ABSTRACT

PURPOSE: The primary outcome of this study is to compare axial length growth of white European myopic children wearing orthokeratology contact lenses (OK) to a control group (CT) over a 7-year period.

METHODS: Subjects 6-12 years of age with myopia -0.75 to -4.00DS and astigmatism ≤1.00DC were prospectively allocated OK or distance single-vision spectacles (SV) correction. Measurements of axial length (Zeiss *IOLMaster*), corneal topography and cycloplegic refraction were taken at 6-month intervals over a 2-year period. Subjects were invited to return to the clinic approximately 5 years later (i.e. 7 years after the beginning of the study) for assessment of their ocular refractive and biometric components. The CT consisted of 4 SV and 12 subjects who switched from SV to soft contact lens wear after the initial 2-years of SV lens wear. Changes in axial length relative to baseline over a 7-year period were compared between groups.

RESULTS: Fourteen and 16 subjects from the OK and CT groups, respectively were examined 6.7±0.5 years after the beginning of the study. Statistically significant changes in axial length were found over time and between groups (both $p<0.001$), but not for the time*group interaction ($p=0.125$). The change in axial length for the OK group was 22% ($p=0.328$), 42% ($p=0.007$), 40% ($p=0.020$), 41% ($p=0.013$) and 33% ($p=0.062$) lower than the CT group following 6, 12, 18, 24 and 84 months of lens wear, respectively.

CONCLUSION: A trend towards a reduction in the rate of axial elongation of the order of 33% was found in the OK group in comparison to the CT group following 7-years of lens wear.

Key words: myopia control, orthokeratology, axial length, myopia progression, long-term efficacy

INTRODUCTION

Globally, uncorrected refractive errors represent the second major cause of vision loss[1] of which myopia is the most common and distinctive in that its prevalence has increased substantially in recent decades. To date, it has been estimated that myopia currently affects approximately 30% of the world's population,[2, 3] although a significant increase to affect around 50% of the world's population by 2050 has been forecast.[2] The prevalence of myopia in young adolescents is also increasing and has approached around 25% and up to 98% in industrialized societies of the West and East Asia, respectively.[3] Of particular concern is that relatively low degrees of myopia may be associated with increased risk of ocular complications, such as vitreous and chorioretinal detachment, macular degeneration, and glaucoma all of which can increase the risk of vision loss.[4–7] Furthermore, myopia incurs substantial expenditure such that in the USA, the annual cost for eye examinations and corrections by spectacles and contact lenses has been estimated to be between $2 and $5 billion.[8, 9] Therefore, finding effective therapies to slow the progression of myopia could potentially benefit millions of individuals and save on substantial healthcare expenditure worldwide.

Several optical treatment options have been used in the past with limited success to eliminate or, at least, reduce myopia progression in children.[10-12] Of these, orthokeratology (OK) contact lens wear appears to be one of the most effective as it has consistently been shown to reduce the axial elongation of the eye by 30 to 50% in comparison with conventional single-vision spectacle (SV) and soft contact lens (SCL).[13-18] Most previous studies have demonstrated reduced rates in axial elongation over 2 years of OK lens wear. A recent meta-analysis study reported that the pooled reduction in axial elongation declined with time, with 55, 51, 51, and 41% obtained after 6, 12, 18, and 24 months of OK lens wear, respectively.[19] However, little is known about the efficacy of OK lens wear in reducing the rate of axial elongation for longer periods of lens wear. Two retrospective studies have shed some light on the latter.[20, 21] Kwok-Hei Mok and Sin-Ting Chung compared changes in myopia over a 7-year period between 34 children with a mean age at baseline of 9 years wearing OK and 36 children with a mean age at baseline of 10 years wearing SV.[20] Determination

99   of the final refractive error of the OK lens wearing subjects was conducted by

100   the washout period method, whereby subjects were refracted after not wearing

101   the lenses for a period of time until the flatter corneal meridian reverted to its

102   pre-OK levels.[20] It took a mean (± standard deviation) of 25.5±1.0 (range 22–

103   29) days for the central flat corneal curvature to return to pre-OK levels.

104   Average myopic progression for the OK group (−0.37±0.49D) was significantly

105   lower than that found for the SV group (−2.06±0.81D) following 7-years of lens

106   wear.[20] Downie and Lowe compared the progression rate of manifest refractive

107   prescription in myopic children under the age of 16 years between 26 OK lens

108   wearers and 30 age- and refraction-matched SV wearers in 2 yearly intervals

109   over a period up to 8 years.[21] The study found that OK wearers showed a

110   significantly more stable myopic refractive prescription than SV over all of the 2-

111   year treatment intervals, indicating that OK can reduce the rate of progression

112   of childhood myopia over the long term.[21] Furthermore, a subpopulation of OK

113   lens wearers (64%) demonstrated an apparent total arrest of manifest myopic

114   refractive change.[21] Although the above two studies have provided preliminary

115   evidence for the long-term efficacy of OK contact lens wear in reducing the

116   progression of myopia their limitations are retrospective study designs, non-

117   randomization of subjects to study groups and the use of non-cycloplegic

118   refractions as primary outcome measures. Furthermore, neither of the studies

119   measured axial length, the key structural correlate of myopic progression in OK-

120   treated eyes.[22] Hiraoka et al. compared changes in axial length between 22 OK

121   and 21 SV Japanese lens wearers with a mean age at baseline of 10 years

122   over a period of 5 years.[23] The study found statistically significant reductions in

123   the annual increases in axial length in the OK group compared with the SV

124   group for the first, second, and third years, but not for the fourth and fifth

125   years.[23]

126

127   We have previously reported the results of the Myopia Control with

128   Orthokeratology contact lens in Spain (MCOS) study which evaluated

129   differences in growth of axial length over a 2-year period in white European

130   children with myopia wearing OK and SV.[17] We found a statistically significant

131   difference in axial length elongation relative to baseline between the OK

132   (0.47±0.18mm) and SV (0.69±0.32mm) groups (p=0.005).[17] Approximately 5

133   years after completion of the MCOS study, subjects were contacted by
134   telephone and invited to return to the clinic for evaluation of their ocular
135   refractive and biometric parameters. The purpose of this study is to compare, as
136   the primary outcome measure, differences in growth of axial length over a 7-
137   year period between white European myopic children wearing OK and a control
138   group (CT) wearing SV or SCL. Additionally, refractive and biometric changes in
139   subjects who switched corrections were also evaluated.

METHODS

This study was part of a larger study designed to assess different aspects of OK lens wear specifically prescribed for the control of myopia progression in children.[17, 24-27] The methods employed in MCOS have been described in detail elsewhere.[17, 24] In brief, normal, healthy white European subjects 6 to 12 years of age with moderate levels of mean spherical myopia (-0.75 to -4.00D) and astigmatism (≤1.00D) and free of systemic or ocular disease were fitted with Menicon Z Night contact lenses for overnight use (Menicon Co., Ltd, Nagoya, Japan). An OK fit was considered to be successful if the subject showed a CCLRU score regarding anterior eye segment signs ≤ 1 unit, a "bull's eye" corneal topography pattern and monocular and binocular visual acuities within ±1 line of the best-correct spectacle visual acuity. All subjects underwent ocular examinations including slit-lamp examination, manifest refraction, and corneal topography at baseline and at 6-month intervals over a 2-year period. Follow-up visits were scheduled to fall within 2 hours of awakening in order to measure subjective refraction and visual acuity without the lens on the eye. A decrease in one line of visual acuity accompanied by a change in subjective refraction at any of the follow-up visits was considered clinically significant and was remedied by supplying new contact lenses. Approximately 5 years after completion of the MCOS study, subjects were contacted by telephone and invited to return to the clinic for evaluation of their ocular refractive and biometric parameters. The study was conducted in accordance with the Tenets of the Declaration of Helsinki and approved by the Institutional Ethical Committee Review Board of Novovision Ophthalmology Clinic (Madrid, Spain). Full informed consent and child assent was obtained in writing from the parents/guardians prior to the start of all experimental work and data collection. Patient participation in the study could be discontinued at the examiner's discretion should significant symptoms or slit-lamp findings occur. Subjects were instructed they could withdraw from the study at any time.

Cycloplegic auto-refraction was performed following the instillation of three drops of cyclopentolate HCl 1% separated 10 min apart in each of the subjects' eyes using a multidose bottle (Alcon Cusí, Masnou, Barcelona, Spain). Ten minutes after the instillation of the third drop, three auto-refraction

178 measurements were taken and a mean obtained (Topcon RM 8000B, CA,
179 USA).

180

181 Measurements of axial length were taken with the Zeiss *IOLMaster* (Carl Zeiss
182 Jena GmbH).[28] Three separate measurements of axial length were recorded
183 and a mean obtained.

184

185 Corneal topography measurements were performed with the Wavelight Allegro
186 Topolyzer (WaveLight Laser Technologies AG, Erlangen, Germany). The
187 instrument incorporates a high resolution placido-ring corneal topographer
188 which detects 22,000 elevated data points of measurement from 22 ring edges
189 with a claimed accuracy and reproducibility of ± 0.10D according to the
190 manufacturer. The first measurement taken for each eye, which provided an
191 optimum index value according to the manufacturer's recommendations, was
192 used for the study. The measurement generates a simulated central
193 keratometry reading and the rate of peripheral corneal flattening/steepening that
194 occurs with displacement from the corneal apex; the latter indicates the degree
195 to which an aspheric surface differs from the spherical form (i.e., the p value).
196 The p value was calculated over a 7-mm chord in accord with the default setting
197 of the instrument.

198

199 **Statistical analysis**
200 Differences in subjects' demographics and baseline data between groups were
201 tested using unpaired sample t-tests for all variables, except for the male:female
202 ratio which was tested using a chi-square test. Changes (from baseline) in
203 refractive and biometric data over time and between groups (i.e. OK vs. CT)
204 were tested using a general linear model (GLM) with repeated measures to test
205 the statistical significance of differences in outcome variables (i.e. axial length,
206 spherical and cylindrical refractive components, corneal power and corneal
207 shape) for the between-subject factor of refractive correction (two levels: OK
208 and CT) and for the within-subject factor of time (five levels: 6, 12, 18, 24 and
209 84 months). The significance of the interaction between OK and CT with respect
210 to time was then tested for all time intervals combined and then separately for
211 each of the five time intervals following post hoc Bonferroni correction. GLM

212 with repeated measures was also used to test the effect of switching treatments
213 from OK to SCL. Additionally, an unpaired sample t-test was used to test, for
214 each time point, differences between the groups in refractive and biometric
215 variables. Equality of variances and sphericity were tested using the Levene
216 and Mauchly tests respectively to select appropriate p-values. Additionally,
217 simple linear regressions between the change in axial length at 7-years relative
218 to baseline and baseline age, mean spherical equivalent refractive error, axial
219 length, mean central corneal power and corneal shape factor were calculated
220 for the OK and CT groups separately. Differences between groups in the slopes
221 of the regression lines were compared using an analysis of covariance. The
222 strength of association between the different factors is summarized using linear
223 regression equations, R^2 squared values and p-values. Data are expressed as
224 mean ± 1 standard error of the mean (SEM). Data from right eyes only were
225 used for analysis. Statistical analyses were performed with *IBM SPSS Statistics*
226 (IBM Corp., Ver. 22, NY, USA) and graphing with *SigmaPlot* (Systat software
227 Inc, California, USA). The level of statistical significance was set at 5%.

243 **RESULTS**

244 At the inception of MCOS sixty-nine subjects were examined for eligibility: 8

245 subjects were not eligible to participate and 31 and 30 children were

246 prospectively allocated to OK and SV, respectively (Figure 1). Twenty-nine and

247 24 subjects from the OK and SV groups, respectively, thus completed the initial

248 2 years of the MCOS study. Seven subjects were subsequently lost to follow-

249 up in each group and no further information was able to be collected from these

250 subjects leading to a total of 39 subjects of the original cohort available for

251 review at the 7-year visit. Of these, 14 and 4 remained in their original OK and

252 SV lens wear categories, respectively. In addition, twelve of the 39 subjects

253 switched to standard SCL wear after 2 years of SV lens wear which thus

254 constituted a control group (CT) of 16 subjects (i.e. 4 SV + 12 SCL). Nine

255 subjects switched lens wear category and the effect of which was assessed

256 separately (see subheading below) (Figure 1).

257

258 **Long-terms effects in the OK and CT groups**

259 The OK and CT groups were followed for 6.9±0.1 and 6.5±0.1 years,

260 respectively; this difference was statistically significant (p=0.001). Subjects

261 reported inserting and removing their OK lenses every night and morning,

262 respectively. None of the subjects from the OK group reported cessation of lens

263 wear for any significant periods of time over the entire 7-year period of OK lens

264 wear. Furthermore, all subjects reported 0.9 uncorrected decimal visual

265 acuities (equivalent to 0.05 logMAR or >20/25) at the 7-year visit. The

266 incidence, type and timeline of adverse events found over the initial 24 months

267 of the study have been previously reported.[25] At the 84-month visit, all subjects

268 underwent a thorough ophthalmic examination and no remarkable adverse

269 events were found. Furthermore, none of the subjects reported any significant

270 complications in the last 5 years of lens wear. The 12 subjects who switched to

271 standard SCL wear after 2 years of SV lens wear and who became part of the

272 CT group worn SCL for 2.5±0.4 years prior to the 7-years visit. No statistically

273 significant differences between the OK and CT groups were found in any of the

274 baseline demographics and refractive and biometric data (Table 1).

275

276 Statistically significant changes were found in axial length both over time and
277 between groups (p<0.001), but not for the time*group interaction (p=0.125)
278 (Figure 2 and Table 2). Changes over time were statistically significant for all
279 pairs of time points (all p≤0.001) (Figure 2 and Table 2). In comparison to the
280 CT group, the change in axial length for the OK group was 22% (p=0.328), 42%
281 (p=0.007), 40% (p=0.020), 41% (p=0.013) and 33% (p=0.062) lower following 6,
282 12, 18, 24 and 84 months of lens wear, respectively (Figure 2 and Table 2).
283

284 Statistically significant differences were also found in the spherical component
285 of the refraction over time, between groups and for the time*group interaction
286 (all p<0.001) (Table 2). Statistically significant differences between time points
287 were found between 6- and 12-, 18-, 24- and 84-months (all p<0.01); between
288 12- and 84-months (p=0.002); between 18- and 24- and 84-months (both
289 p<0.001); and between 24- and 84-months (p<0.001) (Table 2). Statistically
290 significant differences were found between groups at all the different time points
291 (p<0.001) (Table 2). However, no statistically significant differences were found
292 in the cylindrical component of the refraction over time, between groups or for
293 the time*group interaction (p>0.05) (Table 2).
294

295 Statistically significant differences were found in corneal power over time (both
296 p<0.001) and between groups (both p<0.001), but not for the time*group
297 interaction (both p>0.05) for both the flatter and steeper meridians (Table 2).
298 Significant differences were found for pairs of time points between 6-, 12-, 18-,
299 24- and 84-months for both meridians (all p≤0.02) (Table 2). Significant
300 differences were also found between groups in corneal power at all time points
301 for both meridians (all p<0.001) (Table 2). However, no significant differences
302 were found in the corneal shape (i.e. corneal p-value) over time, between
303 groups or for the time*group interaction (all p>0.05) (Table 2).
304

305 Univariate linear regression analysis revealed that the older the age at baseline
306 the smaller the axial elongation at 7-years in both study groups, although the
307 relationship was statistically significant for the CT (R^2=0.274, p=0.022), but not
308 for the OK group (R^2=0.142, p=0.101). The effect of baseline age on axial
309 elongation was, however, similar between groups (p=0.208) (Figure 3 and

310 Table 3). Greater corneal powers at baseline were associated with smaller
311 increases in axial length in the OK group (R^2=0.290, p=0.027), but no significant
312 relationship was found for the CT group (R^2=0.000, p=0.817) (Figure 4 and
313 Table 3). Furthermore, statistically significant differences were found between
314 groups in the slopes of the regression lines (p=0.044) (Figure 4 and Table 3).
315 No significant relationships were found between the change in axial length at 7-
316 years in comparison to baseline and baseline mean spherical equivalent
317 refractive error, axial length and corneal shape for either the OK or CT groups
318 (Table 3). In addition, no statistically significant differences were found between
319 groups in the slopes of the regression lines for either spherical equivalent
320 refractive error, axial length or corneal shape (all p>0.05) (Table 3).

321

322 **The effect of switching treatments**
323 Following 2 years of OK lens wear, eight subjects (4 male and 4 female)
324 switched from OK to SCL 1.7±0.5 years (range 0.2 to 3.9 years) thereafter and
325 wore SCL for the last 3.3±0.5 years (range 1.3 to 5.3 years). A trend was found
326 for increased time of SCL wear to be associated with shorter increases in axial
327 length (Figure 5). The reasons for switching from OK to SCL were (number of
328 subjects): expensive treatment (4), recurrent punctate keratitis (2) and concerns
329 regarding regression (1) and efficacy (1). These subjects had mean ages of
330 9.3±0.4, 11.4±0.4 and 16.4±0.5 at baseline, following 2 years of OK lens wear
331 and at the 7-years study visit, respectively. On average, axial length increased
332 by 0.57±0.06mm during the initial 2 years of OK lens wear and by 0.80±0.16mm
333 on the subsequent 5 years (Table 4), although there was large between-subject
334 variability (Figure 6). As expected, the increase in axial length following
335 cessation of OK lens wear was associated with an increase in myopia, a
336 steepening of corneal curvature and a more prolate corneal shape (Table 3). In
337 comparison to the CT group (Table 2), these subjects experienced mean
338 reductions in the rate of axial elongation of 47%, 30%, 22% and 19% following
339 6, 12, 18 and 24 months of OK lens wear, respectively (Tables 2 and 4).
340 However, when these subjects switched from OK to SCL the rate of axial
341 elongation observed at 84 months in comparison to the CT group was -1%,
342 indicating the effect of OK lens wear in reducing the rate of axial elongation is
343 negligible with discontinuation of lens wear (Tables 2 and 4). One male subject

344   switched from SV to OK lens wear immediately after the initial 2 years of SV

345   lens wear and wore OK lenses for the following 5 years. The reason for

346   changing to OK was to reduce the rate of myopia progression. In this subject,

347   axial length increased by 0.81mm during the initial 2 years of SV lens wear, but

348   only by 0.35mm in the following 5 years of OK lens wear (Table 4).

349

350

351 **DISCUSSION**

352 This study assessed the long-term efficacy of OK lens wear in reducing the rate

353 of axial elongation over a period of as long as 7 years in White European

354 subjects. The significant reduction in manifest myopia and the rate of myopia

355 progression found in the OK group after initial lens wear remained throughout

356 the 7-year period and is primarily attributed to the corneal reshaping effect

357 induced by OK contact lens wear and the resultant change in corneal power

358 and shape (Table 2). The CT group, however, showed an average increase in

359 myopia of 2.84D accompanied by negligible changes in corneal power and

360 shape (Table 2).

361

362 Of interest is the finding of a trend towards a reduction in the rate of axial

363 elongation of the order of 33% in the OK group in comparison to the CT group

364 following 7-years of lens wear (Figure 2 and Table 2). Interestingly, a study

365 estimated that reducing the rate of myopia progression by 33% would lead to a

366 reduction of 73% in the frequency of high myopia (<-5.00D);[29] such reduction

367 could therefore have important implications in terms of reducing ocular-related

368 morbidity[7] and healthcare costs.[8, 9]

369

370 Despite differences in corneal topography and contact lens-induced responses

371 between Caucasian and Japanese ethnicities have been previously reported,[30,

372 31] our results are similar to those reported by Hiraoka et al.[23] We found OK to

373 reduce the rate of axial elongation by 33% after 7 years of lens wear, whereas

374 Hiraoka et al. found OK to reduce the rate of axial elongation by 31% after 5

375 years of lens wear.[23] The study of Hiraoka et al. was performed in Japanese

376 subjects using one particular OK contact lens design (i.e. αOrtho-K; Alpha

377 Corp., Nagoya, Japan),[23] whereas the present study was undertaken in White

378 European subjects using a different OK lens design (i.e. Menicon Z Night,

379 Menicon Co., Ltd, Nagoya, Japan). Interestingly, our results also agree with

380 those of Hiraoka et al. in that the benefit of OK in reducing the axial elongation

381 of eye diminishes with longer periods of lens wear.

382

383 The reduced efficacy of myopia control with long periods of lens wear found in

384 this study may be attributed to the natural history of myopia progression, in

385 which there is a reduced rate of axial elongation with increased age, thereby
386 making it more difficult to find significant differences between groups in axial
387 length over longer periods of lens wear (Figures 2 and 3, and Table 2). In fact,
388 the increases in axial length over the first 24 months of this study were
389 remarkably similar to those found between 24 and 84 months for both the OK
390 (0.42±0.05 and 0.39±0.04mm, respectively) and the CT (0.71±0.10 and
391 0.65±0.11mm, respectively) groups, clearly indicating a decrease in the rate of
392 axial elongation regardless of the visual correction being worn (Figure 3 and
393 Table 2). It is well established that older age is associated with smaller
394 increases in myopia and axial elongation. Furthermore, it has been previously
395 reported that myopia stabilizes at around 16 years of age.[32] Subjects in this
396 study had mean ages of 10 and 12 years at baseline and following 2 years of
397 OK lens wear, respectively. Therefore, a reduced rate of myopia progression
398 would be expected on these subjects during the subsequent 5 years of data
399 collection.

400

401 Greater corneal power was found to be associated with smaller axial elongation
402 in OK wearers (Figure 4). Following OK lens wear, a steeper cornea is likely to
403 provide a smaller treatment zone of central corneal flattening[33] and a wider
404 peripheral ring of increased corneal power. Therefore, it is feasible that a
405 steeper cornea facilitates corneal reshaping and reduction in axial elongation
406 following OK lens wear.[12, 26]

407

408 The large variability in the increases in axial length found in the 8 subjects who
409 discontinued OK lens wear at 2-years and switched to SCL wear could be
410 attributed to the length of time that SCLs were worn after ceasing OK lens wear
411 (Figure 5), individual differences and differences in the power profile between
412 the different SCLs worn (Figure 6).[34] In any event, the results found on the
413 effect of switching treatments appear to be consistent with those found in the
414 OK and CT groups over the 7-year period in that the efficacy of OK diminishes
415 and resumes with discontinuation and restoration of OK lens wear, respectively.

416

417 A limitation of this study is the potential bias introduced by subjects' self-
418 selection to continue wearing OK, SV or SCL. However, the major limitation

419 concerns the relatively small sample size employed in this study. The overall
420 power to detect between-subjects differences (i.e. OK vs. CT) in the general
421 linear model employed in our study was P=0.68 (*IBM SPSS Statistics*).
422 However, the power varied at each of the different time points, being lowest at
423 the 6- (P=0.16) and 84-month visits (P=47) and highest at the 12- (P=0.81), 18-
424 (P=0.76) and 24-month visits (P=0.73), indicating that the relatively low
425 statistical power found at the 84-month visit is not only related to the sample
426 size employed but also to the large variability in changes in axial length in both
427 the OK (0.91 ± 0.63 mm) and CT (1.36 ± 0.63 mm) groups. Taking the standard
428 deviation of the change in axial length (0.63) and the difference in axial length
429 found between groups at the 84-month visit (0.45 mm), a sample size of 32
430 subjects per group would be needed for a designated statistical power of 0.80
431 at alpha = 0.05. Despite the above-mentioned limitations, our study offers
432 notable features such as being the first study to assess the efficacy of OK lens
433 wear in White European subjects in reducing the rate of axial elongation over a
434 period of as long as 7 years. In addition, the study measures changes in axial
435 elongation over the entire follow-up period with the *IOLMaster*, a partial
436 coherence interferometer well known to provide excellent resolution and
437 repeatability.[28] Nonetheless, randomized, controlled, clinical trials are warranted
438 to confirm the findings of this study.

439

440 In summary, a trend towards a reduction in the rate of axial elongation of the
441 order of 33% was found with long-term OK lens wear in comparison to SV and
442 SCL wearers over a period of 7 years. The reduction observed over time in the
443 efficacy of OK lens wear in slowing the axial elongation of the eye might be
444 partly attributed to axial length (and myopia) stabilization as children approach
445 the teenage years.[32] Reducing myopia progression has important implications
446 in terms of reducing ocular-related morbidity[7] and healthcare costs.[8, 9]
