Abstract

Here we present a case study of a patient who presented with both a congenital failure of fusion of the posterior arch of the atlas and a concomitant Jefferson fracture of the anterior arch following trauma. This patient required minor oral surgery prior to open reduction and internal fixation of the fracture and the considerations are discussed.

Keywords: Oral surgery, atlas, fracture.

Clinical Relevance

Some referrals may give the oral surgeon pause. Presented here is an example of one such referral which was dealt with by some extra planning and a short literature search.

Case report

JL is a 23 year old previously fit and well man who was admitted to A+E following an assault during which he was repeatedly kick on the vertex of his head whilst lying prone on the ground. On examination he was found to be haemodynamically stable, had a GCS of 15/15, was complaining of pain at the back his of neck. No neurological deficit was present. He was fitted with a cervical immobilisation collar. On CT he was shown to have an anterior Jefferson fracture of the C1 atlas vertebra. Also revealed, was a concomitant absence of the posterior arch of the atlas, resulting in two independently moving portions and an unstable fracture. There was however good integrity of the posterior ligament. The injury was treated initially with immobilisation in a halo device and a check radiograph demonstrated no anterior slippage of the odontoid peg. Three months later however at subsequent follow-up including repeat imaging, computer

1
2
3 tomography failed to show union of the fracture. At this stage it was decided he would
4
5 benefit from an open surgical fixation.
6
7
8
9

10 However, on admission he was complaining of dental pain in both his right and left upper
11
12 quadrants and on examination he was found to have a grossly **carious 27 tooth (FDI**
13
14 **notation)** which was demonstrated to be tender to percussion. Further radiological
15
16 investigation showed secondary caries under restorations in **both the 16 and 17 teeth and**
17
18 **a periapical radiolucency around the roots of the 16.** It was felt by the consultant spinal
19
20 surgeon that removal of any focus of dental sepsis would be beneficial before open
21
22 reduction and internal fixation of the atlas fracture with metal plates. This was to
23
24 minimise the potential of post operative infection possibly compromising the implanted
25
26 metal fixation plates. The University of Liverpool Dental Hospital was contacted and the
27
28 patient seen by a consultant oral surgeon.
29
30
31
32
33

34 Due to the fracture it was necessary to carefully consider the force that would be
35
36 transmitted to the neck if conventional extractions were undertaken. It was decided that
37
38 these teeth would be best **removed** surgically with the resultant reduction in force applied
39
40 during the procedure. The patient was advised to take some pain relief (2 x Co-Codamol
41
42 30/500mg) 20 minutes prior to the procedure. **Intravenous sedation was not considered**
43
44 **due to potential problems securing the airway in the event of a medical emergency or**
45
46 **over sedation.** Although the halo device is fixed directly to the skull with rigid screws it
47
48 relies on a back and chest extension to prevent neck movement. This is attached to the
49
50 headpiece via a rigid metal skeleton consisting of four vertical bars. One bar at a time
51
52
53
54
55
56
57
58
59
60

1
2
3 could be removed safely to allow for access while still retaining three points of support.

4
5
6 This is demonstrated figure 2.

7
8 All teeth were successfully removed with surgical bone removal and separation of roots
9
10 resulting in minimal force application. The patient reported no neck pain during the
11
12 procedure.

20 Discussion

21
22
23
24 Jefferson fractures of the atlas are fractures where an axial force is transmitted between
25
26 the occipital condyles and the surface of the axis vertebra causing the atlas to be
27
28 compressed between them resulting in a burst fracture to either the anterior or posterior
29
30 arch and separation of the lateral masses. This type of fracture was first described by
31
32 Geoffrey Jefferson in 1920¹.
33
34

35
36 They account for up to 30% of all fractures to the atlas² and as many as 3% of all cervical
37
38 spinal injuries^{3,4}. Complications from manipulation of atlas fractures include luxation of
39
40 vertebrae, airway compromise and even death⁵.
41
42

43
44 Congenital malformations of the atlas have been discussed in the literature
45
46 and posterior arch defects have an estimated incidence of 4% of these defects⁶. Potential
47
48 neurological complications from congenital arch defects include weakness and sensory
49
50 symptoms such as paraesthesia in all four limbs^{7,8,9}.

57
58
59
60

1
2
3 Although the halo vest has been shown to be effective in reducing forces across the
4 neck¹⁰, surgical **removal** was considered necessary to reduce these forces and potential
5
6
7
8 for serious adverse complications.
