3 **Abstract**  
4  
5

6 The human ribcage expands and contracts during respiration as a result of the interaction  
7  
8 between the morphology of the ribs, the costo-vertebral articulations and respiratory muscles.  
9  
10 Variations in these factors are said to produce differences in the kinematics of the upper thorax  
11 and the lower thorax, but the extent and nature of any such differences and their functional  
12 implications have not yet been quantified. Applying geometric morphometrics we measured  
13  
14 402 three-dimensional (3D) landmarks and semilandmarks of 3D models built from computed  
15 tomographic scans of thoraces of 20 healthy adult subjects in maximal forced inspiration (FI)  
16 and expiration (FE). We addressed the hypothesis that upper and lower parts of the ribcage  
17 differ in kinematics and compared different models of functional compartmentalization. During  
18 inspiration the thorax superior to the level of the sixth ribs undergoes antero-posterior  
19 expansion that differs significantly from the medio-lateral expansion characteristic of the thorax  
20 below this level. This supports previous suggestions for dividing the thorax into a pulmonary  
21 and diaphragmatic part. While both compartments differed significantly in mean size and shape  
22 during FE and FI the size changes in the lower compartment were significantly larger.  
23  
24 Additionally, for the same degree of kinematic shape change, the pulmonary thorax changes  
25 less in size than the diaphragmatic thorax. Therefore, variations in the form and function of the  
26 diaphragmatic thorax will have a strong impact on respiratory function. This has important  
27  
28 implications for interpreting differences in thorax shape in terms of respiratory functional  
29 differences within and among recent humans and fossil hominins.

3 **1. Introduction**  
4

5 The human ribcage expands and contracts during breathing as a result of rib motion and the  
6 interaction between the curved ribs, their sternal connections, the anatomy and actions of the  
7 respiratory muscles and the ranges of movement at the costo-vertebral joints (Beyer et al.,  
8 2014; Ratnovsky et al., 2008). Two different patterns of ventilatory rib motion are commonly  
9 described, a “pump handle-like” movement of the upper ribs, and a “bucket handle-like”  
10 movement of the lower ribs (Beyer et al., 2014; Franciscus and Churchill, 2002; West 2012).  
11 Additionally, a “caliper-like” motion has been ascribed to the lowest two (Chila, 2010) or lowest  
12 five ribs (Magee, 2014). However, the impact of these movements on functional changes of the  
13 size and shape of the skeletal thorax during respiration are unclear.

So far, functional studies of thoracic breathing kinematics have focused mainly on external chest wall movements. These studies found that the diaphragm and the lower thorax contribute considerably more to changes in thoracic volume during breathing than the upper thorax (LoMauro et al., 2012; Romei et al., 2010; Silvattia et al., 2012).

A recent *in vivo* 3D kinematic analysis of rib motion in the skeletal thorax suggested that the traditional dichotomy of “bucket handle” and “pump handle” rib rotations applies simultaneously to all levels (Beyer et al., 2014). But how do rib rotations contribute to differences in 3D size and shape changes of the entire thorax during breathing? What are the functional implications of kinematic shape changes of the thorax?

A given rib rotation will have a different effect on thoracic movement when carried out by flatter and straighter ribs than by more curved ribs with greater torsion. Consequently, because curvature and torsion differ among ribs of the upper and lower regions of the thorax (García Martínez et al., 2016), during inspiration the kinematic transformations experienced by these regions should also differ. This is not only important for breathing function in recent humans, but also in fossil hominins. Recent research and discoveries increasingly demonstrate the

1  
2  
3 enormous 3D variation in curvature, torsion and size of fossil hominin ribs (Gómez Olivencia et  
4 al. 2009; Schmid et al., 2013; García Martínez et al., 2014; Bastir et al., 2015; Berger et al., 2013,  
5  
6 Tawane et al., 2016).  
7  
8

9  
10 Consequently, there is a need to better understand the 3D kinematic changes in thoracic size  
11 and shape that occur during breathing in healthy subjects, and the functional significance of  
12 such variations. Such knowledge will be of use in relation to interpreting evolutionary  
13 transformations in rib size and shape in our own lineage and has the potential to be applicable  
14 in clinical contexts, e.g. lung disease, ribcage pathologies etc.  
15  
16  
17  
18  
19  
20  
21

22 From a skeletal point of view, the ribs are conventionally classified into true ribs (1-7), false ribs  
23 (8-10) and floating ribs (11, 12) (Waldeyer and Mayet, 1987; Drake et al., 2010; White et al.,  
24 2011). Comparative ontogenetic study has also shown that growth trajectories of true ribs (1-7)  
25 are similar to each other, and differ from those of lower ribs (García-Martínez et al., 2016).  
26  
27  
28

29 However, within the non-floating ribs (ribs 1-10) recent studies (Bastir et al., 2013) have divided  
30 the thorax into an upper (ribs 1-5), and a lower unit (ribs 6-10). Additionally, it has been  
31 suggested that the first five thoracic vertebrae (T1-T5) and their costo-vertebral joints show a  
32 different pattern of serial morphological shape changes than the lower ones (T6-T10) (Bastir et  
33 al., 2014).  
34  
35  
36  
37  
38  
39  
40

41 From a musculo-skeletal point of view, the thorax has been divided into a pulmonary ribcage  
42 (ribs 1-6) and diaphragmatic ribcage (ribs 7-12) (Ward et al., 1992; Kenyon et al., 1997). This is  
43 based on the apposition of the inner surface of the first six ribs to the lungs, and the attachment  
44 of the diaphragm to the lower six ribs (Ward et al., 1992). Muscle insertions further suggest  
45 such a compartmentalization: the scalenes, parasternal intercostals and the  
46 sternocleidomastoid muscles insert onto ribs 1-6, and the diaphragm arises from ribs 7-12  
47 (Kenyon et al., 1997; De Troyer et al., 2005). Thus, the direct actions of the major extrinsic  
48  
49

59  
60

1  
2  
3 respiratory muscles are almost exclusively on the pulmonary rib cage which differs regarding its  
4 movements from the diaphragmatic and abdominal part of the ribcage (Ward et al., 1992).  
5  
6

7  
8 In this study we quantify in 3D, the kinematic changes among the parts of the thorax bounded  
9 by the first 10 ribs in healthy non-smoker subjects during breathing. We first explore the  
10 geometric shape changes during breathing kinematics in the full thorax and their relation to  
11 classical descriptions in terms of pump and bucket handle and caliper-like movements. We then  
12 examine the extent to which different modes and magnitudes of size and shape change exist  
13 among and within different regions of the upper and lower thorax during breathing.

## 22 **2. Methods**

### 23 *2.1 Subjects*

24  
25 Thoracic computed tomography (CT) scans of 20 adult subjects (16 males, 4 females) in maximal  
26 forced inspiration (FI) and maximal forced expiration (FE) during the CT study were obtained  
27 from healthy non-smoker volunteers. Consistent with the Helsinki protocol (Goodyear et al.  
28 2007) and in compliance with the stipulations of the local ethical committee, written consent  
29 was obtained to use these data for research purposes. Ages ranged from 40 to 67 years  
30 (average 50.9 years). Subjects presented an average total lung volume of 6.8l (sd. 1.19) and  
31 their average residual volume was 2.1l (sd. 0.45).

36  
37  
38  
39  
40

### 41 *2.2. 3D-data*

42  
43 All CT examinations were performed with a 16-MDCT scanner (Somatom Sensation 16, Siemens  
44 Medical Solutions, Erlangen, Germany). Scanning voltage was 120 kV and current was 160 mA.  
45  
46 CT of the thorax was performed from the lung apex to the level of the diaphragm in forced  
47 inspiration (FI) followed by forced expiration (FE). All imaging was performed with a collimation  
48 of  $16 \times 0.75$  mm, table feed of 30 mm/rotation, and rotation time of 0.6 second/360° tube  
49 rotation with a standard reconstruction algorithm. CT capture lasted less than one minute. All  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 subjects were previously instructed how to correctly carry out FI and FE in order to minimize  
4 inter-individual variation in depth of breathing and so, size and shape changes in the thorax.  
5  
6  
7  
8 3D-surface meshes of upper and lower rib cages were extracted by MIMICS software  
9  
10 (<http://biomedical.materialise.com/mimics>) from the CT data and a total of 402 landmarks and  
11 semilandmarks (Bastir et al., 2013) were placed using ViewBox 4 ([www.dhal.com](http://www.dhal.com)) software on  
12 these models: one landmark at the uppermost, one at the lowermost part of the articular  
13 surface of the rib head, and one at the anterior-most point on the intra-articular crest, two  
14 landmarks at the inferior and superior limits of the sternal extremity, one at the most lateral  
15 articular tubercle, and one at the inferior part of the costal angle. In addition, we measured 13  
16 evenly spaced semilandmarks along the shaft of each rib and two landmarks at the manubrium  
17 (Supplementary Figure 1). Because CT-scanning was carried out to include the skeletal thorax to  
18 the level of the diaphragm, in many cases the 11<sup>th</sup> and 12<sup>th</sup> rib were not available for  
19 measurement. In consequence, we only took landmark coordinates on the non-floating ribs (1-  
20 10).

21  
22  
23  
24  
25  
26  
27  
28  
29  
30  
31  
32  
33  
34  
35 While landmarks characterize homologous anatomical structures as points (Oxnard and  
36 O´Higgins, 2009), curve semilandmarks respect homology at a different level. Rather than the  
37 (semi)landmark itself, the curve in total (i.e. the rib shaft) is considered biologically comparable  
38 (Gunz and Mitteroecker, 2013). Semilandmarks were slid twice, the first time to the template  
39 specimen (the first specimen in the sample) and after sliding of all specimens against the  
40 common mean shape they were slid again to the overall mean, so as to minimize the bending  
41 energy between each ribcage and this mean (Gunz and Mitteroecker, 2013). This sliding  
42 manoeuvre minimizes variation due to error in siting of semilandmarks along the curve.  
43  
44  
45  
46  
47

### 48 49 50 51 52 53 *2.3 Geometric morphometric analyses*

54  
55  
56 The 3D coordinates were subjected to a Generalized Procrustes analysis (GPA) that applies  
57 translation, scaling and rotation to the landmark coordinates to produce Procrustes shape  
58  
59  
60

1  
2  
3 coordinates (O'Higgins, 2000). Shape differences are quantified by Procrustes distance ( $Pd$ , the  
4 summed, squared interlandmark distances between corresponding landmarks) (O'Higgins,  
5 2000; Gunz and Mitteroecker, 2013). Size is measured as Centroid size (CS), the summed  
6 squared distances between each landmark and the centre of the full landmark configuration.  
7  
8  
9

10  
11  
12 Centroid size is extracted as a scaling factor that emerges during GPA when all landmark  
13 configurations are standardised to unit size (O'Higgins, 2000; Gunz and Mitteroecker 2013).  
14 Shape data were corrected for sexual dimorphism by multivariate regression of shape on sex-  
15 dummy variables because of unbalanced sex sampling similar to a MANCOVA approach (Rosas  
16 and Bastir, 2002). Asymmetries were removed by computing the mean of each thoracic  
17 landmark configuration and its reflection after GPA (Bastir et al., 2013).  
18  
19  
20  
21  
22

23  
24 Kinematic differences in ribcage shape were assessed by regression of shape on kinematic  
25 status (forced expiration/ forced inspiration) and mean shape comparisons. A permutation test  
26 (N=10000) with permuted kinematic status was used to estimate the statistical significance of  
27 the observed shape difference (Klingenberg, 2011). The differences between mean inspiratory  
28 and expiratory ribcage shapes were visualized using transformation grids calculated using a  
29 triplet of thin plate splines (TPS). TPS-grids were positioned in the coronal and sagittal plane  
30 (red grids) and in two transverse planes, one within the upper (green grid), and the other within  
31 the lower thorax (orange grid). Warpings of the grids were computed between the overall mean  
32 shape (reference) and the mean shapes at FI and FE.  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45

46 In order to identify differences in rib kinematics among regions of the thorax we assessed the  
47 significance of apparent differences among adjacent pairs of ribs. Thus, we compared shape  
48 changes occurring in the portion of the thorax bounded by rib pairs 1-2 with that bounded by  
49 rib pairs 2-3. This was repeated for ribs 3-4 vs 4-5, and so on until rib pair 9-10. Since each pair  
50 is represented by an equivalent set of landmarks we were able to directly perform GPA and  
51 subsequent statistical analyses. These comparisons allowed us to assess the validity in terms of  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 function of subdivision of the thorax into two regions. Thus, the regions enclosed by ribs 1-5  
4 and 6-10, have previously employed by us based on vertebral geometry and for convenience  
5 (equivalent sets of landmarks) of morphometric analysis (Bastir et al., 2013; 2014), while  
6 regions enclosed by ribs 1-6 and 7-10 have been proposed to reflect the functional split  
7  
8  
9  
10  
11  
12 between pulmonary and diaphragmatic divisions (Ward et al., 1992, Kenyon et al., 1997).  
13  
14 Regions enclosed by ribs 1-7 and 8-10 have been differentiated by other workers based on  
15 skeletal anatomical criteria distinguishing between true and false ribs and on the basis of their  
16 ontogenetic trajectories (Waldeyer and Mayet, 1987; White et al., 2011; García Martínez et al.,  
17  
18  
19  
20  
21  
22

60

Regression of the shapes of each partial thoracic region (rib pair) on kinematic status (forced  
inspiration, forced expiration) produced one kinematic vector connecting mean inspiratory and  
mean expiratory shape for each region of the thorax (or rib pair) and provided information on  
the magnitude of shape change due to breathing in the upper and lower thorax region (or rib  
pair). To compare these vectors among successive pairs of ribs, the angle between them was  
calculated. Its significance was estimated using a closed-form formula (Li, 2011) implemented in  
Morpho-J (Klingenberg, 2011; Klingenberg and Marugán-Lobón, 2013). Small angles indicate  
roughly parallel kinematic vectors (similar shape change during breathing), while greater angles  
indicate divergent vectors (different breathing kinematics).

Functional size, that is, the differences in centroid size (CS) and between the inspiratory and  
expiratory configurations of upper and lower thoracic regions was used to test the hypothesis  
of different kinematic size changes of the upper and lower thoracic compartments during  
breathing. Functional shape is defined as the shape difference, measured as Procrustes  
distance, between thorax shape at FI and FE and used to test the hypothesis of different  
kinematic shape changes of the upper and lower thoracic compartments during breathing.  
Mean size and shape differences between inspiration and expiration, and between upper and

1  
2  
3 lower compartments, were compared using a paired t-test, with normality of the differences in  
4  
5 CS and the Procrustes shape distances having been confirmed beforehand by the Kolmogorov  
6  
7 Smirnov test (Sokal and Rohlf, 1998). Reduced major axis regressions were used to compare  
8  
9 scaling relationships of kinematic differences in CS (functional size) and shape (Pd, functional  
10  
11 shape) in the upper and lower thorax (Sokal and Rohlf, 1998).  
12  
13

### 14 **3. Results**

#### 15 *3.1. Mean shape comparisons of full rib cage*

16  
17 Permutation tests (1000 permutations) indicated significant differences in mean shapes  
18  
19  
20  
21  
22  
23  
24 ( $Pd=0.055$ ;  $p<0.004$ ) between whole ribcages in inspiration and expiration. The associated TPS-  
25  
26 transformation grids of Figure 1 are shown in frontal, left lateral and cranial axial views. Frontal  
27  
28 views show that the lateral (midshaft) part of the ribs becomes elevated relative to the spine  
29  
30 throughout the entire ribcage. While the upper thorax expands antero-posteriorly the lower  
31  
32 thorax expands medio-laterally from the 6<sup>th</sup> and 7<sup>th</sup> ribs onwards. There is no mediolateral  
33  
34 expansion at the upper part of the thorax. The arrows drawn at the sternal ends of the fourth  
35  
36 and eight ribs show this differential medio-lateral expansion. In addition, cranial, axial views  
37  
38 illustrate that during inspiration the upper thorax increases in relative antero-posterior  
39  
40 dimensions (green TPS grid), while the lower thorax shows a small increase in relative width  
41  
42 (orange TPS grid). Thus, upper and lower parts of the thorax appear to deform differently  
43  
44 during breathing.  
45  
46

#### 47 *3.2. Kinematic vector angle between adjacent rib pairs*

48  
49  
50 Table 1 presents the associated regression results and tabulates the angles. The angles at rib  
51  
52 level 2 and rib level 6 are slightly larger than at other levels indicating kinematic changes. This  
53  
54 suggests that, from a functional point of view, the thorax can be divided into the thoracic  
55  
56 aperture (1<sup>st</sup> and 2<sup>nd</sup> rib level), a region superior to the 6<sup>th</sup> rib and a region inferior to the 6<sup>th</sup> rib.  
57  
58  
59  
60

1  
2  
3 These latter results are compatible with a division of the ribcage according to kinematics into a  
4 pulmonary and a diaphragmatic part following musculo-skeletal criteria (Ward et al., 1992,  
5  
6 Kenyon et al., 1997). The slight increase in angle at the level 5 may indicate action of the rectus  
7  
8 abdominis muscle.  
9

### 10 11 12 *3.3. Pulmonary and diaphragmatic ribcage compartments*

13  
14  
15 When the results of the previous analyses (Table 1) are taken as basis for a division of the  
16  
17 ribcage into an upper and lower part, kinematic vector comparisons of the pulmonary and  
18  
19 diaphragmatic thoracic regions lend quantitative support to apparent visual differences (Fig. 1).  
20  
21 Mean shapes at FI and FE were different both in the pulmonary ( $Pd=0.046$ ;  $p<0.001$ ) and the  
22  
23 diaphragmatic thorax ( $Pd=0.035$ ;  $p<0.05$ ). Mean centroid sizes (CS) at FE (CS = 1517.2) and at FI  
24  
25 (CS = 1529.8) within the pulmonary ribcage also differed significantly ( $t= -7.892$ ,  $p<0.0001$ ).  
26  
27 Within the diaphragmatic ribcage mean centroid sizes at FE (CS= 1628) and at FI (CS= 1662.5)  
28  
29 differed also significantly ( $t = -7.596$ ,  $p<0.0001$ ). The angle between the pulmonary and  
30  
31 diaphragmatic kinematic vectors was 36.6 degrees ( $p<0.0001$ ) indicating different breathing  
32  
33 kinematics.  
34  
35  
36  
37

### 38 *3.4. Magnitudes of kinematic size and shape differences*

39  
40  
41 Differences in CS between expiration and inspiration (functional size) were significantly greater  
42  
43 in the diaphragmatic thorax (34.47) than the pulmonary thorax (12.62). Normality was not  
44  
45 rejected by the Kolmogorov-Smirnov test ( $d=0.1$ ; ns) and the paired t-test finds a statistical  
46  
47 difference ( $t=-4.54$ ,  $p<0.01$ ).  
48

49  
50 For the pulmonary thorax the Procrustes distance between mean inspiratory and expiratory  
51  
52 shapes (functional shape) is 0.053, and for the diaphragmatic, 0.046. Normality was not  
53  
54 rejected by the Kolmogorov-Smirnov test ( $d=0.20$ ; n.s.) and a paired t-test indicates no  
55  
56 differences in Procrustes distances ( $t=1.07$ , n.s) (Table 2).  
57  
58  
59  
60

1  
2  
3 Thus, the pulmonary thorax produced less size difference during inspiration than the  
4 diaphragmatic part of the ribcage with similar amounts of deformation in shape. This is also  
5 seen in the regression analyses (Fig. 2, Table 3). The slope of the regression of functional size on  
6 functional shape or the pulmonary thorax is significantly smaller than that for the  
7 diaphragmatic, indicating that it needs to deform significantly more than the diaphragmatic  
8 thorax to produce the same size difference. Additionally, the functional size of the pulmonary  
9 thorax is only weakly related to functional size of the diaphragmatic thorax, while functional  
10 shapes of both thorax compartments are very highly correlated (Table 3).  
11

#### 12 13 14 15 16 17 18 19 20 21 **4. Discussion**

22  
23  
24 This study explored the geometric shape changes during breathing in the full thorax in adult  
25 healthy non-smoker subjects. We addressed the relationship of these shape changes to classical  
26 descriptions of rib motion in terms of pump and bucket handle and caliper-like movements  
27 (Beyer et al., 2014; Ratnovsky et al., 2008; West, 2012). We also investigated the basic  
28 functional implications of kinematic size and shape changes of the upper and lower thoracic  
29 compartments and assess our findings in an evolutionary morphological and clinical context.  
30  
31  
32

#### 33 34 35 36 37 38 **4.1. Kinematic deformations, rib rotations and morpho-functional divisions**

39  
40  
41 In recent and fossil hominins there is substantial variation in the size and shape of the upper  
42 and lower thorax (Schmid et al., 2013; Garcia Martínez et al., 2014; Bastir et al., 2015) with  
43 potential implications for breathing. In fact, upper and lower parts of the ribcage have been  
44 proposed to evolve (Schmid et al., 2013) and develop (Bastir et al., 2013, García Martínez et al.,  
45 2016) relatively independently. Various propositions as to how to divide the ribcage into an  
46 upper and lower compartment have been made following statistical, musculo-skeletal and  
47 purely skeletal criteria (Bastir et al., 2013, 2014, Ward et al., 1992, White et al., 2011, García  
48 Martínez et al., 2016). Our results suggest from a kinematic point of view a musculo-skeletal  
49 division of the thorax into a pulmonary part (ribs 3-6) and a diaphragmatic or abdominal part  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 (ribs 7-10) according to Ward et al. (1992) and Kenyon et al. (1997) who proposed such divisions  
4  
5 on the basis of muscle insertions and contact between the ribs and lungs.  
6  
7

8 Table 1 also provides evidence for specific kinematic changes at the upper thoracic aperture  
9  
10 (ribs 1 and 2). This has not previously been observed and may indicate the action of the  
11  
12 accessory respiratory muscles - scalene muscles- necessary in forced inspiration. The flatness of  
13  
14 ribs 1 and 2 compared to the torsion of mid-thoracic and lower ones (Mann, 1993; Dudar, 1993;  
15  
16 Garcia Martínez et al., 2015) and the supine posture in the CT-scanner (Romei et al., 2010) may  
17  
18 well reflect the specific kinematics of this region as indicated by the higher angle (Table 1).  
19  
20  
21

22 The significant and large angle (36.6 degrees,  $P < 0.0001$ ) between pulmonary and diaphragmatic  
23  
24 kinematic vectors together with the differences in transformation grid deformations between  
25  
26 upper and lower thoracic regions (Fig. 1) provide clear evidence for different modes of  
27  
28 deformation of the upper and lower parts of the breathing thorax.  
29  
30

31 The shape changes observed in the thorax do not completely reflect the oversimplification that  
32  
33 “pump handle like” motions of the ribs characterize the upper thorax, and “bucket handle like”  
34  
35 motions, the lower (Chila, 2010; Magee, 2014; West, 2012). In part this is because these terms  
36  
37 are ill defined and so, are difficult to relate to a quantitative analysis of 3D motion, and in part  
38  
39 because both motions are evident to some degree throughout the thorax (Beyer et al., 2014).  
40  
41 This may account for the limited variation in kinematic angles among rib pairs (Table 1.). Also a  
42  
43 third motion, caliper-like spreading apart of the anterior ends of the lower ribs (Chila, 2010;  
44  
45 Magee, 2014) is observed in Figure 1. Rib shape and costosternal joints likely constrain these  
46  
47 motions leading to pump-handle and caliper like motion in these lower parts increasing the  
48  
49 distance between the anterior ends of the ribs of the diaphragmatic thorax. This caliper-like  
50  
51 motion is not, as is commonly stated (Chila, 2010), restricted to the last two ‘floating ribs’ but  
52  
53 affects all lower ribs to some degree, supporting Magee (2014). This caliper-like motion may  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 also reflect active muscle force during forced expiration because of the abdominal muscles  
4  
5 insertions.  
6

7  
8 Respiratory movements of the thoracic cage are produced by the cumulative effects of small  
9  
10 movements of the ribs at each costovertebral joint (Ward and Macklem, 1985). The axes of  
11  
12 movement are complex and, particularly, those of the lower ribs are not well understood (Beyer  
13  
14 et al., 2014). Moreover, these axes change in cranio-caudally as the transverse processes  
15  
16 become increasingly posteriorly orientated (Latimer and Ward, 1993; Bastir et al., 2014) with  
17  
18 kinematic consequences for thoracic shape changes during breathing. Regional differences in  
19  
20 kinematic patterns shown in Figure 2 may reflect the successive changes in the articular  
21  
22 surfaces, rib axes, and attachments. The upper ribs hinge about an axis running along their  
23  
24 neck, their convex tubercle rotating within the concavity of the costo-transverse joint. In  
25  
26 inspiration, the ribs become more horizontal. Their anterior end moves forwards and upwards,  
27  
28  
29 but only slightly laterally due to costosternal constraints. This results in anteroposterior  
30  
31 expansion of the thoracic cavity and elevates the thoracic cage anteriorly (Fig. 1) (Agostini and  
32  
33 D'Angelo, 1985).  
34  
35

36  
37 Because of the increasingly posteriorward sweep of the transverse processes, and so, of the  
38  
39 axes of the necks of the ribs (Bastir et al., 2014), their anterior ends become progressively more  
40  
41 laterally orientated in inspiration (Agostini and D'Angelo, 1985), as is observed in Figure 1.  
42  
43

44 Because the ribs increase cranio-caudally in length and curvature, upward rotation during  
45  
46 inspiration shifts the ribs around the thorax at any given horizontal plane (Agostini and D'Angelo,  
47  
48 1985; Mead et al., 1985). Moreover, the movement of the lower ribs includes a slight degree of  
49  
50 eversion, which elevates the most lateral part of the rib shaft relative to a plane passing  
51  
52 through its head posteriorly and the anterior end of its costal cartilage, anteriorly (Agostini and  
53  
54 D'Angelo, 1985).  
55  
56  
57  
58  
59  
60

1  
2  
3 In the lower thorax the shape and inclination of the costotransverse articular facets also allows  
4 for a gliding component (Ward and Macklem, 1985). In deep inspiration, the rib tubercles glide  
5 posteriorly, superiorly, and medially, swinging the anterior ends of the ribs horizontally laterally,  
6 away from each other (Ward and Macklem, 1985; Agostini and D'Angelo, 1985; Mead et al.,  
7  
8  
9  
10  
11  
12 1985). This further contributes to transverse expansion of the lower chest (Fig. 1a).

58  
59  
60

The breathing kinematics of the upper thorax produce a smaller functional size difference than in the lower thorax (Table 2, Fig. 2). There is also evidence that size changes in the upper and lower thorax are weakly correlated (Table 3). This weak correlation may reflect variation among subjects in breathing preferences with some being predominantly thoracic breathers and others, diaphragmatic breathers. This requires further investigation, however, recent work on sexual dimorphism suggests that the form of the lungs (Torres Tamayo et al., 2016) and that of the ribcage (Bellemare et al., 2003, 2006; Garcia Martínez et al, in revision) correlate with differences in respiratory function. Thus, females, who tend to show more prismatic (barrel shaped) thoraces also show reduced expansion capacities when compared to more pyramidal (funnel) shaped males (Bellemare et al., 2003; Romei et al., 2010; Layton et al., 2011). Variations related to skeletal aging might also contribute to the weak relationship between the functional sizes of the upper and lower parts of the thorax because aging leads to increased ossification in the costo-sternal cartilages and this, in turn, limits upper thoracic mobility (Oskvig, 1999; Gayzik et al. 2008).

The finding of a greater overall contribution to functional thorax size changes of the lower thorax is consistent with studies on external chest wall kinematics that have shown greater volumetric differences in the lower part of the chest than in the (upper) thoracic part (LoMauro et al., 2012; Romei et al., 2010; Silvattia et al., 2012). Because the diaphragm and its movements are not considered in our study, it is likely that changes in size of the upper skeletal

1  
2  
3 thorax with breathing more directly reflect lung volumetric changes than those of the lower  
4 skeletal thorax, although the latter are functionally more relevant than the former.  
5  
6

7  
8 Frontal and lateral views in Figure 1 (and supplementary Movie 1) show that the rib rotations  
9 described by Beyer et al. (2014) lead to different costosternal motions in the upper thorax than  
10 in the lower. Thus, the costosternal joints of the upper ribs deform less than those of the lower,  
11 possibly as a consequence of differences in the lengths and orientations of the costosternal  
12 cartilages (Fig. 1). Thus, short and horizontally aligned cartilages are likely to permit smaller  
13 changes in thoracic width than longer and more caudally oriented costosternal cartilages. This  
14 costosternal constraint may also be reflected in the results of the regression analyses (Table 3),  
15 where the smaller slope in the pulmonary thorax indicates that for the same amount of size  
16 change, the upper thorax needs to change shape much more than the lower during breathing  
17 (Fig. 2). The reduced curvature and torsion of the upper ribs also contributes to smaller  
18 volumetric differences. Thus, greater curvature, torsion and lateral extension of the midshaft in  
19 shallow rib cages produce greater size differences between inspiration and expiration than in  
20 deep rib cages with less curved upper ribs. We have shown elsewhere that this mode of rib  
21 shape variation is a feature of normal variation, rather than pathological (Bastir et al., 2015,  
22 García Martínez et al., 2016).  
23  
24  
25  
26  
27  
28  
29

30  
31 The larger lower ribs enhance the degree of expansion of the lower rib cage during breathing  
32 (Table 2). As noted above, a recent study on modern human sexual dimorphism demonstrates a  
33 larger and relatively wider lower thorax in males combined with a significantly greater  
34 expansion capacity when compared to females (García Martínez et al. in revision). The present  
35 findings with respect to how kinematic size and shape changes of upper and lower thoraces  
36 relate to rib and thorax shape are consistent with this, in that a wider thorax is expected to  
37 show greater volumetric changes during breathing. Further, the larger sizes of the mid- and  
38 lower thoracic ribs relative to the upper ribs in fossil hominins, such as Neandertals (García

3 Martínez et al., 2014; Bastir et al., 2015) and *Australopithecus* (Schmid et al., 2013, Tawane et  
4 al., 2016) can be expected to have important implications for breathing kinematics in these  
5 hominins, and so potentially contribute to better understanding of the energy demands and  
6 behaviours of our fossil relatives . This is a topic to be explored in future work.  
7  
8  
9

### 10 11 12 **4.3. Clinical implications**

13  
14 This study has focused on healthy subjects but the findings are of relevance to future research  
15 in pathological subjects. Thus, Chronic Obstructive Pulmonary Disease (COPD) results in  
16 pulmonary hyperinflation and respiratory muscle dysfunction (O'Donnell, 2001, Bellemare et  
17 al., 2001). Muscle dysfunction is characterized by changes in mechanical advantages and  
18 alterations of muscle fibre lengths, and intrinsic muscle structure (Marchand and Decramer,  
19 2000). The diaphragm shows a flatter dome configuration, and loses its capacity to further  
20 expand the lower thorax (Marini, 1998). In consequence, the intercostal muscles become  
21 critical for inspiratory flow generation in these patients.  
22  
23  
24  
25  
26  
27  
28  
29  
30

31  
32 Such changes in respiratory muscles likely directly affect the kinematics of the upper and lower  
33 ribcage and these are further impacted by changes in the diaphragm that result in decreased  
34 lower chest expansion. Changes in ribcage kinematics in COPD impact lung expansion with  
35 consequences for the ventilation/perfusion ratio. Indeed, recent work shows that lung  
36 morphology and kinematics differ between COPD patients and healthy controls (Torres-Tamayo  
37 et al., 2015). The regional kinematic differences shown here (Figs. 1, 2; Table 2) are likely  
38 important in the light of mismatching between ventilation and flow, the commonest cause of  
39 hypoxemia in lung diseases (Kent et al., 2011). As such, it will be of interest to apply the  
40 methods used in the present study to a comparison of the breathing kinematics of upper and  
41 lower thoracic compartments among COPD patients and healthy subjects.  
42

47  
48  
49  
50

51  
52 Alveolar recruitment, that is, opening of alveoli that remain closed during breathing at low lung  
53 volumes, can be a compensatory mechanism to minimize the consequences of gas exchange  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 imbalance (Rodríguez-Roisin and Wagner, 1990; West, 1990; Engel and Paiva, 1981). The lateral  
4 displacement of the lower thorax observed in this study (Fig. 1a,c) likely favors increased lung  
5 expansion during inspiration and, consequently, may be a key mechanical mechanisms  
6 underlying alveolar recruitment, with significant clinical implications in asthma and chronic  
7  
8  
9  
10  
11  
12 bronchitis (Palmer et al., 1967).

13  
14 Age is another factor that impacts breathing kinematics as alveolar recruitment will decrease  
15 with aging and its associated clinical problems (Oskvig, 1999). This is because as we age the ribs  
16 come to lie more horizontally. This is illustrated for the lower ribs by Weaver et al. (2014).  
17 Further with increasing age comes increasing thoracic kyphosis (Gayzik et al., 2008). This further  
18 impacts rib orientation, which reduces respiratory muscle strength, one of the most important  
19 physiological changes in the respiratory system associated with aging (Janssens et al., 1999).  
20 With age, joints become stiffer and less flexible and ribcage calcification extends from the  
21 costochondral junctions to the sternocostal junctions (Ontell et al., 1997). The resulting  
22 stiffening of ribcages in older subjects compromises their respiratory biomechanics, leading to  
23 “hyperinflation”, with possible clinical effects similar to those of COPD patients. The approaches  
24 we have applied in the present study may well have application in future clinical assessment of  
25 these age changes.  
26  
27  
28  
29

30  
31 Other potential applications include assessment of the progress and effects of thoracic and  
32 spinal skeletal dysplasias and of progressive thoracic skeletal deformities such as occur in  
33  
34  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44  
45  
46 *Osteogenesis imperfecta*. In fact, in a recent study of chest wall motion in Type III *Osteogenesis*  
47  
48 *imperfecta* patients, asynchronies between upper and lower thorax kinematics were reported  
49 (LoMauro et al., 2012). These authors related these asynchronies to the presence of more  
50 horizontally aligned ribs. Figure 1 shows clearly that inspiratory expansion of the upper thorax  
51 occurs in the antero-posterior direction facilitated by kinematic elevation of upper ribs.  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Therefore, disease leading to more horizontal upper ribs will also likely lead to clinical problems  
4 related to ventilation.  
5  
6

7  
8 In this study we assessed the size and shape changes that occur in the upper and lower skeletal  
9 thorax during breathing by means of CT. This provides different insights into breathing  
10 mechanics than those that arise from the more usual studies of the diaphragm and intercostal  
11 muscle function (Romei et al., 2010; LoMauro et al., 2012; Silvattia et al., 2012) because  
12 breathing also involves the actions of the serratus, scalene, pectoral and abdominal wall  
13 muscles (Drake et al., 2010; Thibodeau and Patton, 2008; White et al., 2011). While CT studies  
14 cannot reveal respiratory muscle morphology and functioning during breathing they can  
15 potentially reveal the changes in function that arise as a consequence of muscular changes.  
16 Future research examining breathing kinematics using could be complemented by magnetic  
17 resonance imaging and electromyography to allow integration of data on muscle functioning  
18 with data on thorax motion.

### 33 **5. Conclusions**

34  
35  
36 Our study shows that the pulmonary and diaphragmatic parts of the thorax differ in terms of  
37 breathing kinematics, particularly in their modes of shape change during breathing while the  
38 degree of shape change is similar in both compartments. In contrast, the diaphragmatic part  
39 undergoes greater changes in size than the pulmonary part. In consequence a greater degree of  
40 deformation of the upper thorax is required to produce a similar degree of size change to that  
41 of the lower thorax. This has important implications with regard to the functional impact of  
42 variations in rib cage form among living and fossil hominins. The approaches employed in this  
43 study have potential clinical applications in assessing the impact and progress of the effects of  
44 disease and aging on breathing kinematics.

**Table 2.** Kinematic differences in centroid size (mm) and shape (Procrustes distance, Pd) between forced inspiration and forced expiration in the pulmonary thorax and the diaphragmatic thorax. (ns not significant).

units	Pulmonary Thorax	Diaphragmatic Thorax	t	p
Centroid size	12.62	34.47	-4.54	<0.0001
Procrustes distance	0.053	0.046	1.07	ns

**Table 3.** Relationships between functional size (*fs*) and functional shape (*fsh*) of the pulmonary thorax (PT) and diaphragmatic thorax (DT). Reduced major axis regression analyses (slopes, 95% confidence intervals), intercept, correlation coefficient, and p-value.

units	slope (95% C.I.)	intercept	r	p
Functional size: PT vs DT	0.35 (0.21-1.13)	0.47 (-25.19-4.52)	0.41	0.07
Functional shape: PT vs DT	0.99 (0.75-1.09)	0.007 (0.001-0.016)	0.95	0.0001
PT <i>fs</i> vs PT <i>fsh</i>	335.6 (191.8-422.9)	-5.34 (-20.03-6.385)	0.73	0.0002
DT <i>fs</i> vs PT <i>fsh</i>	946.22 (609.7-1097)	-9.27 (-20.03-6.385)	0.77	0.0002

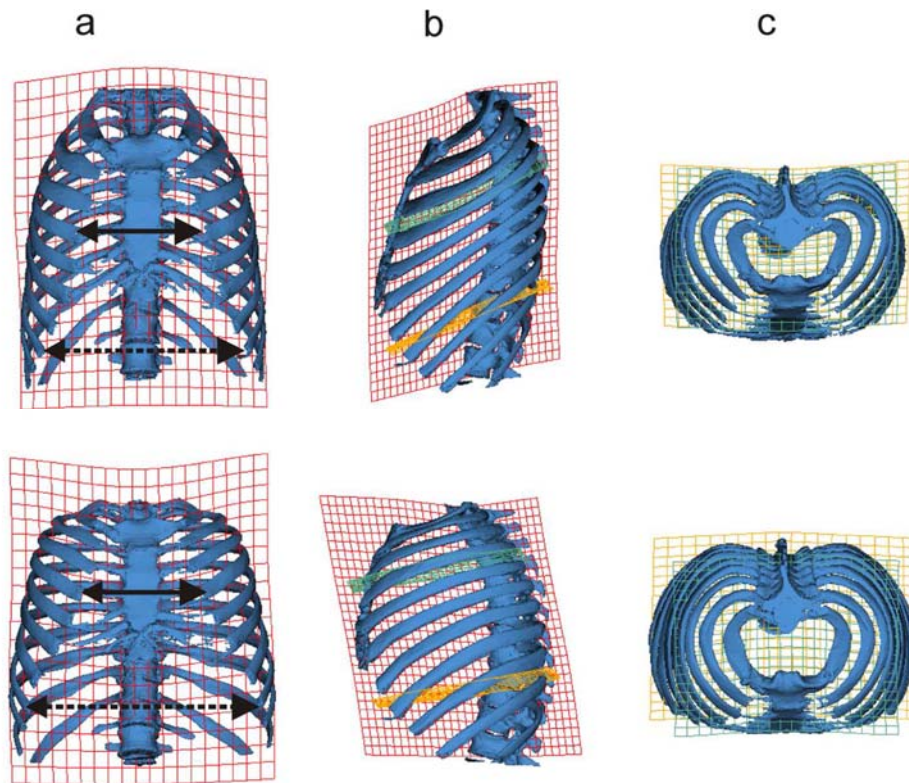

Figure 1. How the thorax changes shape during breathing. Upper row: forced expiration; lower row: forced inspiration; a, anterior; b, left lateral; c, superior axial views.

Grids are warped from the overall mean shape to the mean shapes at forced inspiration and forced expiration. In frontal view the red transformation grids are drawn through the centre of the ribcage, in lateral view the grids are drawn through the midsagittal plane. In axial view grids are drawn in the transverse plane at the level of the mid upper thorax (green grid) and mid lower thorax (orange grid). a) shows the relatively lower position of the lateral parts of the ribs which become elevated during inspiration.

In addition, the lower thorax becomes mediolaterally wider relative to the upper, also shown by transformation grids in (c). The solid line and arrows show no change in width in the upper part of the

thorax. The dashed line and arrows show medio-lateral expansion in the lower thorax during inspiration. Left lateral views (b) show a considerably more marked antero-posterior expansion of the upper than of the lower thorax. The cranial axial views also illustrate that the upper thorax in expiration (c) is shallower in the antero-posterior direction relative to the lower thorax, becoming relatively deeper during inspiration. Thus, the green transformation grid in the upper thorax is relatively shorter in FE than in FI, while the orange grid changes in its medio-lateral width, but not in its anteroposterior depth.

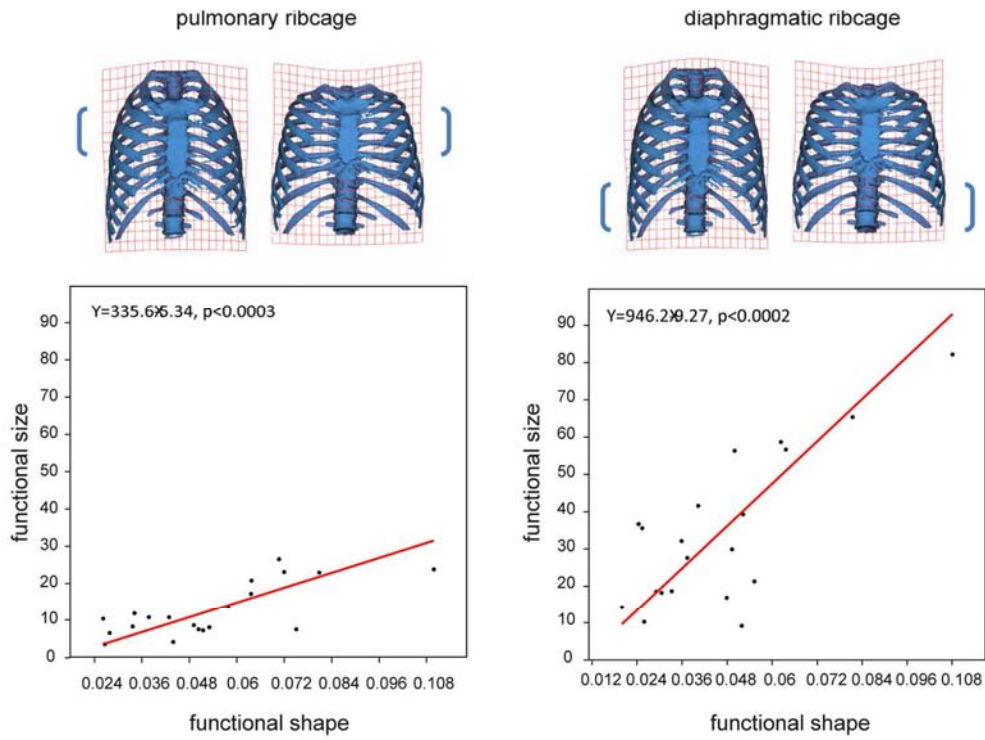

Figure 2. Functional size and shape changes of the pulmonary and diaphragmatic ribcage. The slope of the pulmonary ribcage is considerably smaller than that of the diaphragmatic ribcage. Therefore, within the lower thorax, less shape change is necessary to produce the same degree of size difference as in the upper thorax.
