19 ABSTRACT

Viruses are a major cause of coccolithophore bloom demise in both temperate and sub-20 temperate oceanic regions. Here we observe the competitive interactions between two 21 22 coccolithovirus strains, EhV-86 and EhV-207 during the infection of the cosmopolitan marine micro-alga Emiliania huxleyi. EhV-207 displayed a shorter lytic cycle and increased 23 production potential than EhV-86, and was remarkably superior under competitive 24 conditions. The observation of such clear phenotypic differences between genetically distinct, 25 yet similar, coccolithovirus strains by flow cytometry and quantitative real time PCR allowed 26 27 links to the burgeoning genomic, transcriptomic and metabolic data currently available to be made. We speculate on the tentative identification of the genetic source of the phenotypic 28 29 variation observed and the factors driving their selection (such as the functional relevance of 30 the encoded sphingolipid biosynthesis associated genes). This work illustrates that, even within a family, not all viruses are created equally and the potential exists for relatively small 31 genetic changes to infer disproportionately large competitive advantages for one 32 33 coccolithovirus over another, ultimately leading to a few viruses dominating the many.

34

35 Keywords: coccolithoviruses, infection dynamics, competition, phenotypes, E. huxleyi

36 INTRODUCTION

Viruses are a major cause of coccolithophore bloom demise in both temperate and sub-37 temperate oceanic regions (Bratbak et al., 1995; Martinez et al., 2007; Brussaard et al., 2008; 38 39 Sorensen et al., 2009). Their role in regulating coccolithophore populations has been firmly established via studies of natural environmental systems (Wilson et al. 2002, Schroeder et al. 40 2003, Martinez et al. 2007), and induced semi-natural blooms in the Norwegian fjords 41 (Bratbak et al. 1993, Jacquet et al. 2002, , Pagarete et al. 2009, , Kimmance et al. 2014). In 42 addition to the direct reduction in total cell abundance, the species-specific nature of viruses 43 44 leads to the regulation of interspecies competition and succession within a mixed phytoplankton community (Brussaard, 2004; Fuhrman, 1999). 45

46

47 Within a coccolithophore bloom, the success of specific coccolithovirus strains vary and is influenced, among other factors, by the type of host strains present and the physico-chemical 48 environment in which they are found (Wilson et al., 2002a; Martinez et al., 2007, 2012; Rowe 49 et al., 2011; Coolen, 2011). Under bloom conditions, there is typically an initial and diverse 50 pool of low abundance virus (Sorensen et al. 2009) and host strains (Schroeder et al. 2003), a 51 subset of which become more dominant than others as the bloom progresses (Martinez et al. 52 2007; Sorensen et al. 2009), and an indication that some virus genotypes win over others 53 (Pagarete et al, 2014, Highfield et al, 2014). Virus abundance and diversity is controlled by 54 55 external (environmental) influences that drive evolutionary processes (Coolen et al. 2011; Martinez et al. 2012). However, the molecular diversity observed within samples is a mere 56 snapshot of that particular time, and although useful, it does not reveal how and why 57 coccolithovirus strains vary with regards to infection strategies and mechanisms. Given that 58 there are clear genetic differences between coccolithovirus isolates (Allen et al. 2006, 59 Nissimov et al. 2011, 2012, 2014, Pagarete et al. 2013) it is likely that within a mixed 60

community of coccolithoviruses during bloom conditions, subtle variations in their
phenotypic properties, i.e. infection and lysis rates, may have a profound impact on shaping
the ultimate genetic richness and composition of the host and viral community.

64

However, the fundamental question remains as to how differences in coccolithovirus 65 phenotypes influence host growth dynamics, virus succession and population survival. A 66 previous study by Bidle and Kwityn (2012) demonstrated that different Emiliania huxleyi 67 strains vary in their susceptibility to infection by a single coccolithovirus strain, yet, to date, 68 69 the significance of coccolithovirus strain-specific differences have not yet been fully investigated. Whether the enormous genetic potential contained within their large genomes 70 71 (~400-500 MBs) produces variations in the infection strategies employed by different 72 coccolithovirus strains, remains to be determined. Like in all other virus systems, intra-73 familial competition among coccolithoviruses for successful infection and replication must exist. The molecular encoded components at the interface of this ongoing evolutionary 74 75 struggle are currently unknown, yet our current whole genomic knowledge of a dozen coccolithovirus strains suggests their identification is now possible. 76

77

Here we use an experimental approach to assess the phenotypic differences in two E. huxleyi 78 virus (EhV) strains, and their manifestation during infection of a single host strain. Infection 79 80 experiments were performed with two coccolithovirus strains which were originally isolated from the same location in the English Channel: EhV-86 and EhV-207, and have been shown 81 previously to successfully infect the same host (E. huxleyi CCMP 2090) (Nissimov et al, 82 2011; 2012), yet differ in genomic composition (Nissimov et al. 2014). For simplicity, it was 83 decided that the focus would be to identify any potential differences in viral production and 84 host lysis during infection, and not to consider host strain variability here. The main goal was 85

to reveal the competitive interactions of two genetically distinct viruses infecting side by side,
and assess the implications for host growth and virus productivity. Strain specific primers
were designed for each coccolithovirus, and the change in EhV abundance was monitored for
one week post- virus addition by means of quantitative real time PCR (qPCR) and Analytical
Flow Cytometry (AFC).

91

92 MATERIALS AND METHODS

93 Culture conditions and experimental setup

Prior to the start of the experiment, cultures of E. huxleyi CCMP 2090 were grown in filtered 94 (30 kDa, TFF GE Healthcare), autoclaved natural seawater enriched with f/2 nutrients 95 (Guillard 1975), in 2 L InforsMinifors chemostat bioreactors (INFORS UK Ltd). Cultures 96 were maintained with a light and dark cycle of 16:8 hours, at a white light intensity of ~86 97 μ M photons m⁻² s⁻¹, and a temperature of 18°C, with continuous gentle mixing and aeration. 98 Emiliania huxleyi abundance was measured daily using analytical flow cytometry (AFC, see 99 below for protocol), and when cellular density reached 1.5×10^6 cells mL⁻¹ (i.e. beginning of 100 exponential growth, $\mu = > 0.7$), aliquots of 100 mL were distributed into 12 polystyrene, 101 102 sterile, 250 mL tissue culture flasks (Greiner, CellStar). The 12 algal subculture flasks and nine additional flasks containing only f/2 media (controls; Table S1) were then returned to the 103 104 same light and temperature conditions as above, and left to acclimatise for 48 h.

105

106 The virus pathogens EhV strain EhV86 (Wilson et al. 2002) and EhV-207 (Nissimov et al. 107 2012) were obtained from the Plymouth Marine Laboratory virus collection and for each EhV 108 strain, a fresh batch of viral lysate was prepared prior to experiments to ensure a high amount 109 of infective virions. For this, 500 mL of an exponentially growing *E. huxleyi* CCMP2090 110 culture ($\sim 4 \times 10^6$ cells mL⁻¹) was infected with 5-10 mL of an EhV lysate stock. When the

culture had lysed (complete loss of pigmentation, monitored using analytical flow cytometry, 111 AFC, see below) lysates were gently vacuum-filtered through 0.2 µm pore size sterile filters, 112 Millipore Express) to remove E. huxleyi cell debris, and stored in the dark at 4°C until 113 required. On the day of the experiment (t0), the experimental flasks were set up to represent 114 seven different treatments (A-G) as described in Table S1. Ten minutes before the first 115 sampling point (t0), flasks 1-3 (A) were inoculated with EhV-86 lysate at a virus:host ratio of 116 1:1; flasks 4-6 (B) were inoculated with EhV-207 at a virus:host ratio of 1:1; and flasks 7-9 117 (C) were inoculated with a combination of both EhV-86 and EhV-207, providing an overall 118 119 virus:host ratio of 1:1 (with a 1:1 ratio of each virus). Flasks 10-12 (D) were virus controls that contained no host (only culture media), but were inoculated with the same volume of 120 EhV-86 lysate as flasks 1-3. Likewise, flasks 13-15 (E) contained only culture media and an 121 122 inoculum of the same volume of EhV-207 lysate as flasks 4-6. Flasks 16-18 (F) contained only culture media and an inoculum of combined EhV-86 and EhV-207 lysates equivalent to 123 that in flasks 7-9. Finally, flasks 19-21 (G) were the negative controls containing host culture 124 with an addition of EhV-86 and EhV-207 lysates equivalent to treatments (C) and (F), 125 however prior to addition lysates were inactivated through a series of treatments: autoclaving 126 at 126°C, filter sterilization through 0.2 µm sterile cellulose acetate syringe filter (Gilson), 127 followed by overnight exposure to UV light in a PCR station (Labcaire), prior to their 128 addition to the control flasks. 129

130

131 Sampling procedure

Once experimental conditions were set up in the flasks the cultures were left for ten minutes to allow viruses to establish initial attachments/infections with the host cells. Then 3 mL of sample were taken out from each flask at the following time intervals: 0 (t0), 1 h (t1), 2 h (t2), 3 h (t3), 4 h (t4), 8 h (t5), 12 h (t6), 24 h (t7), 48 h (t8), 72 h (t9), 96 h (t10), 120 h (t11), 144 136 h (t12), and 168 h (t13). The 3 mL samples were then further divided into three sub-samples: 1 mL was fixed with 0.5% (final conc.) glutaraldehyde for the enumeration of host abundance 137 using analytical flow cytometry (AFC), and 1 mL was centrifuged at 20,000g for 30 sec., of 138 139 which the top phase was carefully removed into a sterile, 2 mL Eppendorf polypropylene tube, fixed with 0.5% (final conc.) glutaraldehyde, and the pellet re-suspended in 1 mL of 140 DNA free water and fixed in 0.5 % glutaraldehyde for the subsequent enumeration of free 141 and attached VLPs respectively by AFC. All samples were snap frozen in liquid nitrogen 142 (LN₂) and stored at -80°C for further analysis. The same procedure was performed with the 143 144 third 1 mL subsample, with the exception of the addition of the glutaraldehyde, as these samples were used for DNA extractions and subsequent quantitative real time PCR analysis. 145

146

147 Enumeration of host and virus abundance

All samples were analysed en masse following the conclusion of the experiment. Fixed, 148 frozen samples were defrosted at room temperature and then analysed using AFC following 149 standard protocols (Marie et al. 2000; Brussaard et al. 2004). Samples were analysed on a 150 FACScan flow cytometer (Becton Dickinson, Oxford, UK) equipped with a 15 mW laser 151 exciting at 488 nm and with a standard filter set up. Counts of E. huxleyi were conducted at 152 high flow rate (~ 80 μ L min⁻¹) and files were analysed using WinMDI 2.8 software (Joseph 153 Trotter, [http://facs.scripps.edu]. For virus analysis, sub-samples were diluted 500-fold with 154 TE buffer (10 mmol L⁻¹ Tris-HCL pH8, 1 mmol L⁻¹ EDTA), stained with SYBR Green 1 155 (Molecular Probes; Marie et al., 2000) at a final dilution of 5×10^{-5} the commercial stock, 156 incubated at 80°C for 10 min in the dark, then allowed to cool for 5 min before flow 157 cytometric analysis. Samples were analysed at a flow rate of ~ 20 μ L min⁻¹ and EhVs were 158 identified on the basis of their RALS versus green fluorescence. Data files were analysed 159 using WinMDI 2.8 software (as above). The two EhV strains could not be separated by their 160

AFC profiles in the combined EhV-86 and EhV-207 treatments, as they gave identicalfluorescence vs. scatter signatures.

163 **Probe design and optimisation**

- 164 The selection for specific primer probes for the two viruses EhV-86 and EhV-207 was
- 165 performed on the IMG/ER analysis platform, in which the total protein coding genes of EhV-
- 166 86 and EhV-207 were BLAST searched against each other with a maximum E value of $1e^{-05}$
- and minimum percent identity of 40%. Following this analysis, EhV-86 and EhV-207 strain
- specific genes were identified (i.e. ehv290 [510 bp] and EQVG00465 [1059 bp],
- 169 respectively) and selected for the design of strain specific PCR primers. The final sequence
- 170 lengths that were to be amplified by PCR/quantitative real time PCR were 209 bp and 353 bp
- 171 for EhV-86 and EhV-207 respectively (primers sequence: qPCR(EhV-86)-F [5'-
- 172 GCACAACTTTCAACAATTCG-3']; qPCR(EhV-86)-R [5'-
- 173 TCAGCTCAACTTTTGGATCA-3']; qPCR(EhV-207)-F
- 174 [5'CATAGGGTTGGCAATATTCA-3'] and qPCR(EhV-207)-R [5'-
- 175 TTCGAAACAACTTGGTCAAC-3'], Sigma-Aldrich Company Ltd).
- 176

To first establish that the designed primers were strain specific, a standard PCR was 177 performed on fresh lysate stocks of EhV-86 and EhV-207 with the primers for ehv290 (i.e. 178 qPCR(EhV-86)-F and qPCR(EhV-86)-R) and EQVG00465 (i.e. qPCR(EhV-207)-F) and 179 180 qPCR(EhV-207)-R). Reactions were conducted in a VWR JENCONS Uno Thermal Cycler in 25 µL final volume reactions (unless otherwise stated). PCR reactions were set as follows: 1 181 μ L of virus lysate template (or ~50 ng μ L⁻¹ of extracted DNA) was mixed with 5 μ L of 1 × 182 PCR reaction buffer (Promega), 1.5 µL of 25 mM MgCl₂, 0.1 µL of Taq DNA polymerase 183 (Promega), 2 µL of 10 µM of each primer, 1.25 µL of 2 mM dNTPs and DNA-free molecular 184 biology grade water (Sigma-Aldrich). PCR was conducted in triplicate and the conditions 185

were as follows: an initial denaturation step at 95°C for 3 min, followed by 34 cycles at 95°C,
60°C and 74°C for 30, 60 and 90 sec respectively, and a final cycle at 95°C, 60°C and 74°C
for 30 sec, 5 min and 5 min respectively.

189

190 DNA extraction from top phase and pellet samples

Phenol-chloroform DNA extraction was performed on the samples intended for qPCR 191 analysis based on the detailed protocol described by Schroeder et al, (2002). Briefly, 0.5 mL 192 aliquots from the 1 mL top phase and pelleted sub-samples collected at the different time 193 194 points during the experiment were placed into sterile tubes in a heating block at 90°C for 1 min and then transferred onto ice for a further minute, repeating this three times. Then to the tubes 195 were added 20 µL 0.5 M EDTA pH 8.0 at a final concentration of 20 mM, 5 µL proteinase K at a 196 final concentration of 50 µg mL⁻¹, and 25 µL of 10% SDS at a final concentration of 0.5%, and 197 incubated in a water bath for 1 h at 65°C. After the incubation the tubes were transferred onto ice 198 and gently mixed with 60 µL of phenol. Then 500 µL of chloroform/isoamyl alcohol (24:1) was 199 added to the tubes, mixed gently, after which they were centrifuged at 10,000 rpm for 5 min. 200 201 After removing the top phase into a clean Eppendorf microfuge tube and adding 500 µL of 7.5 M ammonium acetate, they were left at room temperature for 30 min. A centrifugation step at 202 10,000 rpm for 15 min followed after which the supernatants were placed into clean 2 mL 203 Eppendorf tubes. To these tubes 1 mL of 100% ethanol (ETOH) was added, leaving them to 204 precipitate for 3 h at 4°C, and then centrifuging them at 13,000 rpm for 30 min after which the 205 supernatants were removed and discarded. Finally, the pellets were washed by centrifugation for 206 207 10 min with 500 µL of 70% ETOH and air dried overnight. The genomic DNA pellets were re-208 suspended in 50 µL of TE buffer and then quantified by spectrophotometer (i.e. NanoDrop) and a 209 1% agarose gel electrophoresis.

210

211 Quantitative real-time PCR

212 Quantitative real-time PCR (qPCR) assays on extracted DNA samples were carried out in optical-grade 96-well plates in an ABI PRISM®7000 Sequence Detection System (Applied 213 Biosystems, UK) with the Qiagen Quantifast Sybr Green PCR kit containing a ready to use 214 master mix. The calibration curve (or standards) for the qPCR to which each experiment 215 DNA sample was compared to consisted of triplicates of the serial dilutions $(10^{-1} \text{ to } 10^{-10})$ of 216 amplified and gel extracted PCR products of ehv290 (for EhV-86) and EQVG00465 (for 217 EhV-207) at initial DNA concentrations of 65.7 ng μ L⁻¹ and 57.4 ng μ L⁻¹ respectively (i.e. 218 predicted DNA copy number of 2.91 \times 10¹¹ and 1.51 \times 10¹¹ μ L⁻¹ respectively). The 219 220 calibration curve diluted samples were loaded each time on the same plate as the DNA samples from the experiment in order to reduce bias occurring due to small shifts in 221 fluorescence signal from one 96 well plate to another. The reactions of both standards and 222 223 samples consisted of 12.5 µL of Sybr Green master mix, 0.5 µL of primer qPCR(EhV-86)-F or qPCR(EhV-207)-F (at a final conc. of 0.2 µM), 0.5 µL of primer qPCR(EhV-86)-R or 224 qPCR(EhV-207)-R (at a final conc. of 0.2 μM), 1 μL of template DNA (sample, standard, or 225 NTC [no template control]) and 10.5 µL of RNAse free water (final volume of 25 µL). The 226 thermal cycling conditions (on the ABI PRISM 7000 cycler) were as follows: an initial cycle 227 of 95°C for 10 min followed by 40 cycles at 95°C for 30 sec and 60°C for 30 sec. The 228 automated generation of the calibration curve by the ABI PRISM 7000 sequence detection 229 system allowed the logarithmic plotting of each standard concentration against the cycle 230 231 number at which the detected fluorescence signal increased above the threshold value- CT. Then, the Sequence Detection System software calculated the target gene DNA copy number 232 (or concentration) from the CT value obtained for each of the samples with unknown 233 concentration. The calibration curve slope was used to determine the reaction efficiency (E) 234 using the following equation: $E = -1 + 10^{(-1/slope)}$. For instance, if E equalled to 1 then this meant 235 a 100% product doubling in each amplification cycle. 236

238

239 Oligonucleotide specificity

PCR amplification of EhV-86, EhV-207 and EhV-86+EhV-207-combined lysates revealed that the newly designed qPCR primers were strain specific (Fig. S1). When each set of primers was used in a sample from which the target strain was not present (EhV-86 or EhV-207), amplification was not detected; i.e. the amplification was specific to the set of primers used and only samples that had the target strain produced PCR amplicons. The amplified products of the EhV-86 and EhV-207 specific targets corresponded to the predicted size fragments of 209 and 353 bp for EhV-86 and EhV-207 respectively.

247

248 Calibration curve efficiencies of the quantitative real time PCR sample analysis

The calibration curves (Fig. S2) that were conducted to establish the optimum conditions for the qPCR analysis indicated that under the described PCR conditions, the serial dilutions of the known concentrations of ehv290 (for EhV-86) and EQVG00465 (for EhV-207) PCR generated DNA was log-linear for both, with a correlation coefficient (R^2) of 0.99. The calculated efficiency ($E= -1+10^{(-1/slope)}$) of the reactions were 102.21 % and 88.70 % respectively. The calibration curves were interrogated to allow the accurate quantification of DNA template in both single and dual infection samples.

256

257 **RESULTS**

258 Genetically distinct viruses produce contrasting host lysis rates

Emiliania huxleyi CCMP 2090 abundance increased steadily in all flasks during the first 24 h to an average (\pm SD) maximum of 2.6 × 10⁶ ±4 × 10⁵ cells mL⁻¹ (Fig. 1). However, by day 3, both the EhV-207 and EhV-86+EhV-207-infected populations crashed dramatically, with a

96 % loss of cells in these flasks from $2.48 \times 10^6 \pm 2.73 \times 10^5$ (SD) to $9.83 \times 10^4 \pm 2.87 \times 10^4$ 262 cells mL⁻¹ (SD). The crash was simultaneous between these two treatments (Fig. 1). In 263 contrast, during the same time period (24-72 h post-addition of virus), there was a 14% 264 increase in *E. huxlevi* abundance in the EhV-86 infected cultures to 3.15×10^6 cells mL⁻¹ 265 $\pm 1.41 \times 10^5$ (SD). However by 96 h host density also began to decrease in the EhV-86 266 infected cultures, but at a much slower rate (~17 % reduction in host cell density) compared 267 to the EhV-207 and EhV-86+EhV-207-infected cultures (Fig.1). These differences were also 268 evident from the fluorescence profiles of *E. huxleyi* derived during the AFC analysis (Fig. 2) 269 in which the mean cellular red fluorescence (proxy for chlorophyll *a*) at 72 h post-infection, 270 was much lower in the EhV-207 and EhV-86+EhV-207-infected cultures than in those 271 infected only with EhV-86. By the end of the experiment (168 h), the majority of the E. 272 huxleyi cells in the EhV-86 infected cultures had lysed (Figs.1, 2). However a small, 273 relatively healthy (as indicated by high cellular red fluorescence observed during AFC 274 analysis) host population remained in the EhV-86 infected cultures, and the average (±SD) 275 cell abundance was 2.77×10^5 (±6.89 × 10⁴ mL⁻¹), as opposed to 2.52×10^2 (±3.36 × 10¹ mL⁻¹) 276 ¹) and 1.18×10^3 ($\pm 1.24 \times 10^3$ mL⁻¹) in the EhV-207 and EhV-86+EhV-207-infected cultures 277 respectively. With regards to the control cultures that contained inactivated EhVs, E. huxleyi 278 abundance remained high at the end of the experiment with 4.32×10^6 cells mL⁻¹ ±3.04 × 10⁵ 279 (SD), (Fig. 1, 2). 280

281

EhV abundance decreased in all non-control flasks two hours post-infection to an average (\pm SD) of 2.91 × 10⁵ \pm 1.42 × 10⁴ mL⁻¹ (Fig. 3). This suggests that by two hours post-virus addition, almost half (45%) of the inoculated EhVs were either attached to the host cell receptors or had penetrated into the cells for replication. The first round of mass EhV release from the infected cells in all treatments was 3 h post-addition (Fig. 3). After this point there 287 appeared to be a separation between EhV treatments, with the samples containing EhV-207 producing a higher number of virions compared to those containing EhV-86. However, this 288 was not statistically significant until (8 h post-addition) when there was significantly more 289 free EhVs in the EhV-207 and EhV-86+EhV-207 infected cultures than in the EhV-86 290 infected treatments (P<0.05). The trend of significantly lower and slower virion 291 production/release from the EhV-86 infected cultures continued until the end of the 292 experiment 7 days post-addition (P<0.01). At this point, the amount of free EhV mL⁻¹ in the 293 EhV-86 infected cultures $(5.19 \times 10^7 \pm 3.88 \times 10^6 \text{ SD})$ was on average 92% less than in the 294 EhV-207-infected (6.58 \times 10⁸ ±1.09 \times 10⁸ SD) or EhV-86+EhV-207 (7.04 \times 10⁸ ±8.55 \times 10⁷ 295 SD) combined treatments (Fig. 3). Throughout the experiment, there was no difference in the 296 297 number of EhV between cultures infected by EhV-207 and those infected with both EhV-298 86+EhV-207 combined, with the exception of one hour post-infection, where the number of free EhVs in the combined virus treatment was significantly lower (P<0.05) (Fig. 3). 299

300

301 Quantifying strain-specific differences in virus genome copy number

Quantitative real time PCR analysis (qPCR) was used to determine EhV-86 and EhV-207 302 genome copy number (GCN) in both cell-free and cell-associated fractions. Total GCN 303 estimates were derived from a combination of the two fractions. Cell-associated GCN will 304 include genomes found within virions adsorbed to the cell surface, unreleased intracellular 305 306 virions, as well as unpackaged genomes undergoing replication. Cell-free GCN estimates, on the assumption that one virus genome copy is found per free floating virion, can be directly 307 compared to the AFC measurements of non-cell associated virions. This comparison, of EhV 308 virion abundance determined by AFC with genome copy number quantified by qPCR, 309 revealed that there was a consistent 100-fold decrease in the predicted genome copy number 310 detected by the qPCR method, a phenomena most likely caused due to inefficiencies during 311

312 the phenol-chloroform DNA extraction step (Table S2). This reduction in apparent virus abundance was consistent throughout the experiment and was thus taken into consideration 313 when interpreting the qPCR results of the dual virus infection treatments. In addition, the 314 resolution of the qPCR was accurate only 12 h post-EhV addition at GCN higher than 10^3 315 mL^{-1} , hence the qPCR results of t0 – t5 were below reliable detection levels and are not 316 shown here. Regardless of whether the two virus strains were added to the host cultures 317 combined or in isolation, EhV-207 and EhV-86 appeared to exhibit different infection 318 dynamics, and the qPCR results revealed more than what was initially observed with the AFC 319 320 analysis alone.

321

In the single virus-addition treatments, EhV-207 exhibited faster infection than EhV-86 and 322 323 replicated to produce new virions quicker; i.e. combined GCN was higher (Fig. 4). In the dual infection treatments (EhV-207 + EhV-86), the presence of EhV-86 did not appear to reduce 324 the infection potential of EhV-207, and GCN produced was comparable to that in the EhV-325 207-only infected treatments. In contrast, EhV-86 was affected by the presence of EhV-207 326 in the dual infection treatments and the amount of EhV-86 GCN at the end of the experiment 327 was 1000 fold less than in the single EhV-86 infected cultures ; i.e. $6 \times 10^3 \pm 2.86 \times 10^3$ (SD) 328 and $4 \times 10^6 \pm 1.28 \times 10^6$ (SD) mL⁻¹ respectively (Fig. 4). Thus, EhV-207 appeared to be not 329 only a faster strain than EhV-86 with regards to its rate of infection under the conditions 330 331 studied, but also a 'superior' strain that out-competed its EhV-86 rival to infect a host population when they were combined at equal abundance 332

333

To gain a deeper understanding of the competitive interactions between the two EhVs, we also measured the GCN of each virus strain that was associated with the cellular fraction, with the assumption that the GCN in the pelleted fraction represents viruses or synthesised 337 viral genomes within the cells or virus particles attached to the cell receptors (infecting or still attached). Throughout the experiment, the amount of cell-associated EhV-207 GCN in 338 both dual and single virus treatments was higher than the amount of free EhV-207 GCN, with 339 the exception of 168 h post-infection. At this point the average (±SD) amount of free and 340 cell-associated EhV-207 GCN was equivalent: i.e. 6.9×10^6 (±2.6 × 10⁵) and 5.59 × 10⁶ 341 $(\pm 1.01 \times 10^6)$ respectively (Fig. 4). In comparison, the amount of cell-associated EhV-86 342 GCN in both dual and single virus treatments was also higher than the amount of free EhV-86 343 GCN throughout the experiment, with the exception of 12 h post infection, where the average 344 (±SD) amount of free and attached cell-associated EhV-86 GCN was equivalent: i.e. $1.27 \times$ 345 $10^{3} (\pm 1.85 \times 10^{2})$ and $1.69 \times 10^{3} (\pm 8.6 \times 10^{2})$ respectively (Fig. 4). 346

347

The presence of EhV-86 in the dual infection treatments did not affect the amount of cell-348 associated or free EhV-207, as the GCN of both fractions was similar to the GCN of the cell-349 associated and free EhV-207 in the EhV-207 single virus treatments. At 48 h post-infection 350 the average (±SD) cell-associated EhV-207 GCNs in the dual and single virus treatments 351 were 5×10^7 ($\pm 2.83 \times 10^7$) and 4.47×10^7 ($\pm 1.52 \times 10^7$) respectively, while the average 352 (±SD) free EhV-207 GCNs in both the dual and single virus treatments were 3.89×10^6 353 $(\pm 2.62 \times 10^5)$ and $5.25 \times 10^6 (\pm 7.07 \times 10^4)$ respectively. In contrast, in the dual-infected 354 treatments the presence of EhV-207 decreased the GCN of both cell-associated and free EhV-355 86. At 12 and 48 h post-virus addition there were 72 % and 65 % less cell-associated EhV-86 356 genomes, and 18 % and 42 % less free EhV-86 genomes in the dual infected treatments, 357 respectively, in comparison with the single virus treatments (Fig. 4). 358

359

360 By the end of the sampling period the cell-associated EhV-86 copy number in the dual 361 infection treatments was more than three orders of magnitude lower than that of cellassociated EhV-207. Similarly, the average GCNs of free EhV-86 in both the single and dual
infected treatments were approximately 15 and 2500 times lower respectively, than the
average GCN of free EhV-207 after 168 h (Fig. 4).

365

366 **DISCUSSION**

To date, potential differences in infection rates between coccolithovirus strains have been 367 assessed briefly in only one previous study (Nissimov et al, 2013), and to our knowledge this 368 is the first time where these dynamics have been investigated under controlled laboratory 369 370 conditions that includes an in-depth quantitative coccolithovirus genome analysis. Strainspecific genetic markers enabled us to differentiate production rates of two EhV strains 371 during dual-strain E. huxleyi infection experiments. Assessment of the competitive 372 373 interactions of these viruses during infection of the host identified major differences in their infection strategies. When infecting in combination, EhV-207 was not affected by the 374 presence of EhV-86 whereas EhV-86 was quickly out-competed, and a significant reduction 375 in free and cell-associated EhV-86 was seen two days after the initial infection. Thus, when 376 infecting alongside EhV-207, the EhV-86 strain appeared to be "inferior" and its persistence 377 in this experimental setup was under threat. The significance of the results here are 378 fundamental in our understanding of how viruses interact with their hosts and with each 379 other. They provide an insight into the complex and competitive interactions between viruses 380 381 in the natural environment, interactions that we currently have a limited knowledge of.

382

383 The losers and winners of the virus "fight club" – a numbers game

Throughout the experiment EhV-207 appeared to be superior to EhV-86 (and perhaps more potent) in that it was a faster replicating virus with regards to its rate of infection and lysis of *E. huxleyi* CCMP 2090, regardless of the competition with EhV-86. As both virus strains 387 were fresh lysates produced immediately prior to the experiment, and both AFC and qPCR analysis revealed no obvious differences between the physical properties of the two strains, 388 this suggests that they were of equivalent abundance and provenance. An equivalent number 389 390 of EhVs were added at the start of the experiment (in both single and dual-virus treatments) and by 2 h post-inoculation EhV abundance in all EhV treatments decreased to an identical 391 amount, suggesting that at least initially, there was no advantage for EhV-207 with regards to 392 adsorption kinetics. However, by 8 h there was significantly more EhV-207 than EhV-86; 393 suggesting that EhV-207 was able to develop a fairly rapid competitive advantage following 394 395 adsorption. The dramatic increase in EhV-207 24 h post-infection in both the single and dualvirus treatments and the rapid decrease in E. huxleyi thereafter, demonstrates that the initial 396 397 advantage following adsorption was not abated with time. If we consider this in the context of 398 the combined-virus treatments, by generating a significant advantage over EhV-86 as early as 399 8 h post-infection, EhV-207 was most likely responsible for the demise of the majority of the host cells, subsequently leaving EhV-86 less hosts for its own propagation. 400

401

The mechanisms that allow EhV-207 to outcompete EhV-86 under these experimental 402 403 conditions are currently not known and a future study combining a complete transcriptomic or microarray analysis during infection should be considered. Nevertheless, these results 404 suggest that EhV-207 may have a shorter latent period within the host cells than EhV-86, and 405 406 that under these experimental conditions, EhV-207 packages, assembles and releases new virus progeny much quicker than its EhV-86 rival. A second possible explanation to the EhV-407 207 dominance is that the amount of EhVs produced per infected host cell (burst size) was 408 much higher when hosts were infected by EhV-207 compared to EhV-86. Over multiple 409 rounds of reinfection, this would quickly result in EhV-207 dominating EhV-86. However, 410 only the second explanation explains the decreased productivity of EhV-86 in comparison 411

412 with EhV-207 in the single virus infection treatments. Indeed, if the former were true, presumably with a longer reinfection cycle, EhV-86 would be expected to produce more, not 413 less, progeny since the host cells would have longer to grow and therefore have a greater 414 415 overall virus production potential. Lytic viruses typically exhibit a short latent period and a low burst size (Parada et al. 2006), however an extension of the latent period is a strategy 416 employed by some temperate phage during periods of low multiplicity of infection and low 417 host abundance (Wilson and Mann 1997, Parada et al. 2006). Although not measured directly 418 here, we calculated the potential burst sizes of the two EhV strains (estimated as the ratio of 419 420 the maximal number of viruses produced to the maximum cell concentration reached by the specific host before cell decrease (Jaquet et al. 2002), as 16.5 for EhV-86 and 248 for EhV-421 207; thus, there was potentially over an order of magnitude difference in burst size between 422 423 the two virus strains. Although limited, these calculations suggest that differences in burst 424 size could be a critical factor in deciding the outcome of competition dynamics between virus strains. 425

426

What strategies lytic viruses such as EhVs can utilise during periods of intense competition is 427 as yet unknown, but it is clear that EhV-207 confers a competitive advantage over EhV-86 428 (ultimately affecting burst size and/or lysis rates), and the cause of such an advantage will be 429 encoded upon their respective genomes. With regards to this, EhV-207 has an extra tRNA not 430 431 found in the genome of EhV-86 and also 49 genes (of which 47 have no assigned or predicted function) that have no homologs with EhV-86. Among these are two genes predicted to 432 encode for glycosyl-transferases (data not shown). Although rare in viruses, glycosyl-433 transferase encoding genes have been previously reported in bacteriophages, poxviruses, 434 herpesviruses and baculoviruses (Markine-Goriaynoff et al., 2004). In some bacteriophages, 435 glycosyl-transferases have the ability to modify the virus DNA in order to protect it from host 436

437 restriction endonucleases, and in Chlorella viruses such as PBCV-1 they have been implicated in the synthesis of glycan components of the virus major capsid protein (Zhang et 438 al., 2007). Hence the presence of these genes could be beneficial to EhV-207 and aid in its 439 440 much increased rate of genomic assembly and capsid construction prior to release from the infected cells. It is unlikely that the genetic features unique to EhV-86 that EhV-207 does not 441 contain (i.e. genes predicted to encode for a longevity-assurance (LAG1) family protein, a 442 443 PDZ domain protein, a putative DNA-binding protein, a putative helicase, and 55 extra membrane proteins or proteins with an unknown function) act to inhibit the infection rate of 444 445 EhV-86 (data not shown), although this cannot be ruled out at this stage. Alternatively, it is possible that the phenotypic difference observed is caused by functional variation in shared 446 genetic components. 447

448

Indeed, previous studies have reported that coccolithoviruses biochemically highjack the host 449 sphingolipid biosynthesis pathway (Pagarete et al, 2009; Bidle and Vardi, 2011; Michaelson 450 451 et al, 2010) and produce virally-encoded glycosphingolipids that in turn trigger ROS (reactive oxygen species), caspase activity and PCD (programmed cell death) in the infected host cells 452 (Bidle et al, 2007; Vardi et al, 2009, 2012). The rate limiting step in this *de novo* sphingolipid 453 biosynthesis pathway is the first step in the reaction where serine palmitoyltransferase cleaves 454 palmitoyl Co-A or myristoyl Co-A with serine (Han et al, 2006; Monier et al, 2009). Recent 455 456 protein structural analysis has suggested that there is a difference in the protein fold of the SPT enzyme encoded by different coccolithoviruses, that may affect the rate and efficiency of 457 this first step in the virally-encoded sphingolipid biosynthesis pathway (Nissimov et al, 458 459 2013). These potential differences between coccolithovirus strains in viral SPT activity in the first few hours post-infection may prove to be crucial in determining which strain dominates 460 during competitive interactions such as those shown in this study. 461

Another facet that is worthy of consideration is the possibility that a single host cell was 463 simultaneously infected by both virus strains. In this case, an internal intra-cellular battle over 464 the host cellular metabolic machinery would have occurred between the two viruses. Such a 465 scenario although theoretically possible, is maybe less likely due to the mutual exclusion 466 theory proposed by Luria and Delbruck (1943) in which was suggested that a virus particle 467 that infects first a host cell alters it to the extent of which a second infection by another virus 468 is unlikely. This was indeed shown to be the case in the co-infection of *Chlorella* by two 469 closely related viruses PBCV-1 and NY-2A (Greiner et al., 2009). In this previous study, 470 infection by the PBCV-1 virus depolarised the host cell membrane to exclude further 471 472 infections by NY-2A. Genomic comparison among EhV strains (Allen et al, 2006, Nissimov 473 et al, 2011a, 2011b, 2012a, 2012b, 2014, and Pagarete et al, 2013) suggests that many genes 474 have indeed been transferred between closely related virus strains, possibly a result of coinfection and retrovirus involvement (Nissimov J., PhD thesis; 2013). Hence it is not 475 476 currently known whether mutual exclusion mechanisms such as the ones observed in Chlorella exist in coccolithoviruses, but it is worth considering and investigating further. 477 Regardless of the mechanisms involved, EhV-86 appeared to be a poor competitor to EhV-478 207 and lost the battle over infection and replication when placed into direct competition with 479 480 its intragenus opponent.

481

Finally, investigating the differences in free EhV GCN compared to the cell-associated EhV GCN revealed an aspect never previously observed in the study of coccolithovirus replication. For both EhV strains, cell-associated GCN was higher than the free GCN, suggestive that not all the newly synthesized genomes were able to be packed into virions and released from the cells. This is indicative of a nucleotide independent factor that limits the 487 burst size of these two EhV strains and ultimately the amount of new virus progeny produced. The EhV virion consists of dsDNA genomic material encased within a protein shell 488 (predominantly composed of the major capsid protein), enveloped by a lipid membrane. GCN 489 490 clearly indicates the production of genomic material is not limiting, therefore either protein production or membrane lipid availability and integrity are the likely limiting factors. The 491 latter is of particular interest considering the acquisition of the near complete pathway for the 492 synthesis of sphingolipids from the host by the coccolithoviruses, and the prominent role of 493 such lipids in the formation of membrane rafts to instigate virus release. 494

495

496 The ecological significance of the virus "fight club"

497 To date, virus-induced decline of algal populations in the natural environment are often 498 viewed as a one dimensional battle between hosts and their viruses. However the additional element of competition between viruses is fundamental when trying to predict viral-induced 499 impacts on primary productivity and the role of viruses as ecological drivers of diversity. 500 501 Although a laboratory study, the results here may also be representative of natural systems, where indeed there is mounting evidence that such processes occur. For instance, natural 502 coccolithophore assemblages in the North Sea, Norwegian fjords, English coast, and the vast 503 Atlantic Ocean, were characterised by extremely numerous and diverse co-occurring 504 coccolithovirus communities (Wilson et al., 2002; Martinez et al., 2007, 2012, Rowe et al, 505 506 2011, Nissimov et al, 2013). In a recent mesocosm experiment in the Norwegian fjord (Sorensen et al., 2009), it was observed that the number of distinct EhV genotypes decreased 507 with the propagation of an E. huxleyi infection; i.e. early on during the development of the 508 509 bloom the EhV community was more diverse, and there were more distinct EhV genotypes (detected by DGGE) than towards the end of the bloom (Martinez et al, 2007, 2012; Sorensen 510 et al, 2009). Hence the dominance of certain coccolithovirus strains over others will be a 511

512 direct consequence of competitive interactions and the specific phenotypic characteristics manifested during host-virus infection dynamics. Depending on the virus strain type/s present 513 in a particular environment and its/their succession over other virus strains, such variation in 514 phenotypic characteristics will affect the overall propagation of an infection, its outcome with 515 regards to the demise of the host population, and subsequently the rates of carbon and 516 nutrient recycling (Wilhelm and Suttle, 1999). Thus if we exclude other factors such as 517 grazing and nutrient limitation from the equation, the ecological significance under the 518 described scenario (i.e. EhV-207-like viruses dominating) would be a localised short-time 519 520 rapid increase in the rate of carbon export and recycling of nutrients, but a reduced overall carbon and nutrient export, as the host population growth would be rapidly diminished. 521 Alternatively, if EhV-86-like genotypes were to be hypothetically the "winners" of these 522 523 competitive interactions, then this would have resulted in slower infection kinetics which would have allowed the host population to reach higher densities, resulting in a greater total 524 amount of carbon and nutrient re-circulation, over a longer time scale. Ultimately, in a 525 changing marine environment it is important to understand both the phenotypic and genotypic 526 diversity changes that occur within a microbial community and how these changes affect 527 globally important ecological and biogeochemical processes. 528

529

The evolutionary significance of intragenus virus competition is the fuelling of the coevolutionary arms race between the host and its virus. During the described competition scenario, if the two strains were the only ones present in a given environmental niche, then an increase in the fitness of EhV-207 would have resulted in the decrease in fitness of EhV-86 to the point of its extinction or near extinction. Viruses possessing these phenotypes, will infect the most active coccolithophore species and/or strains in consistence with the "killing the winner" hypothesis (Thingstad and Lignell, 1997, Winter et al. 2010), essentially

transforming the host "winners" to "losers" with time. Then, the new host "winners" will 537 most likely be a sub-population that is resistant to EhV-207-like strains but possibly more 538 sensitive to EhV-86-like strains (or other similarly low activity genotypes that have optimal 539 infection strategies for these new host "winners"). This fits within the "virus-host stable co-540 existence" theory in which was hypothesised the phenotypic plasticity of the algal hosts and 541 their ability to recover post-virus infection, is what makes the co-existence of these hosts and 542 543 their viruses possible, both on short and also on evolutionary time scales (Thyrhaug et al. 2003). 544

545

The emergence of novel viruses with niche-specific characteristics for infection, are to a large 546 extent, a result of these competitive interactions. For instance, in plants, the occurrence of 547 548 more than one RNA virus and their environmental association with their host is common (Roossinck, 2005). If these viruses are similar to one another then they will be in direct 549 competition, whilst if they are not similar then they will not be. Indeed it was shown that 550 plant RNA virus evolution occurs due to "survival of the fittest" scenario, during which 551 closely related viruses increased the positive selection of some of these viruses over others 552 (Roossinck and Palukaitis, 1995). Thus, the competitive interactions between the closely 553 related coccolithoviruses EhV-86 and EhV-207 may not only drive the fitness and evolution 554 555 of their hosts, but also their own.

556

The competitive interactions displayed here by coccolithoviruses raise exciting questions with regards to the ability of these different strains to evolve strategies for the utilisation of new resources; i.e. the infection of a new host. Recently it was shown that resource competition between bacteriophages (i.e. competition over host availability for infection and replication) promoted the evolution of novel bacteriophage phenotypes with the ability to tillise new hosts, suggesting that this sort of competition was essential for driving the evolution of host range expansion (Bono et al., 2013). Although coccolithoviruses are fundamentally different from bacteriophages with regards to their rate of mutation (much slower), a similar resource competition over a larger time scale may explain the large range of susceptible infectious hosts to some coccolithovirus strains (personal observations).

567

568 Furthermore, resource expansion depends most likely also on whether a virus is an r or a K strategist, and the type of trade-offs adapted by viruses and their hosts; a concept that has 569 570 been applied recently to viruses from the classical life history theory (De Paepe and Taddei, 2006, Winter et al, 2010,). The question of whether a particular virus strain is an r strategist, 571 whereby able to quickly utilize its resource in order to produce abundant virus progenies 572 573 (usually characterised by a lower percentage of potent virus particles and therefore poor 574 competitors); or a K strategist, whereby the emphasis is on fewer but highly potent, competitive virus progenies, remains to be seen. Based on the classical description of K and r 575 576 selection theory one would have expected that EhV-86 would have been a better competitor than EhV-207 as it is characterised by slower multiplication rates. However it appears that 577 the latter is a stronger competitor that utilises the available resources quicker and produces a 578 larger number of progeny. Hence both viruses studied here, under optimal conditions, employ 579 580 aspects of both an R and a K specialist. However, additional factors such as the potential 581 trade-off between high multiplication rates and increased virion decay rates (De Paepe and Taddei, 2006), should also be considered in future studies, particularly under resource-582 limiting conditions. 583

584

585 CONCLUSIONS

586 Whether a particular coccolithovirus strain (and all its associated genomic, proteomic, and metabolomic characteristics) will proliferate, is determined by its ability to co-evolve with 587 one or more host genotypes and outcompete other viruses less fit in a particular environment. 588 One can only imagine the complexity of the interactions described here in naturally occurring 589 blooms where at any given time there are many different coccolithophore genotypes (and 590 subsequently phenotypes) and an even larger number of distinct coccolithoviruses, often 591 experiencing annual variable environmental conditions. The dominance of a select few virus 592 genotypes at the end of a bloom or an infection event is a paradox of which the drivers still 593 594 remain anonymous. However specific characterisation of coccolithovirus genotypes and phenotypic interrogation of their infection dynamics, in tandem with the analysis of their 595 phylogenetic history and functional biodiversity, can shed new light on coccolithovirus 596 597 evolution and ultimately their role in microbial oceanography.

598

599 ACKNOWLEDGMENTS

This work was funded by the NERC Oceans 2025 program, Plymouth Marine Laboratory's Research Program, and a NERC PhD grant awarded to JIN, co-supervised by the Plymouth Marine Laboratory and the University of Nottingham in the UK. We would like to acknowledge Dr. Simon Thomas for providing initial assistance during the qPCR part of the experiments, and also Paul Rooks and Mark Jones for always making sure that the work was conducted in a suitable, tidy and organized environment.

Fig. 1. *Emiliania huxleyi* CCMP 2090 average cells mL⁻¹ (triplicates ±SD) following
infection by EhV-86 (red line) EhV-207 (blue line), and combined EhV-86 and EhV-207
(green line). Control cultures containing inactivated viruses are shown by theblack line. The
first measurements of the host cultures taken one day before the addition of the virus stocks
(i.e. t -24 h).

- . . .

Fig. 2. Flow cytometry plots of red (chlorophyll) fluorescence versus side scatter at 0 h and
168 h during the time course experiment for infected (EhV-86, EhV-207 or combined EhV86&EhV-207 co-infected) and control *Emiliania huxleyi* cultures.

Fig. 3. Average density mL⁻¹ of EhV-86 (red line), EhV-207 (blue line), and combined EhV86&EhV-207 (green line) during the time-course experiment. Data points represent triplicate
measurements (±SD). The abundance of free EhVs was enumerated using AFC (green
fluorescence *vs* side scatter).

Fig. 4. EhV-86 (A) and EhV-207 (B) virus copy number averages (triplicates ± SD) from *Emiliania huxleyi* cultures infected with either EhV-86 (single infection), EhV-207 (single
infection) or combined EhV-86&EhV-207 (combined infection), 12 h, 24 h, 48 h and 168 h
post infection; performed with qPCR strain specific primers for the discrimination of one
coccolithovirus strain from the other.

Table S1.Virus treatments A-G and their initial volume* at the beginning of the experiment (t0). Each treatment was performed in triplicate (i.e. a total of 21 flasks; 12 containing *E. huxleyi* CCMP 2090 at a cellular density of 1.5×10^6 mL⁻¹). + indicates the presence of EhV-86, EhV-207, or host in a given flask, – indicates inactivated virus.

Flask n°	Volume of f/2 media (mL)*	EhV-86	EhV-207	<i>E.huxleyi</i> host	Experimental treatment
1	100	+		+	
2	100	+		+	А

**Fig. S1.** Gel electrophoresis of PCR products conducted with primers specific to EhV-86 and EhV-207. The products are amplified regions from lysates taken from three different culture conditions: EhV-86 infected host (A), EhV-207 infected host (B), and host infected simultaneously by both EhV-86 and EhV-207 (C). In the last two lanes to the right (top and bottom) are the control DNA free water samples.

Fig. S2. Calibration curve for the qPCR amplification of known amounts of purified DNA of
EhV-86 (ehv290) and EhV-207 (EQVG00465). CT= cycle number, (log CO= known
concentrations of purified EhV-86 (A) and EhV-207 (B) DNA products.
