporting information). In order to interpret the results obtained, molecules were grouped on the basis of their chemical characteristics. A total of 16 classes were identified: fatty acids, cycle-alkanes, alkanes, cycle-alkenes, alkenes, alcohols, ketones, cycle-ketones, aldeydes, furans, isoprenoids, alogenurs, nitrogen compounds, pyran compounds, silanes and aromatic molecules.

The raw material (OFMSW+wood chips) showed a high content of aliphatic hydrocarbon molecules (Table S1-supporting information, Table 3). Alkenes (that account for the 28% of the pyrogram) were represented mainly by 1-alkene and 2-alkene compounds (C7-C17) that represented the pyrolysis products of bacteria lipids (Dignac et al., 2006; González-Vila et al., 2009). On the other hand, alkane compounds (8.9% of the pyrogram), that showed the same range of C number of the alkenes (C7-C17), represented the pyrolysis product of lipids coming from the organic matter of waste (Dignac et al., 2006). Both cyclo-alkanes (C4-C16) and cyclo-alkenes (C5-C6) that only account for a small percentage of the pyrograms (respectively 3% and 1.6%) come from cyclization phenomena during the pyrolysis of triglycerides (Alencar et al., 1983). The small molecules of fatty acids, such as acetic acid found in the pyrogram, probably comes from bacteria (Dignac et al., 2005).

The N compounds class (11.3 % of pyrogram) (Table 3) was mainly constituted by pyridine and pyrrole molecules, suggesting their origin from both microbial proteins and vegetables and animal proteins contained in the organic fraction of waste (i.e. food) (Dignac et al., 2005; González-Vila et al., 2009).

Furan molecules were less represented in the pyrogram with respect to other organic compound classes (1.5 % of the pyrogram). These molecules came from the polysaccharides fraction of microorganisms. On the other hand, cyclo-ketones (mainly of the cyclopent-1-one derivates) and pyrans molecules indicated the presence of polysaccharides fraction from vegetal material (cellulose) degraded and not degraded, respectively (Dignac et al., 2005).

Aromatic molecules that represented the most abundant compounds in the pyrogram can be divided into sub-classes on the basis of the different chemical properties and origin i.e., methoxy-phenols and methyl ketones (aromatic molecules from lignin) (González-Vila et al., 2009), benzene ethenyl (aromatic molecules from plastic) (Dignac et al., 2005), and benzenes and phenols (aromatic molecules from unknown origin) (Table S1- supporting information) (Dignac et al., 2006; González-Vila et al., 2009). The lignin presence indicated the presence of ligno-cellulose fraction in the starting mixture (wood chips and vegetal material).

Nevertheless, the low content of lignin-derived molecules (0.6 % of the pyrogram) identified in the program was due to both the composition of the OFMSW and also, to the low resolution capability of the columns adopted (apolar phase) for these molecules, that enhanced the resolution of apolar compounds (lipids) (Dignac et al., 2006).

The isoprenoids molecules class was attributed to the terpenes fraction derived from vegetable material contained in the organic fraction of waste (Dignac et al., 2005; González-Vila et al., 2009).

Poliaromatic molecules, i.e. naphthalene, alkylnaphtalene and indene were probably originated from poly-aromatic molecules such as humic-like substances (Schulten and Gleixner, 1999).

Classes of alcohols and aldehydes are not well defined although literature reported that they could come from lignin and/or lipids.

Finally, plastic derived molecules (benzene ethynil), silane and alogenure compounds, that were found in a very small amount, were due to the presence of chemical and others impurities (like plastics) in the OFMSW.

Composting process did not modified significantly the chemical composition of the pyrograms (Table 3), except for the alkene class, which showed in the composted materials the presence of dienes (pentadiene and hexadiene) that represented the pyrolysis products of partially degraded triglycerides (Alencar et al., 1983). From a quantitative point of view the modification of the organic compounds by composing the organic material could be followed by studying the specific pyrograms (Table 3). During the composting process there was a progressively reduction of the lipid and polysaccharides fractions. In particular, the polysaccharides from plants (cycle-ketones) showed the highest reduction, while the same fraction coming from microorganism increased. At the same time, the protein content increased because of a concentration effect as a consequence of the high rate degradation of the other fractions. The proteins class increase could be attributed to the higher presence of bacteria, such it is suggested by the increase of the polysaccharide fraction. Lignin-like fraction did not showed a significant increase indicating that degradation was compensated by the concentration effect due to degradation of other molecules. Moreover, the fact that polyaromatic fractions increase during composting could indicate that lignin-like molecules did not degrade but were humified (Adani et al., 1997).

The compost sieved after maturation did not permit discussing the evolution of the organic matter with respect to the raw material as the composition was artificially altered. However, the comparison between the raw material and the final compost showed a lower presence of lipid and polysaccharides and a higher content of recalcitrant fractions as previously reported (Adani et al., 1997).

3.2.3 Sewage sludge line

The pyrograms of the sewage sludge mixture were very similar to those of OFMSW mixture composting process, from both quantitative (number of pyrogram compounds, i.e. 252-161) and qualitative (compounds classes) point of view. Anyway the pyrolysates of sewage sludge mixture indicated a higher presence of proteins, probably due to presence of proteins in sewage sludge (Dignac et al., 2009), lignin and polysaccharides, due to the higher presence of lignocelluloses with respect to the OFMSW (Table 3) and due to the added of CRW in the mixture. In general, sewage sludge contains a high amount of lipids (Rèveilllè et al., 2003), which probably were diluted in the mixture because of the presence of bulking agent and CRW.

During the composting process (before the final sieving phase) a reduction of both proteins and lipid contents occurred because of degradation process (Table 3). Polysaccharide fraction also showed a decrease during composting, as a result of the degradation of the vegetable fraction, being the fraction of polysaccharides of microbial origin more abundant. However, the increase of lignin compounds suggested a concentration effect of the more recalcitrant fraction of the organic matter because of the degradation of labile fractions.

4. Conclusions

ATu was a suitable assay to calculate the BOC/N and correct the C/N ratio in organic mixtures avoiding the deficiency or excess of nitrogen. Correct definition of BOC/N ratio instead of C/N ratio should be the key to obtain optimal mixtures to carry out successfully a biological treatment such as a composting process. TOC/BOC ratio could be a new process index to estimate the real state of biodegradation of the organic samples during the different treatment phases in a complex waste treatment plant. Pyrolysis GC/MS can be a good

opportunity to investigate the change of the molecules of organic matter after every process step.
