Abstract

Adaptive cellular responses are often required during wound repair. Following disruption of the intestinal epithelium, wound-associated epithelial (WAE) cells form the initial barrier over the wound. Our goal was to determine the critical factor that promotes WAE cell differentiation. Using an adaptation of our *in vitro* primary epithelial cell culture system, we found that prostaglandin E2 (PGE₂) signaling through one of its receptors, Ptger4, was sufficient to drive a differentiation state morphologically and transcriptionally similar to *in vivo* WAE cells. WAE cell differentiation was a permanent state and dominant over enterocyte differentiation in plasticity experiments. WAE cell differentiation was triggered by nuclear β -catenin signaling independent of canonical Wnt signaling. Creation of WAE cells via the PGE₂-Ptger4 pathway was required *in vivo*, as mice with loss of Ptger4 in the intestinal epithelium did not produce WAE cells and exhibited impaired wound repair. Our results demonstrate a mechanism by which WAE cells are formed by PGE₂ and suggest a process of adaptive cellular reprogramming of the intestinal epithelium that occurs to ensure proper repair to injury.

Introduction

The intestinal epithelium is comprised of a single layer of columnar epithelial cells that separate the luminal contents from the rich networks of vascular, structural, and immune cells that reside in the lamina propria. This semipermeable cellular barrier functions to

reduce exposure to pathogenic and commensal microbes, toxins, and other immunogenic substances (Turner, 2009). During homeostasis, the epithelial cell barrier is maintained by highly active stem cells residing at the base of the crypts that provide continuous and perpetual cell renewal, with the majority of the differentiated cells being replaced every 3–5 days (Cheng & Leblond, 1974b; Potten *et al.*, 1992; Crosnier *et al.*, 2006; Barker *et al.*, 2007; Noah *et al.*, 2011). However, in response to injury (i.e. infection, ischemia, toxin exposure), additional mechanisms are rapidly implemented to restore the epithelial barrier. Delay or failure to do so can facilitate exposure to luminal antigens and potentially direct invasion of luminal microorganisms into the host, resulting in a heightened pro-inflammatory response, worsened tissue damage, and systemic infection.

Adaptive cellular responses are triggered by injury or damage to promote the survival and regeneration of a diverse array of mammalian tissues. Two general classes of these responses have been recognized. In one state, a transient class of repair cells is formed that has an atypical differentiation state for that tissue. In a second state, cells lost during damage are directly replaced (Jessen *et al.*, 2015). The intestinal epithelium appears to employ the first approach in a process termed epithelial restitution (Svanes *et al.*, 1982; Ito *et al.*, 1984; Lacy, 1988). The critical driver is a transient, specialized repair cell type, which we subsequently termed wound-associated epithelial (WAE) cells (Seno *et al.*, 2009; Stappenbeck & Miyoshi, 2009). These atypical epithelial cells migrate over the surfaces of intestinal wounds within minutes to hours after injury to re-establish the epithelial barrier. The initial restitution phase of repair does not depend on altered cellular proliferation rates of nearby stem cells (Podolsky, 1999; Dignass, 2001); however, a subsequent repair phase requires enhanced proliferation of stem and progenitor cells in the crypts adjacent to the wound to replace crypts lost during severe damage (Seno *et al.*, 2009).

Several factors have been proposed to affect epithelial restitution, including growth factors (e.g. TGF- β , EGF, IGF-1), cytokines (e.g. IL-2, IFN- γ , IL-1 β), and a variety of peptide (e.g. trefoil factors) and non-peptide (e.g. lysophosphatidic acid, polyamines, short chain fatty acids) molecules (Moore *et al.*, 1989, 1992; Nusrat *et al.*, 1992;

Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, MO, USA

[†]These authors contributed equally to this work

Dignass & Podolsky, 1993; Dignass *et al*, 1994; Wilson & Gibson, 1997; Dignass, 2001). However, due to the limitations of the experimental model systems used in these previous studies, it is still unclear as to which of these factors, if any, are necessary and sufficient for the WAE cell formation that occurs in the initial phase of repair. Understanding the regulation of such WAE mediators in the intestine could provide a potential avenue for regenerative therapies.

We and others have modeled WAE cells *in vivo* using a biopsy injury system to generate focal wounds in the mouse colon. This method allows the investigator to study mucosal repair with control over spatial and temporal variables (Becker *et al*, 2005; Seno *et al*, 2009; Manieri *et al*, 2012, 2015; Miyoshi *et al*, 2012; Leoni *et al*, 2013). Following biopsy injury, wound surfaces are rapidly covered by WAE cells (Seno *et al*, 2009). Multiple lineage tracing models have shown that these WAE cells emanate from crypts adjacent to the wounded area and are replaced by columnar epithelial cells in a subsequent repair phase (Seno *et al*, 2009; Miyoshi *et al*, 2012). With this injury method, we found that mice deficient for prostaglandin-endoperoxide synthase 2 (Ptgs2), which encodes the inducible prostaglandin synthase family member cyclooxygenase 2, have multiple defects in repair including incomplete covering of biopsy wounds with WAE cells (Manieri *et al*, 2012, 2015). Prostaglandins likely exert their effects near their site of production due to their chemical and/or metabolic instability (Narumiya *et al*, 1999; Matsuoka & Narumiya, 2007). We previously found that Ptgs2-expressing mesenchymal stem cells localize specifically in the colonic wound bed in close association with crypts adjacent to the wound and their associated WAE cells (Manieri *et al*, 2012). From these observations, we reasoned that prostaglandins were promising candidate molecules to investigate for capacity to directly induce adaptive cellular reprogramming of the intestinal epithelium and stimulate WAE cell formation during early wound repair.

Ptgs2-mediated synthesis of prostaglandins increases during acute inflammation, and the resulting influx of these lipid mediators acts to orchestrate pro-inflammatory and anti-inflammatory responses in a cell type- and context-dependent manner (Ricciotti & FitzGerald, 2011; Kalinski, 2012). Thus, to study the direct effects of prostaglandins on intestinal epithelial cells, we utilized our culture system for primary intestinal epithelial cells (Miyoshi *et al*, 2012; Miyoshi & Stappenbeck, 2013). With this system, primary epithelial cell lines are generated from any region of the gastrointestinal tract and propagated as spheroids enriched for epithelial stem cells in a conditioned media containing Wnt3a, R-spondin 3, and noggin (Miyoshi & Stappenbeck, 2013), the critical factors that support intestinal stem cell growth (Sato *et al*, 2009). As WAE cells are known to be post-mitotic (Lacy, 1988), a key advantage of the spheroid culture system is that withdrawal of the conditioned medium promotes exit from the cell cycle and differentiation to mature intestinal epithelial cell types (Miyoshi *et al*, 2012; Patel *et al*, 2013; Moon *et al*, 2014; Sun *et al*, 2015; VanDussen *et al*, 2015). Here, we use this culture system to show that prostaglandin E₂ (PGE₂) signals through the EP4 receptor on epithelial stem and/or progenitor cells to directly induce WAE cells and validate these findings *in vivo* with our biopsy injury model and a genetic mouse lacking EP4 receptor expression specifically in the intestinal epithelium.

Results

PGE₂ induces differentiation of intestinal epithelial stem cells to WAE cells through EP4

To investigate whether prostaglandins can directly promote the formation of WAE cells, we utilized our culture system for primary intestinal epithelial cells (Miyoshi *et al*, 2012; Miyoshi & Stappenbeck, 2013). Stem cell-enriched spheroids from the jejunum were passaged and then cultured in serum- and canonical Wnt-free differentiation medium (supplemented with EGF) for 24 h in the absence or presence of stabilized PGE₂ analog 16,16-dimethyl PGE₂ (dmPGE₂; Narumiya *et al*, 1999) or prostaglandin I₂ (PGI₂) analog iloprost (Schrör *et al*, 1981; Abramovitz *et al*, 2000) (Fig 1A). These two prostaglandins rescue repair defects in Ptgs2-deficient mice (Walker *et al*, 2010; Manieri *et al*, 2012). Treatment with dmPGE₂ stimulated WAE cell formation. There was a dose-dependent effect on spheroid size (Fig 1B and C), cell flattening (Fig 1D), and mRNA expression of the one previously described WAE cell marker, Claudin-4 (Cldn4) (Seno *et al*, 2009; Fig 1E). In contrast, spheroids treated with the PGI₂ analog iloprost did not stimulate WAE cell phenotypes at equivalent dosages (Fig 1F). Thus, PGE₂ treatment appeared to directly stimulate WAE cells.

PGE₂ can signal through four prostaglandin E receptors: Ptger1 (encoding EP1), Ptger2 (encoding EP2), Ptger3 (encoding EP3), and Ptger4 (encoding EP4; Narumiya *et al*, 1999). All four of these receptors were readily detectable in whole organ preparations of lung, small intestine, and colon (Fig 2A). In contrast, only Ptger1 and Ptger4 mRNAs, but not Ptger2 or Ptger3 mRNAs, were detectable in jejunal spheroid epithelial cells (Fig 2A). The PGI₂ receptor Ptgir was also undetectable in the spheroids. These data corroborated a previous *in situ* hybridization study reporting mRNA expression of Ptger1 and Ptger4 throughout the intestinal epithelium (Morimoto *et al*, 1997) and our own validation of Ptger4 mRNA localization (Appendix Fig S1). To determine which cellular receptor mediated the effects of PGE₂ on WAE cell formation, spheroids were treated with dmPGE₂ and specific pharmacological inhibitors for EP1 (SC 51322), EP2 (PF 04418948), EP3 (L-798,106), or EP4 (L-161,982). Of these, only EP4 inhibitor (EP4i) blocked the dmPGE₂-induced WAE formation (Fig 2B–D). These results support a role for dmPGE₂ signaling through EP4 to promote WAE formation. We next utilized a genetic model of Ptger4 deficiency to confirm the effect of the PGE₂-EP4 signaling pathway on WAE formation. Spheroid lines were established from the jejunum of the Ptger4^{flox/flox} mouse (Schneider *et al*, 2004) and delivered transient recombinant Tat-Cre (Shaw *et al*, 2008; Morimoto *et al*, 2010; Patel *et al*, 2013) to generate heterozygous Ptger4^{flox/Δ} and knockout Ptger4^{Δ/Δ} spheroid lines (Fig 2E and F). Ptger4^{Δ/Δ} spheroids did not make WAE cells by any of the above criteria (Fig 2G–I).

We then tested whether PGE₂ signaling through EP4 was important for the formation of WAE cells in human lines. In response to treatment with dmPGE₂, human ileal spheroids exhibited morphological changes and induction of CLDN4 mRNA (Fig 2J–L) similar to mouse spheroids. EP4i blocked these responses (Fig 2J–L). Thus, PGE₂-EP4 signaling appears to be a conserved mechanism in mouse and human.

In vitro*-induced WAE cells resemble WAE cells *in vivo

Our next goals were to validate that PGE₂-treated cells highly resembled WAE cells and to identify additional markers to describe this cell population more precisely. To do this, we performed microarray transcriptional profiling of these cells compared to stem cell-enriched spheroids as well as EP4i-treated spheroids (Fig 3A). We used EP4i-treated cells to eliminate the effects of endogenous PGE₂ present in the culture medium or produced by the spheroid epithelial cells. We observed significant and differential expression of 11,925 probes between the groups of cells. Unsupervised hierarchical clustering showed that dmPGE₂-treated and EP4i-treated spheroids were more related to each other than to stem cells (Fig 3B). The clustering analysis also highlighted six major gene clusters. Detailed analysis of these clusters developed the hypothesis that stimulation or

inhibition of PGE₂ signaling directed distinct differentiation states.

The two largest clusters corresponded to genes that encode mRNAs either highly expressed in stem cell spheroids (Cluster 1; 5,289 probes) or in post-mitotic intestinal epithelial cells (Cluster 4; 4,636 probes). Cluster 1 was enriched for cell cycle and mRNA processing pathways and cellular component gene ontology (GO) terms related to the nucleus, whereas Cluster 4 was enriched for metabolism pathways and GO terms related to the endoplasmic reticulum (Fig 3C and D), suggesting that mitotic state is driving the major transcriptional feature distinguishing stem cell spheroids from dmPGE₂- or EP4i-treated spheroids. We validated that PGE₂- and EP4i-treated cells were post-mitotic by assessing proliferation with an EdU incorporation assay (Fig 3E and F) and a spheroid proliferation reporter line (Cdc25a-CRBLuc; Fig 3G; Sun *et al.*, 2015). Additionally, the mRNA levels of the intestinal stem cell marker

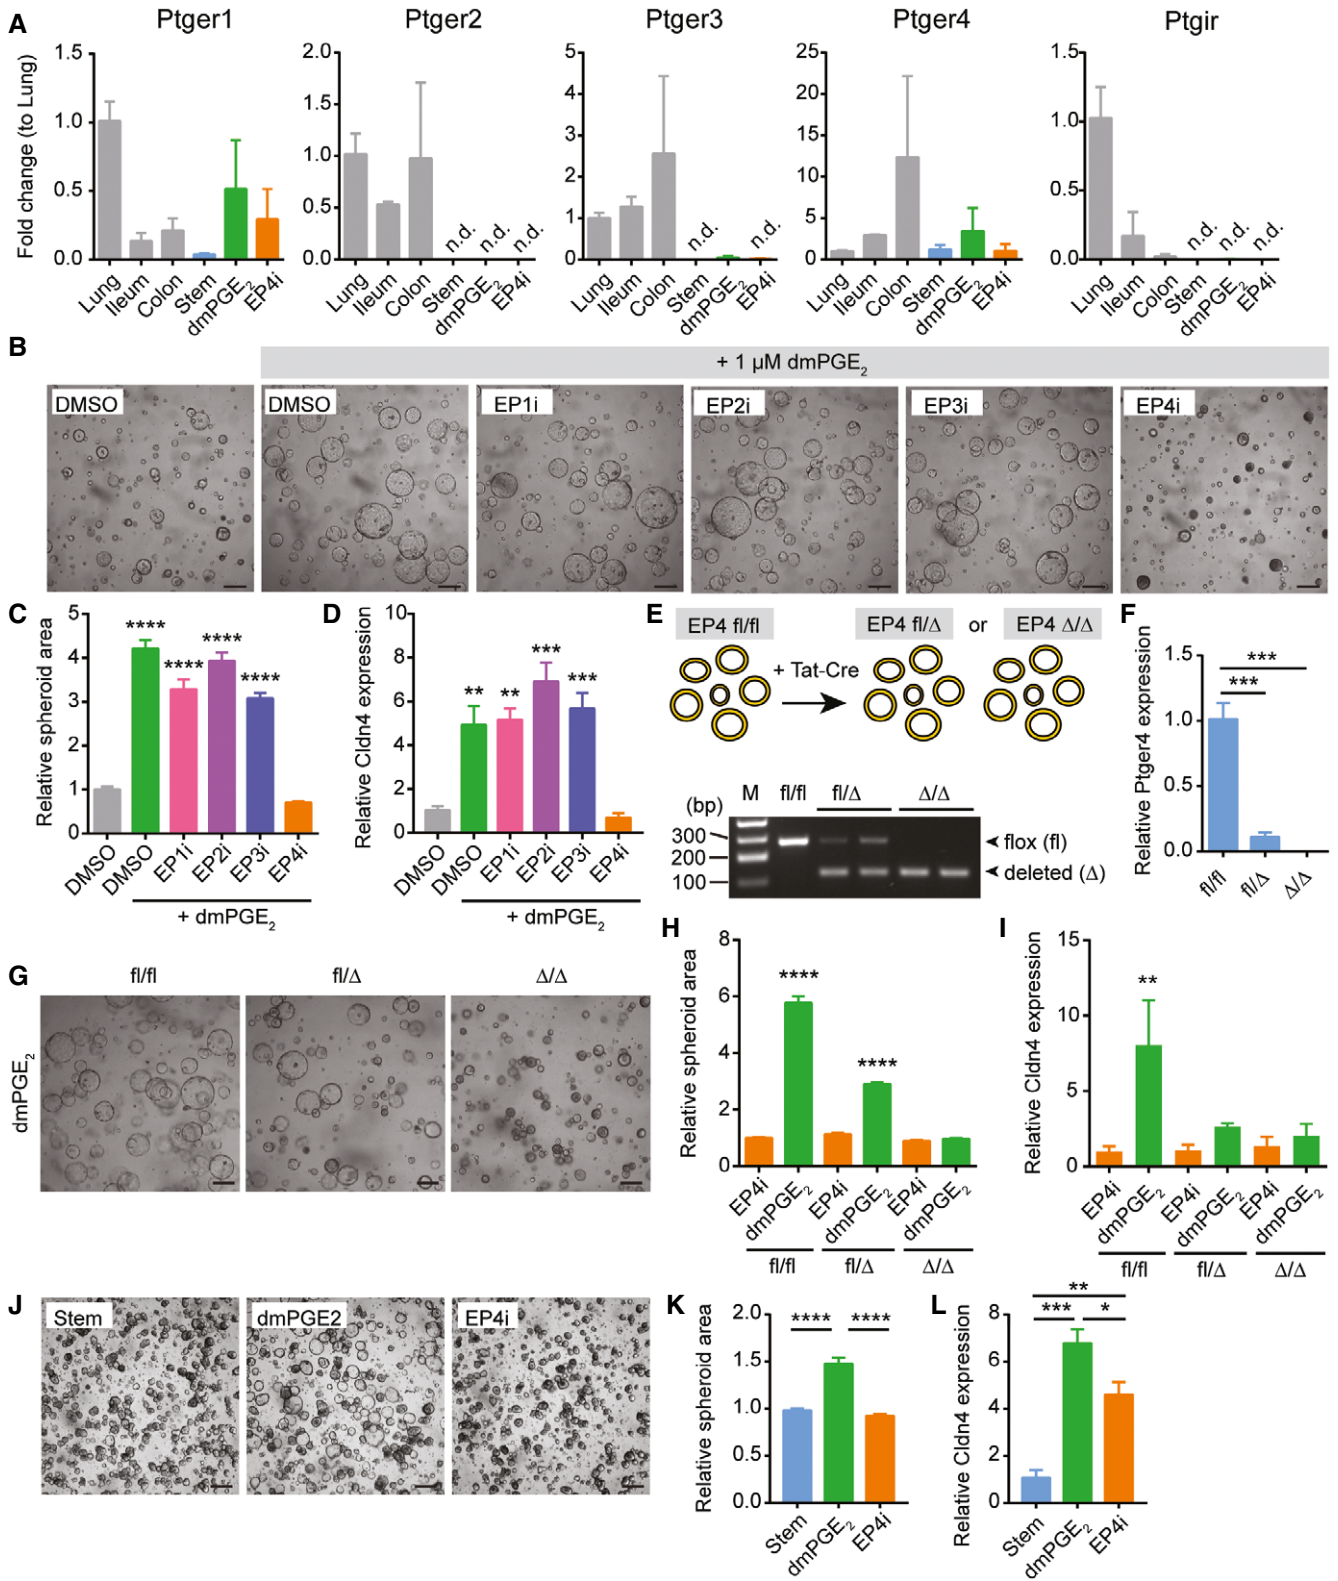

Figure 2.

leucine-rich repeat containing G protein-coupled receptor 5 (Lgr5) (Barker *et al*, 2007) and the proliferation marker antigen identified by monoclonal antibody Ki-67 (Mki67) (Iatropoulos & Williams,

1996) were lower in PGE₂- and EP4i-treated spheroids than stem cells (Fig 3H). We also found that dmPGE₂ treatment had no obvious effects on the proliferation of stem cell spheroids (Appendix Fig S2).

(J) Representative bright-field images. Scale bars, 200 μ m. (K) Quantification of average spheroid area \pm s.e.m. ($n = 4$ images with a minimum of 50 spheroids counted per group from three independent donor lines examined over 3 passages each) and (L) the average expression \pm s.e.m. of CLDN4 mRNA ($n = 3$ independent donor lines) relative to stem spheroids.

Two gene clusters discriminated PGE₂-treated cells, Cluster 5 (616 probes) and Cluster 6 (701 probes) (Fig 3B). These clusters contained genes associated with focal adhesion, cell junction organization, regulation of actin cytoskeleton, and the MAPK and Rap1 signaling pathways (Fig 4A and B). These functions and pathways are consistent with the migratory properties of WAE cells (Dignass, 2001; Blikslager et al, 2007).

To confirm that *in vitro* WAE cells were transcriptionally similar to *in vivo* WAE cells, we compared the gene sets from Cluster 5 and Cluster 6 to previous microarray data obtained from laser capture microdissected WAE cells that covered colonic biopsy wounds (Miyoshi et al, 2012). We found a statistically significant overlap of the *in vivo* and *in vitro* WAE cell gene sets ($P = 0.0026$) by hypergeometric probability test and similar pathway overrepresentation (Fig 4C). One difference between these two data sets was that the *in vivo* WAE cell cluster was additionally enriched for genes associated with cytokine and chemokine signaling pathways, which was likely a consequence of the inflammatory response that occurred in the wound bed. These data suggest that small intestinal WAE cells generated *in vitro* have similarity to colonic WAE cells *in vivo*.

Cellular markers to distinguish WAE cells are lacking. We previously reported Cldn4 protein expression in WAE cells *in vivo* (Seno et al, 2009). We confirmed this expression pattern in WAE cells generated *in vitro* (Fig 4D). Cldn4 mRNA robustly distinguishes dmPGE₂- and EP4i-treated spheroids, but is also expressed in stem cell-enriched spheroids (Fig EV1). Despite this, mitotic state (Fig 3) and morphology (Fig EV1) can be used to distinguish stem and WAE spheroids. Thus, we used our transcriptional profiling data to identify additional mRNA markers that were enriched in dmPGE₂-treated spheroids as compared to both stem and EP4i-treated spheroids. We validated the genes diffuse panbronchiolitis critical region 1 (Dpcri1) and CD55 decay accelerating factor for complement B (Cd55b; also known as Daf2) as novel mRNA markers for WAE cells that were induced by PGE₂ signaling through EP4 receptor in mouse and human small intestinal epithelial cells as well as mouse colonic epithelial cells (Figs 4E and F, and EV2).

To further confirm that *in vitro* WAE cells resembled *in vivo* WAE cells, we next compared their ultrastructure and histology. Cells treated with dmPGE₂ had an increased cytoplasmic to nuclear ratio compared to spheroid stem cells and an apical brush border (although the microvilli were short), consistent with being a

- H Quantification of the average expression \pm s.e.m. of Lgr5 and Mki67 mRNAs in jejunal spheroids cultured in stem cell (Stem) or in differentiation medium with the indicated supplements relative to the stem cell group ($n = 3$ independent experiments). **** $P < 0.01$, **** $P < 0.0001$** by one-way ANOVA and Dunnett's post-test. n.d., not detected.

β -catenin to visualize the plasma membrane. The dmPGE₂-treated spheroids were composed of flattened, squamous cells with thin apical F-actin staining, similar to *in vivo* WAE cells (diclofenac-induced ulcer) (Fig 4K). Together, these data demonstrate that the transcriptional, histological, and ultrastructural features of the WAE cells generated *in vitro* upon dmPGE₂ treatment closely resemble WAE cells observed *in vivo*.

Inhibition or absence of PGE₂-EP4 signaling leads to enterocyte differentiation

We noted that the EP4i-treated cells exhibited a columnar shape and apical enrichment for F-actin, features consistent with enterocytes (Fig 5A; Crawley *et al*, 2014). Therefore, we analyzed the genes most highly enriched after EP4i treatment and found many genes known to be highly enriched in enterocytes, including *Fabp1*, *Ace2*, and *Maoa* (Iemhoff & Hulsmann, 1971; Gordon *et al*, 1985; Sivasubramaniam *et al*, 2003; Hamming *et al*, 2004; Narisawa *et al*, 2007). We used quantitative PCR to validate the enrichment of these mRNAs in the EP4i-treated spheroids (mouse and human; Figs 5B and EV2) and immunostaining to validate the expression of *Ace2* protein (Fig 5C) in the EP4i-treated spheroids. For mouse colonic spheroids, we validated that EP4i treatment resulted in induction of a colonocyte marker, *Car4* (Kaiko *et al*, 2016; Fig EV2). Pathway and GO term analysis of the gene cluster specifically associated with EP4i treatment (Cluster 3; 289 probes) showed enrichment for functions associated with mitochondria, including metabolism, TCA cycle, respiratory electron transport, and oxidative phosphorylation pathways (Fig 5D and E). Ultrastructure analysis of EP4i-treated cells showed that these cells had a columnar shape, basally located nucleus, large cytoplasm with abundant mitochondria, and a well-developed brush border composed of long, densely packed microvilli (Figs 4H and I, and 5F and G). These features were all consistent with enterocytes (Cheng & Leblond, 1974a; Crawley *et al*, 2014).

We used the Seahorse Bioscience assay to test the differences in oxidative phosphorylation predicted by microarray. We found a higher oxidation consumption rate to extracellular acidification rate (OCR/ECAR) ratio with EP4i-treated cells as compared to stem cells or PGE₂-treated cells (Fig 5H), suggesting that EP4i-treated cells favor oxidative phosphorylation. This result is consistent with a recent report demonstrating greater OCR/ECAR ratio in differentiating daughter cells compared to *Lgr5*-positive intestinal stem cells (Fan *et al*, 2015). We also assessed secretory

cells (endocrine, goblet, and Paneth cells) in the EP4i-treated spheroids and found that these constituted a very small proportion (~5%) of the total cell number (Fig EV3). Overall, the transcriptional analysis and its validation suggested that PGE₂-EP4 signaling regulates a cell fate decision primarily between enterocytes and WAE cells.

PGE₂ treatment dominates cell fate plasticity

We next tested whether the cell fate choice between WAE cells and enterocytes was permanent. To do this, we first determined the time course of differentiation; mRNA expression levels of WAE cell genes (*Dpcr1* and *Cd55b*) and enterocyte genes (*Fabp1* and *Ace2*) were assessed at 2, 6, 12, and 24 h after starting treatment with differentiation medium containing dmPGE₂ or EP4i. The WAE cell mRNAs were detected by 6 h of treatment (Fig 6A). In contrast, enterocyte mRNA induction did not occur until 12–24 h of treatment (Fig 6B). These results suggest that WAE cell genes are rapidly and directly induced by EP4 signaling, whereas enterocyte genes are more slowly induced, likely indicative of a transcriptional cascade orchestrating enterocyte differentiation. To test whether expression of these markers was permanent, we treated spheroids with either dmPGE₂ or EP4i for 12 h. We then washed out the media and re-fed with the opposing treatment for an additional 12 h. If spheroids were treated during the second 12-h period with dmPGE₂, then the WAE cell markers *Dpcr1* and *Cd55b* were expressed, regardless of the treatment during the initial 12 h (Fig 6C). In contrast, the enterocyte markers *Fabp1* and *Ace2* were suppressed if spheroids were treated with dmPGE₂ in either phase (Fig 6D). These results indicate that PGE₂ is a potent inhibitor of enterocyte differentiation that irreversibly alters epithelial cell fate.

We observed that dmPGE₂ was unable to induce WAE cells in EP4-deficient spheroids (Figs 2 and 6E). This finding led us to next interrogate whether these cells were instead directed to the enterocyte fate. We found that the enterocyte markers *Fabp1* and *Ace2* were similarly induced following dmPGE₂ or EP4i treatment in EP4-deficient cells (Fig 6F), suggesting that the enterocyte program is the default differentiation pathway. Moreover, these data further support that, during the response to injury, PGE₂ not only augments the WAE program of differentiation but also suppresses the enterocyte program of differentiation. Of note, EP4 heterozygous spheroids exhibited an intermediate phenotype, with partial induction of both WAE and enterocyte markers (Figs 2 and 6E and F). These data suggest that a certain threshold of PGE₂-EP4 signaling must be met

for full suppression of enterocyte differentiation and full activation of WAE cell differentiation.

Inhibition of GSK-3 β suppresses enterocyte differentiation

We next investigated the cellular signaling events that occur downstream of the EP4 receptor to direct differentiation to the WAE cell

lineage. EP4 signaling is known to activate adenylate cyclase followed by cAMP formation (Konya *et al*, 2013). We confirmed this in our system by treating spheroids with forskolin, an adenylate cyclase activator. This treatment stimulated the WAE cell-associated morphological alterations and induced Cldn4 mRNA in small intestinal spheroids (Fig 7A and B). The morphologic effects were similar to previous reports using forskolin (Dekkers *et al*, 2013; Schwank

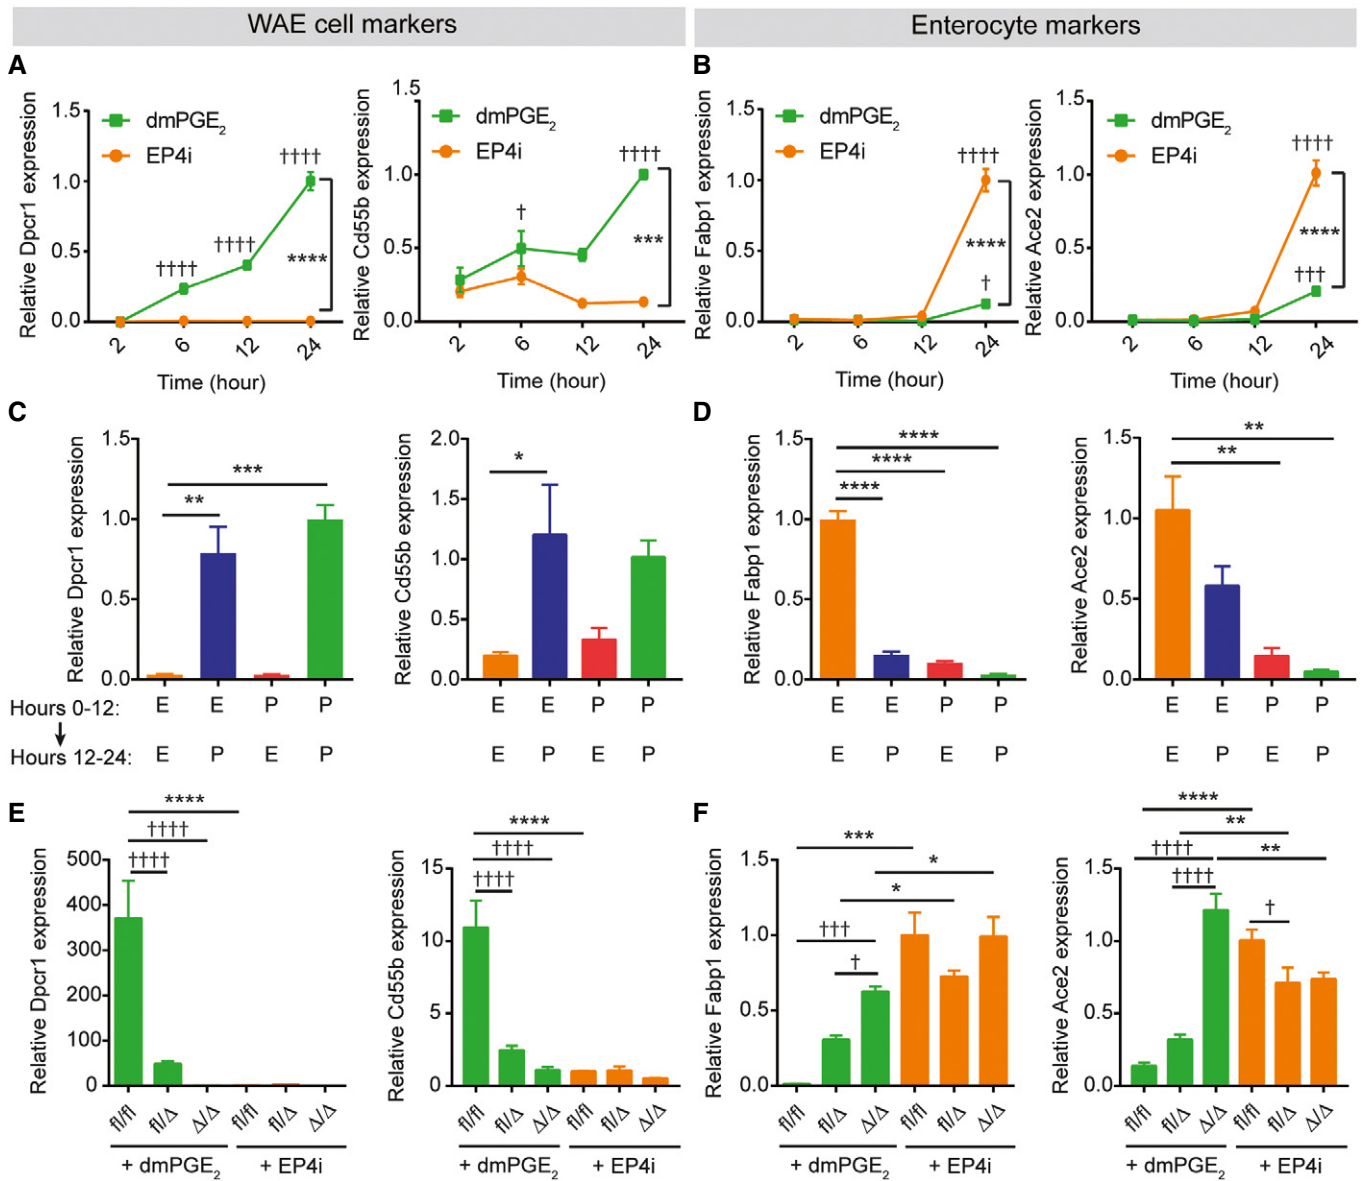

Figure 6. PGE₂-EP4 signaling controls a differentiation switch between wound-associated epithelial cells and enterocytes.

A–D Quantification of the average expression ± s.e.m. of Dpccr1 and Cd55b mRNAs (A, C) or Fabp1 and Ace2 mRNAs (B, D) in mouse jejunal spheroids cultured in differentiation medium containing EP4i or dmPGE₂. (A, B) Gene expression analyzed 2, 6, 12, or 24 h after the start of treatment (*n* = 3 independent experiments). ****P* < 0.001, *****P* < 0.0001 comparing the two treatment groups and †*P* < 0.05, †††*P* < 0.001, ††††*P* < 0.0001 compared to the 2-h time point of the same medium by two-way ANOVA and Sidak's multiple comparisons test. (C, D) Gene expression was analyzed after culturing spheroids in EP4i (E) or dmPGE₂ (P) for the first 12 h followed by washout and re-feeding with EP4i or dmPGE₂ for the second 12 h as shown (*n* = 3 independent experiments). **P* < 0.05, ***P* < 0.01, ****P* < 0.001, and *****P* < 0.0001 by one-way ANOVA and Dunnett's post-test.
 E, F Gene expression was analyzed in *Ptger4*^{fl/fl}, *Ptger4*^{fl/Δ}, and *Ptger4*^{Δ/Δ} spheroids and expressed as fold change relative to EP4i-treated *Ptger4*^{fl/fl} (*n* = 3 independent experiments). **P* < 0.05, ***P* < 0.01, ****P* < 0.001, *****P* < 0.0001 by two-way ANOVA and Tukey's post-test comparing the genotypes within a treatment group. †*P* < 0.05, ††*P* < 0.01, †††*P* < 0.001, ††††*P* < 0.0001 by two-way ANOVA and Sidak's post-test comparing the effects of the treatments within a genotype.

et al, 2013). cAMP is known to activate a multitude of effector proteins. Because of the abundant transcript differences and the altered differentiation states between PGE₂- and EP4i-treated cells, we reasoned that a transcriptional regulator would be altered downstream of PGE₂-EP4 signaling. We took a candidate approach based on the literature and focused on glycogen synthase kinase-3β (GSK-3β), as several lines of evidence have indicated that PKA signaling

(a target of cAMP) can suppress GSK-3β (Jensen *et al*, 2007; Hundsrucker *et al*, 2010; Whiting *et al*, 2015). GSK-3β phosphorylates β-catenin and promotes its degradation (Krausova & Korinek, 2014). Therefore, we determined protein levels of nuclear β-catenin in spheroids cultured as stem cells or cultured in differentiation medium and treated with dmPGE₂ or EP4i (Figs 7C and EV4). As expected, significant levels of nuclear β-catenin were detected in

stem cell spheroids but not in EP4i-treated spheroids. This is consistent with canonical Wnt signaling *in vivo*, which is active in intestinal stem cells and inactive in enterocytes (Clevers, 2013; Krausova & Korinek, 2014). Interestingly, dmPGE₂-treated spheroids exhibited high levels of nuclear β -catenin that were similar to those in stem cell spheroids. To functionally test whether inhibition of GSK-3 β could recapitulate the effects of dmPGE₂, we treated spheroids with the GSK-3 β inhibitor CHIR 99021 in addition to EP4i (to ensure inhibition of endogenous PGE₂ signaling). CHIR 99021 inhibited the degradation of nuclear β -catenin (Figs 7D and EV4). CHIR 99021 also suppressed mRNA expression of the enterocyte marker *Fabp1* and induced mRNA expression of the WAE cell marker *Cldn4* in a dose-dependent manner (Fig 7E and F). Histological analysis of *Ptger4* ^{Δ/Δ} spheroids showed that the accumulation of actin filaments on the apical surface observed in DMSO-treated spheroids was abolished by CHIR 99021 (Fig 7G). Together, these results indicate that PGE₂ suppresses enterocyte differentiation to promote WAE cell differentiation through maintenance of nuclear β -catenin.

We considered that active canonical Wnt signaling could cause nuclear β -catenin localization in WAE cells (Krausova & Korinek, 2014). As the differentiation medium used to generate WAE cells does not contain Wnt ligands, we tested whether the WAE-enriched spheroids were secreting and responding to Wnts in a cell-autonomous manner. Our microarray data highlighted mRNAs encoding several Wnt ligands that were potentially expressed in the PGE₂-treated cells (Appendix Fig S3). Due to functional redundancy among Wnt ligands, we chose to block all Wnt secretion with a pharmacological inhibitor of porcupine, an essential enzyme for Wnt lipidation and secretion (Proffitt *et al.*, 2013). We first determined the effective concentration of porcupine inhibitor using the L-WRN cell line because these cells abundantly secrete Wnt3a (Miyoshi *et al.*, 2012). L-WRN cells were cultured in the presence or absence of the porcupine inhibitor C59 to generate conditioned media. These media were applied to 293FT cells expressing the TOP/FOPFlash luciferase reporter system to measure the Wnt signaling activity (Fig 7H). C59 concentrations from 10 μ M to 100 pM potently inhibited Wnt secretion by L-WRN cells.

We next tested whether C59 had an inhibitory effect on the formation of WAE cells. We found that spheroids treated with PGE₂ and C59 had a similar induction of *Cldn4* mRNA as those treated with PGE₂ alone (Fig 7I), and low expression levels of *Fabp1* mRNA were observed in both of these treatment groups compared to EP4i-treated spheroids (Fig 7J). These data show that WAE differentiation in the spheroids is not mediated by cell-autonomous Wnt signaling. Furthermore, they suggest that a mechanism other than canonical Wnt signaling is driving the accumulation of nuclear β -catenin in WAE cell spheroids. Accordingly, we observed that the mRNA levels of *Axin2*, a transcriptional readout for canonical Wnt signaling (Jho *et al.*, 2002; Lustig *et al.*, 2002), were extremely low in WAE cells compared to stem cells (Fig 7K).

EP4 is required for WAE cell differentiation and wound healing *in vivo*

We have shown that PGE₂ is sufficient to form WAE cells using our *in vitro* model. However, there are many factors that have been proposed to affect intestinal epithelial restitution (Dignass, 2001) and these or others could potentially compensate for loss of PGE₂-EP4 signaling *in vivo*. Thus, to test the requirement for EP4-mediated signaling to form WAE cells during wound healing, we utilized a colonic biopsy injury model (Seno *et al.*, 2009; Manieri *et al.*, 2012, 2015; Miyoshi *et al.*, 2012). We chose this model because the location and timing of injury and mucosal healing is controlled and well understood (Seno *et al.*, 2009). To examine the role of PGE₂-EP4 signaling in the intestinal epithelium, we bred *Ptger4*^{fl_{ox}/fl_{ox}} mice (Schneider *et al.*, 2004) with *Vil*^{Cre} mice (Madison *et al.*, 2002) and generated mice that were deficient for *Ptger4* expression specifically in intestinal epithelial cells (*Vil*^{Cre} *Ptger4*^{fl_{ox}/fl_{ox}}). *Vil*^{Cre} *Ptger4*^{fl_{ox}/fl_{ox}} and *Ptger4*^{fl_{ox}/fl_{ox}} littermate controls were biopsy-injured and wound repair was assessed 4 days post-injury, a time at which WAE cells should completely cover the wound surface (Seno *et al.*, 2009). Although similar numbers of crypts were initially removed during biopsy injury, we consistently observed decreased healing in the *Vil*^{Cre} *Ptger4*^{fl_{ox}/fl_{ox}} mice

compared to the controls 4 days post-injury by whole-mount microscopy (Fig 8A and B), suggesting impaired or delayed healing. In addition, fibrin clots were frequently found to be covering the

wound surface in *Vil^{Cre} Ptger4^{lox/lox}* mice to a greater extent than control mice (Fig 8C). Histological analysis of wounded regions showed that a layer of flattened, *Cldn4*-positive cells was covering

Figure 7.

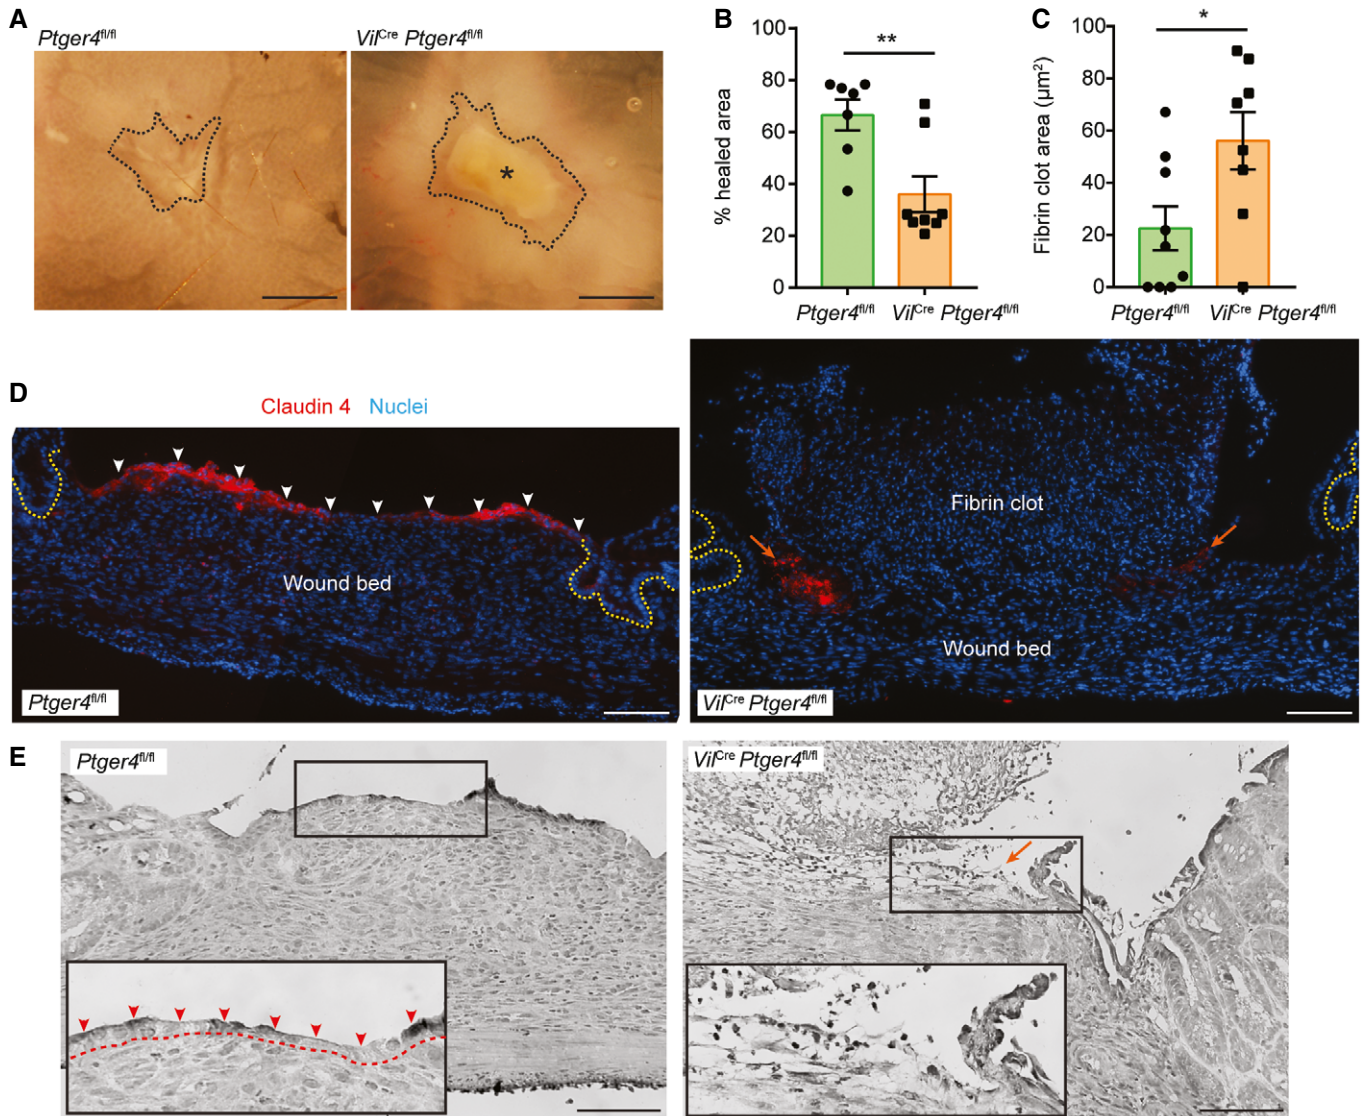

Figure 8. Intestinal epithelium deficient for *Ptger4* lacks wound-associated epithelial cells and has delayed wound repair following biopsy injury.

A Representative whole-mount images of wounds from *Ptger4^{fllox/fllox} (Ptger4^{fl/fl})* and *Vil^{Cre} Ptger4^{fllox/fllox} (Vil^{Cre} Ptger4^{fl/fl})* mice 4 days post-biopsy injury. Scale bars, 750 μm . Wounds are outlined with a black dashed line. Asterisk indicates fibrin clot.

B, C Quantification of percent healing ($1 - [\text{day 4 wound area}/\text{original wound area}] \times 100$) (B) and fibrin clot areas (C) \pm s.e.m. ($n = 7-8$ mice per genotype with 3-4 wounds each, three independent experiments). * $P = 0.0270$, ** $P = 0.0057$ by two-tailed unpaired t-test.

D, E Representative images of serial wound tissue sections from the indicated genotypes. (D) Fluorescent images of sections stained for Claudin-4 (red). Nuclei are visualized with bisbenzimidazole (blue). Epithelial crypts adjacent to the wound bed are indicated by dashed yellow lines. Layer of adherent WAE cells indicated by white arrowheads. Non-adherent residual WAE cells indicated by orange arrows. (E) Grayscale images of hematoxylin- and eosin-stained sections. Insets of the boxed regions show a higher magnification of the region typically containing WAE cells (red arrowheads, dashed line indicates border with wound bed). Orange arrow indicates region of non-adherent residual WAE cells. Scale bars, 100 μm .

the wound surface in control injured mice (Fig 8D and E). These wound surface cells also exhibited accumulation of nuclear β -catenin (compared to surface epithelial cells of uninjured regions of colonic tissue), lacked *Axin2* and *Lgr5* expression, and were non-proliferative, similar to *in vitro* WAE cells (Fig EV5). In contrast, a layer of flattened, *Cldn4*-positive epithelial cells was lacking at the *Vil^{Cre} Ptger4^{fllox/fllox}* wound surfaces (Fig 8D and E). Instead, *Cldn4*-positive cells were only located at the edge of the wound and were frequently non-adherent. These data confirm that

expression of EP4 in the intestinal epithelium is critical for complete covering of the wound bed with WAE cells and proper epithelial restitution in response to intestinal biopsy injury.

Discussion

We identified the prostaglandin PGE₂ as a factor that is necessary and sufficient to promote WAE differentiation and wound repair

after mucosal injury. In the older literature, flattened, migratory epithelial cells were shown to be responsible for quickly re-establishing the epithelial barrier after mucosal injury (Svanes *et al*, 1982; Ito *et al*, 1984; Lacy, 1988; Moore *et al*, 1989). Subsequent tracing experiments showed that WAE cells emanate from crypt stem cells adjacent to the wound bed (Miyoshi *et al*, 2012). Here, we identified PGE₂ as a potent inductive factor that directly acts on crypt epithelial cells to produce this atypical epithelial cell type. This mechanism appears to be conserved in mouse and human. Primary columnar intestinal epithelial cells cultured with PGE₂ rapidly transitioned to a squamous cell shape and induced WAE cell markers within 2–6 h after treatment. Inhibition of the EP4 receptor in intestinal epithelial cells either pharmacologically or by genetic deficiency abolished these effects and impaired wound healing *in vivo*. We showed that WAE cells were post-mitotic and exhibited transcriptional and ultrastructural features consistent with *in vivo* WAE cells. Our findings agree with early epithelial restitution studies, which also reported the short time frame of this process and indicated a

primary dependence on cellular migration that was independent of cellular proliferation (Lacy, 1988; Wilson & Gibson, 1997; Dignass, 2001). Thus, our work highlights the unique nature of the gastrointestinal wound response and WAE cells in particular. In contrast, skin wound healing requires dedifferentiation of epidermal cells and migration of this proliferative cell type to cover and re-epithelialize wound surfaces (Singer & Clark, 1999; Gurtner *et al*, 2008).

We found that PGE₂ suppressed the enterocyte differentiation program and redirected differentiating intestinal epithelial cells to the WAE cell lineage. In the intestine, stem cells located at the crypt base continually produce daughter cells that migrate out of the crypt and onto the villus to replenish the intestinal epithelium. Our data suggest that PGE₂ produced in response to injury can direct intestinal stem cells, progenitor cells, and/or immature enterocytes to the WAE lineage. Addition of PGE₂ 12 h into the differentiation process could still activate WAE cell differentiation. Thus, the continually renewing intestinal epithelium provides a perpetual source of cells that, when called upon, can rapidly acquire a migratory phenotype and act to

Figure 9. Model of wound-associated epithelial cell formation in response to mucosal injury.

In the absence of injury, PGE₂-EP4 signaling does not reach the signal threshold required for WAE cell formation, and enterocytes differentiate from intestinal epithelial stem cells in accordance with their normal program of differentiation. Upon mucosal injury, Ptgs2-expressing mesenchymal cells become localized to the wound bed in close proximity with the migrating WAE cells. High local production of PGE₂ signals to the EP4 receptor on differentiating intestinal epithelial cells to induce formation of WAE cells, which migrate to cover and seal the wound bed, thereby re-establishing the epithelial barrier.

cover wound surfaces. It is important to note that the presence of WAE cells is transient and typically lasts only a few days (Seno *et al*, 2009; Miyoshi *et al*, 2012). In addition, once epithelial cell commitment to the WAE lineage has been triggered by PGE₂, enterocyte differentiation is irreversibly blocked. We propose that the quick onset and durability of WAE differentiation is a protective mechanism for the host. Once a wound is sealed by WAE cells, prostaglandins diminish (Manieri *et al*, 2012). The WAE cells are then rapidly replaced by newly formed enterocytes during the later phase of repair.

Cross talk between mesenchymal cells and epithelial cells is critical for wound repair in the intestine. We have previously reported that intestinal injury results in activation and enrichment of mesenchymal stem cells that express Ptg2, the rate-limiting enzyme for PGE₂ production, in close proximity to the crypts adjacent to injured regions and migrating WAE cells (Brown *et al*, 2007; Malvin *et al*, 2012; Manieri *et al*, 2012). Proper activation and positioning of the Ptg2-expressing cells is dependent both on injury and Myd88 signaling (Brown *et al*, 2007; Malvin *et al*, 2012). Taken together with the current study, we propose the following model for the early repair process (Fig 9): (i) Mucosal injury results in activation of TLR/Myd88 signaling in the stromal compartment, (ii) TLR/Myd88 signaling activates and enriches for Ptg2-positive cells at the site of injury to stimulate high local production of PGE₂, (iii) PGE₂ signals to several local target cell populations, including intestinal epithelial cells, to mediate the repair response, (iv) PGE₂ signals through the EP4 receptor to direct intestinal stem cells, progenitor cells, and likely immature enterocytes to form WAE cells. This mechanism allows the intestinal epithelium to rapidly mount an adequate early repair response and form sufficient numbers of WAE cells without relying on cellular proliferation.

We found accumulation of nuclear β -catenin in WAE cells, and this was functionally important for their formation. In the intestine, Wnt/ β -catenin signaling is critical for maintenance of the intestinal epithelial stem cell compartment (Krausova & Korinek, 2014). Inducible loss of β -catenin in the intestinal epithelium results in rapidly diminished proliferation and differentiation of stem cells (Ireland *et al*, 2004; Fevr *et al*, 2007), whereas forced β -catenin expression results in polyp and tumor formation (Wong *et al*, 1996, 1998; Harada *et al*, 1999; van Es *et al*, 2005). Thus, it is challenging to genetically manipulate β -catenin signaling *in vivo* or *in vitro* within a time frame that allows for the study of its role in WAE cells and intestinal wound repair. Instead, we used a GSK-3 β inhibitor to treat spheroid epithelial cells deficient in EP4 and showed that the resulting accumulation of nuclear β -catenin was sufficient to suppress enterocyte gene induction and promote WAE cell formation. There is an accumulating body of evidence linking cell adhesive and migratory properties with alterations in β -catenin signaling (Daugherty & Gottardi, 2007; Maher *et al*, 2009; Amini-Nik *et al*, 2014). As WAE cells are migratory and exhibit high levels of nuclear β -catenin, our data provide further support of this literature. However, as canonical Wnt signaling was not active in WAE cells, some factor other than canonical Wnt ligands (e.g. extracellular matrix components) (Bielefeld *et al*, 2011) must be critical for regulating β -catenin in these cells. Further study of the transcriptional mechanisms that regulate WAE cells could yield new insights into the relationship between cell adhesiveness and β -catenin signaling.

EP4 agonist treatment has been shown to provide a beneficial effect in rodent models of colitis (Kabashima *et al*, 2002; Nitta *et al*,

2002; Jiang *et al*, 2007; Okamoto *et al*, 2012; Watanabe *et al*, 2015) and in a Phase II trial with ulcerative colitis patients (Nakase *et al*, 2010). Accordingly, there is interest in the potential for using EP4 agonists to treat inflammatory bowel disease patients. Although the beneficial effects of EP4 agonists are likely mediated through multiple EP4-expressing cell types, our data suggest that one benefit could be an improved wound repair response of the intestinal epithelium. We found that Ptg2 expression levels were critical for WAE cell formation. Intestinal spheroids heterozygous for *Ptger4* exhibited a haploinsufficiency phenotype, with impaired WAE cell formation and skewing toward the enterocyte lineage. These data are intriguing because *PTGER4* is the closest gene to one of the most significant susceptibility loci for inflammatory bowel disease (Jostins *et al*, 2012; Liu *et al*, 2015). SNPs within this locus have been proposed to regulate *PTGER4* gene expression (Libiouille *et al*, 2007; Glas *et al*, 2012); however, it is currently unknown how this susceptibility region contributes to disease. *PTGS2* (aka COX-2) has also been implicated as a candidate susceptibility gene for inflammatory bowel disease in a recent meta-analysis of patients of European descent (Liu *et al*, 2015). Thus, we speculate that genetic variations at these loci could potentially affect PGE₂-EP4 signaling in human intestinal epithelial cells, leading to inter-individual variation in the ability to form WAE cells and efficiently repair wounds upon mucosal damage.

Materials and Methods

Mice

All animal studies were performed according to protocols approved by the Washington University School of Medicine Animal Studies Committee. Mice were maintained in a specific pathogen-free barrier facility with a strict 12-h light cycle. Experiments utilized mice that were 8–10 weeks old. *Vil^{Cre}* mice (Madison *et al*, 2002) obtained from Jackson Laboratory (Bar Harbor, ME) were crossed to previously described *Ptger4^{flox/flox}* mice (Schneider *et al*, 2004) to generate intestinal epithelium with *Ptger4^{flox/flox}*, *Ptger4^{flox/ Δ}* , or *Ptger4 ^{Δ / Δ}* genotype. All experimental mice were littermates on the C57BL/6 background. The following primers were used for PCR genotyping: *Vil^{Cre}* forward primer 5'-gtg tgg gac aga gaa caa acc-3'; *Vil^{Cre}* reverse primer 5'-aca tct tca ggt tct gcg gg-3'; *Ptger4* locus forward primer 5'-gtg cgg aga tcc aga tgg tc-3'; *Ptger4* locus reverse primer 5'-cgc act ct tct ctc cca agg aa-3'. Lgr5-EGFP-IRES-creERT2 mice (Barker *et al*, 2007) were obtained from the Jackson Laboratory.

Colonic biopsy and tissue preparation

Colorectal injuries (3–4 wounds/mouse) were created using a high-resolution miniaturized colonoscope as previously described (Seno *et al*, 2009; Manieri *et al*, 2012, 2015). Mice were sacrificed 4 days after biopsy injury unless stated otherwise. Dissected colons were opened longitudinally to obtain images of the mucosal gross morphology using an Olympus SZX12 stereo dissection microscope equipped with an Olympus DP70 digital camera and DP Controller software. Tissues fragments (10 \times 10 mm) with the wound located at the center were then frozen in OCT. Perpendicular serial 5- μ m sections from the center of each wound were prepared with a

cryostat and used for later analysis. Wound and fibrin clot areas were determined with ImageJ (Schneider *et al*, 2012). Percent healing was determined as $(1 - [\text{wound area on day 4}/\text{original wound area}] \times 100)$. Adobe Photoshop CS6 was used to uniformly adjust the brightness and contrast and crop images.

Spheroid culture of primary small intestinal epithelial cells

For mouse spheroid culture, small intestinal or colonic crypts were isolated from the jejunum of the indicated mice and grown as three-dimensional epithelial spheroids in Matrigel as previously described (Miyoshi *et al*, 2012; Miyoshi & Stappenbeck, 2013). For human spheroid cultures, spheroid lines were established from biopsy tissues obtained from three adults during routine endoscopy at the Washington University School of Medicine. This study was approved by the Institutional Review Board of Washington University School of Medicine. Written informed consent was obtained from all donors. The procedures for establishing and maintaining the human spheroid cultures have been previously described (VanDussen *et al*, 2015).

Stem cell media contained 50% L-WRN conditioned medium, which is a 50/50 mix of L-WRN conditioned medium (CM) (collected from an L cell line engineered to secrete Wnt3a, R-spondin 3, and noggin as previously described (Miyoshi & Stappenbeck, 2013) and fresh primary culture media, which is Advanced DMEM/F-12 (Invitrogen) supplemented with 20% fetal bovine serum, 2 mM L-glutamine, 100 units/ml penicillin, and 0.1 mg/ml streptomycin. Differentiation medium is primary culture medium without serum supplemented with 50 ng/ml EGF (Peprotech) and 10 μ M Y-27632 (ROCK inhibitor; R&D Systems). For WAE cell medium, differentiation medium was supplemented with 1 μ M dmPGE₂ (R&D Systems), unless indicated otherwise. For enterocyte medium, differentiation medium was supplemented with 10 μ M L-161,982 (EP4 inhibitor, R&D Systems). To induce synchronized differentiation, stem cell-enriched spheroids were trypsinized, plated into fresh Matrigel in 24-well or 96-well tissue culture plates, and then grown in differentiation medium containing the indicated supplements for 24 h.

Other cell culture reagents used were SC 51322 (EP1 inhibitor; R&D Systems), PF 04418948 (EP2 inhibitor; R&D Systems), L-798,106 (EP3 inhibitor; R&D Systems), CHIR 99021 (GSK-3 β inhibitor; R&D Systems), iloprost (PGI₂ analog; Cayman Chemical), and Wnt-C59 (porcupine inhibitor; R&D Systems). Tat-Cre mediated recombination was used to generate *Ptger4*^{fllox/ Δ} and *Ptger4* ^{Δ / Δ} spheroid lines from *Ptger4*^{fllox/fllox} spheroids as previously described (Patel *et al*, 2013). For spheroid genotyping, genomic DNA was isolated with the Qiagen DNeasy Mini kit according to the manufacturer's instructions followed by PCR with the *Ptger4* genotyping primers listed above. The luminescence assay with spheroids generated from the jejunum of the Cdc25A-CBRLuc fusion protein knock-in mouse was performed as previously described (Sun *et al*, 2015). Metabolic profiling was performed using a Seahorse XF96e analyzer (Seahorse Bioscience) as previously described (Kaiko *et al*, 2016).

Live spheroids were imaged with a Pupil Cam camera (Ken-a-Vision) fixed to a phase microscope (Fisher Scientific) equipped with an LPL4/0.10 4 \times objective lens. ImageJ (Schneider *et al*, 2012) was used to determine the average individual spheroid area from bright-field images taken in the center of each tissue culture plate well of each sample ($n = 4$ four images [i.e. wells] and a minimum

of 50 spheroids analyzed per sample). Similar densities of spheroids were seeded for all area measurement experiments. Adobe Photoshop CS6 was used to convert images to grayscale, uniformly adjust brightness and contrast, and crop images.

Antibodies

The following antibodies were used for immunostaining: polyclonal goat anti-Ace2 (AF933, R&D Systems), polyclonal rabbit anti-ChgA (ab15160, Abcam), polyclonal rabbit anti-Muc2 (sc-15334, Santa Cruz), polyclonal goat anti-Lyz (sc-27958, Santa Cruz), polyclonal rabbit anti-Claudin-4 (36-4800, Thermo Fisher), monoclonal rabbit anti-Ki67 (VP-RM04, Vector), polyclonal rabbit anti- β -catenin (Sigma), and monoclonal mouse anti- β -catenin (14/B-catenin, BD Transduction Laboratories). F-actin was visualized with a rhodamine-phalloidin conjugate (Invitrogen). For immunoblotting, the following antibodies were utilized: anti-actin (A2066, Sigma), monoclonal mouse anti- β -catenin (14/B-catenin, BD Transduction Laboratories), mouse monoclonal anti-GAPDH (6C5, Advanced ImmunoChemicals), and monoclonal mouse anti-lamin A/C (clone 14, EMD Millipore).

Immunohistochemistry, immunofluorescence, and *in situ* hybridization

Dissected tissues or recovered intestinal spheroids were fixed with 4% paraformaldehyde (PFA) overnight at 4°C in phosphate-buffered saline (PBS), immersed in 20% sucrose solution, and then quickly frozen in OCT compound (Sakura Finetek) or embedded as unfixed tissues. Histological sections (4- μ m) were prepared and post-fixed with 4% PFA, 10% neutral buffered formalin, or methanol. Histological sections were incubated in blocking buffer (3% BSA or 10% normal serum and 1% Triton X-100 in PBS) followed by addition of diluted primary antibodies in blocking buffer. For immunofluorescence, sections were incubated with Alexa Fluor secondary antibodies conjugated to 488 or 594 fluorophores (Invitrogen), counterstained with bis-benzamide (Hoechst 33258; Invitrogen) and coverslips were mounted with Fluoromount (Sigma). For immunohistochemistry, sections were incubated with biotin-conjugated secondary antibodies (Vector Laboratories) followed by visualization with the VECTASTAIN Elite ABC and DAB (3,3'-diaminobenzidine) Substrate Kits (Vector Laboratories) and coverslips were mounted with Cytoseal XYL (Thermo Scientific). EdU detection was performed using the Click-iT Plus EdU imaging kit with Alexa Fluor 594 and a 1-h EdU incorporation period prior to fixation and embedding of spheroids (Molecular Probes, C10639). For the *in situ* hybridization, antisense probe was generated from a SmaI-digested *Ptger4* mouse cDNA plasmid (GE Dharmacon, Clone ID 3481696) using the T7 promoter and a previously reported probe for *Axin2* and methods (Miyoshi *et al*, 2012). Fluorescent images were acquired with a Zeiss Axiovert 200M inverted microscope equipped with Apochromat (10 \times /0.25 Ph1 and 20 \times /0.80) and LD-A-Plan 20 \times /0.30 Ph1 objective lenses, an AxioCam MRm digital camera, and Axiovision LE software. Bright-field images were acquired with an Olympus BX51 microscope equipped with UPlan 20 \times /0.50 and 10 \times /0.30 objective lenses, an Olympus DP70 camera, and DP Controller software. Adobe Photoshop CS6 was used to uniformly adjust brightness and contrast, sharpen and crop images.

Immunoblotting

Matrigel-embedded intestinal spheroids were first recovered using cell recovery solution (Corning). Next, the NE-PER Nuclear and Cytoplasmic Extraction Kit (Thermo Fisher Scientific) was used for fractionation of nuclear and cytoplasmic proteins in conjunction with protease inhibitors (Sigma) and phosphatase inhibitors (Nacalai). Denatured protein samples were run on 10% Tris–HCl gels (Bio-Rad) and transferred onto nitrocellulose membranes (Bio-Rad). Membranes were incubated in blocking reagent (Blocking One, Nacalai) for 1 h at 4°C, then incubated with primary antibodies diluted with Blocking One overnight at 4°C. Membranes were washed with Tris-buffered saline containing 0.1% Tween-20 (TBS-T) and incubated with horseradish peroxidase-conjugated secondary antibodies (Bio-Rad) before detecting signals using the SuperSignal West Dura chemiluminescent kit (Thermo Fisher Scientific).

Transmission electron microscopy

Spheroid–Matrigel mixtures were scraped out of the tissue culture plate wells with a pipette tip in 1 ml of PBS and centrifuged for 5 min at $113 \times g$ to pellet the cells. Mouse colon tissue and pelleted spheroids were fixed with 2% paraformaldehyde/2.5% glutaraldehyde in 100 mM cacodylate buffer, pH 7.2 for 2 h at room temperature. Samples were washed in cacodylate buffer and post-fixed in 1% osmium tetroxide (Polysciences Inc.) for 1 h. Samples were then rinsed extensively in dH₂O prior to en bloc staining with 1% aqueous uranyl acetate (Ted Pella Inc., Redding, CA) for 1 h. Following several rinses in dH₂O, samples were dehydrated in a graded series of ethanol and embedded in Eponate 12 resin (Ted Pella Inc.). Sections of 95 nm were cut with a Leica Ultracut UCT ultramicrotome (Leica Microsystems Inc., Bannockburn, IL), stained with uranyl acetate and lead citrate, and viewed on a JEOL 1200 EX transmission electron microscope (JEOL USA Inc., Peabody, MA) equipped with an AMT 8 megapixel digital camera (Advanced Microscopy Techniques, Woburn, MA). Adobe Photoshop CS6 was used to uniformly adjust brightness and contrast and crop images. ImageJ was used to quantify the cytoplasmic and nuclear areas of imaged cells as well as microvillar lengths.

RNA isolation and quantitative RT–PCR

Total RNA was purified using NucleoSpin RNA II kit (Macherey-Nagel, Duren, Germany). cDNA was synthesized using SuperScript III (Invitrogen), and qPCR was performed using SYBR Green reagents (Clontech, Palo Alto, CA) on an Eppendorf Mastercycler. Primer sequences are listed in Appendix Table S1. Relative expression levels were normalized to GAPDH or B2m (Miyoshi *et al*, 2012), which were expressed at similar levels in all samples.

Microarray analysis

RNA was isolated from spheroids cultured as described above ($n = 4$ /group). Samples were tested for quality with the Agilent Bioanalyzer followed by cDNA synthesis with the MessageAmp II kit and hybridization to Agilent $4 \times 44K$ mouse gene expression

microarrays at the Washington University Genome Technology Access Center (GTAC). Data are deposited at ArrayExpress (<http://www.ebi.ac.uk/arrayexpress/>; accession number E-MTAB-3952). Microarray data from *in vivo* laser capture microdissected WAE cells in wild-type mice were previously reported and deposited at ArrayExpress (accession number E-MTAB-1175; Miyoshi *et al*, 2012). Data normalization, statistical analysis, and hierarchical clustering were performed using Partek software. Genes considered to be significantly differentially expressed between at least two treatments had a false discovery rate-adjusted $P < 0.05$. Pathway and GO term analyses were performed using the ToppGene Suite (<https://toppgene.cchmc.org/>).

TOPFlash reporter assay

L-WRN cells were cultured in 24-well plates until post-confluent and then re-fed with primary culture medium containing C59 (concentration range from 10 μ M to 1 pM) or without C59 for 24 h. Conditioned mediums were collected as previously described from three independent passages of cells (Miyoshi & Stappenbeck, 2013). Prior to use in the reporter assay, these media were diluted with 293FT media. M50 Super8x TOPFlash (Addgene plasmid #12456) and M51 Super8x FOPFlash (TOPFlash mutant; Addgene plasmid #12457) were gifts from Randall Moon (Veeman *et al*, 2003). The reporters were transiently transfected into 293FT cells cultured in 24-well plates using Lipofectamine 2000 (Thermo Fisher Scientific) according to the manufacturer's directions. The following day, the 293FT cells were stimulated with the conditioned mediums for 24 h. Cell lysates (120 μ l total volume) were generated using $1 \times$ Cell Culture Lysis Buffer and luminescence (1 s reads) was measured using 20 μ l of cell lysate and 100 μ l of luciferase substrate (Luciferase Assay System; Promega) with a Cytation 5 Multi-mode Reader (BioTek). The total protein content of each sample was determined by BCA assay (Thermo Fisher Scientific) and used to perform initial normalization of luciferase activity values. These normalized values were then used to generate the TOP/FOPFlash ratios for each treatment.

Statistical analysis

GraphPad Prism software (version 6) was used to perform all statistical analyses unless indicated otherwise with $P < 0.05$ considered to be significant.

Acknowledgements

The authors thank Dr. Wandy Beatty for transmission electron microscopy. We thank the Genome Technology Access Center (GTAC) in the Department of Genetics at Washington University School of Medicine for help with genomic analysis. This work was supported by grants from the National Institutes of Health (NIH) (DK07161907) and the Crohn's and Colitis Foundation of America (CCFA) Genetics Initiative/Leona M. and Harry B. Helmsley Charitable Trust (# 274415) to T. S. Stappenbeck. K. L. VanDussen was supported by a CCFA Research Fellowship Award (# 290895) and a K01 from the NIH (DK109081). The GTAC is partially supported by the NCI (P30 CA91842 to the Siteman Cancer Center) and the NIH National Center for Research Resources (UL1 TR000448 to the Washington University ICST/CTSA) and the NIH Roadmap for Medical Research.

Author contributions

HM, KLV, and TSS contributed to the conception and design of the study. HM, KLV, SHR, and C-WL performed the *in vitro* spheroid experiments. NPM and NMS performed the *in vivo* mouse experiments. YW performed the *in situ* hybridization experiment. HM, KLV, SHR, YW, NMS, and NPM contributed to data analysis and interpretation. HM and KLV drafted the manuscript. All authors contributed to editing of the manuscript. TSS obtained funding and supervised the study.

Conflict of interest

The authors declare that they have no conflict of interest.
