We conducted flask-based measurements of concentration,  $\delta^{13}\text{C}$ ,  $\delta\text{D}$  of atmospheric CH<sub>4</sub> at Churchill, Canada (CHL; 58°44'N, 93°50'W) and Ny-Ålesund, Svalbard (NAL; 78°55'N, 11°56'E) during 2007–2014; CHL locates on the northern perimeter of the Hudson Bay Lowland (HBL); NAL is a background station remote from regional CH<sub>4</sub> sources. The CH<sub>4</sub> concentration at CHL is generally higher than that at NAL, while  $\delta^{13}\text{C}$  and  $\delta\text{D}$  at CHL are lower than those at NAL, likely reflecting CH<sub>4</sub> emissions from regional to local boreal wetlands in nearby area of CHL. Clear seasonal cycles are observed in CH<sub>4</sub> and  $\delta^{13}\text{C}$  with the respective seasonal maximum (minimum) values in January–February (June) and May (October).  $\delta\text{D}$  also shows a clear seasonal cycle, but it is not the case for CH<sub>4</sub> and  $\delta^{13}\text{C}$ , which exhibit large weekly-monthly variability. The summertime minimum of CH<sub>4</sub> concentration and maxima of  $\delta^{13}\text{C}$  and  $\delta\text{D}$  at CHL are about 1 month earlier than those at NAL. A simple 1-box model indicates that contribution of biogenic CH<sub>4</sub> emissions peaks earlier at CHL than at NAL, causing the phase differences between the two sites. At CHL, short-term CH<sub>4</sub> variations are observed through the year but most pronounced in summer. By inspecting the relationships between CH<sub>4</sub> concentration and the isotope ratios, we estimated the source isotope signatures to be  $-63.4 \pm 2.8\text{‰}$  for  $\delta^{13}\text{C}$  and  $-316 \pm 24\text{‰}$  for  $\delta\text{D}$  in summer (May–October), and  $-47.7 \pm 4.5\text{‰}$  for  $\delta^{13}\text{C}$  and  $-244 \pm 52\text{‰}$  for  $\delta\text{D}$  in winter (November–April). These values indicate predominant contribution of wetlands emissions to CH<sub>4</sub> in summer and that of fossil fuel sources in winter. In addition, we use an atmospheric chemistry transport model at  $1.12 \times 1.12^\circ$  horizontal resolution to investigate the cause of seasonal and short-term CH<sub>4</sub> variations at the two sites. While the model reproduces the CH<sub>4</sub> concentration variations at NAL well, it overestimates summertime CH<sub>4</sub> level at CHL. Tagged tracer experiments imply that the highly elevated CH<sub>4</sub> concentrations come from emissions in boreal northern America, suggesting that our a-priori wetland flux in the region might be overestimated.
