Shiga-toxigenic bacteriophages are converting lambdoid phages that impart the ability to produce Shiga toxin to their hosts. Little is known about the function of most of the genes carried by these phages or the impact that lysogeny has on the *Escherichia coli* host. Here we use next-generation sequencing to compare the transcriptomes of *E. coli* strains infected with an Stx phage, before and after triggering of the bacterial SOS response that initiates the lytic cycle of the phage. We were able to discriminate between bacteriophage genes expressed in the lysogenic and lytic cycles, and we describe transcriptional changes that occur in the bacterial host as a consequence of Stx phage carriage. Having identified upregulation of the glutamic acid decarboxylase (GAD) operon, confirmed by reverse transcription-quantitative PCR (RT-qPCR), we used phenotypic assays to establish the ability of the Stx prophage to confer a greater acid resistance phenotype on the *E. coli* host. Known phage regulators were over-expressed in *E. coli*, and the acid resistance of the recombinant strains was tested. The phage-encoded transcriptional regulator CII was identified as the controller of the acid response in the lysogen. Infection of an *E. coli* O157 strain, from which integrated Stx prophages were previously removed, showed increased acid resistance following infection with a nontoxigenic phage, ϕ 24_B. In addition to demonstrating this link between Stx phage carriage and *E. coli* acid resistance, with its implications for survival postingestion, the data set provides a number of other potential insights into the impact of lambdoid phage carriage on the biology of *E. coli*.

Bacteriophages have become widely recognized as important drivers of bacterial diversification and evolution (1–4). They play important roles in the adaptation of established pathogens to new metazoan hosts as well as the general emergence of new pathogens (5–7); bacteriophages can transform their commensal bacterial host to a pathogen or simply add to the virulence of pathogenic bacterial hosts (7–9), a process termed “lysogenic conversion.” In the particular case of Shiga-toxigenic *Escherichia coli* (STEC), especially the subset of enterohemorrhagic *E. coli* (EHEC), infection with Shiga toxin-encoding bacteriophages (Stx phages) was the key event leading to the emergence of these pathogens as a major health concern following their first association with an outbreak of foodborne disease in 1982 (10–12). EHEC is able to colonize the intestinal tract with great efficiency; the resulting gastrointestinal infection is potentially fatal due to the production and release of Shiga toxin, leading to hemorrhagic colitis and, in some cases, hemolytic-uremic syndrome (HUS) (12–14).

Stx phages are lambdoid phages because they possess genomes that have an organization similar to that of bacteriophage lambda (λ) (7). A recent genomic comparison of 11 Stx phages and λ revealed a high degree of mosaicism in this group, and all but one, ϕ P27, had a significantly larger genome than that of λ (15). The function of this extra genomic material has yet to be determined. Between 40 and 60% of the genes carried by these 11 sequenced Stx phages are of unknown function, including genes that are highly conserved across this group (15). While Shiga toxin itself has been extensively studied (16–18) and putatively assigned the biological role of protecting a STEC population from predation by grazing protozoa (19, 20), little attention has been paid to the identification of other possible virulence or fitness factors encoded on the genome of Stx phages. The key feature of Shiga toxin production by *E. coli* lysogens (STEC) is that Shiga toxin gene

expression, and hence, disease, is a direct consequence of the Stx prophage entering the lytic phase when infectious bacteriophage particles are released along with the toxin itself. The lytic replication cycle of Stx prophages, in common with all known lambdoid bacteriophages, is induced by the autocleavage of the CI repressor, which is driven by the activation of RecA and can be achieved *in vitro* by exposure to UV radiation, mitomycin C, norfloxacin, or other agents that result in DNA damage (21, 22).

There is some evidence that Stx phages have a more profound impact on the *E. coli* host than merely enabling it to produce Shiga toxin. Preliminary data acquired during signature-tagged mutagenesis experiments identified genes implicated in increased gut adhesion of STEC in calves; of the 59 genes identified, 7 were carried by Stx prophages (23). Microarray analysis of the impact of lysogeny with the Stx2 phage ϕ Min27 on the transcriptome of *E. coli* MG1655 showed upregulation of the expression of 104 genes and downregulation of 62 genes (24). Finally, the lambdoid phage transcriptional regulator CII has been linked to repression of the

type III secretion system in EHEC (25), the expression of which is necessary for colonization of the mammalian gut (26).

We previously described the identification of Stx phage genes that are expressed in an *E. coli* lysogen culture and linked the expression of at least two Stx phage genes of unknown function, *vb_24B_13c* and *res* (15, 27), to the lysogenic state. In any lysogen culture, there is always a background of spontaneous phage induction, which confounds the ability to link the expression of a specific gene with the lysogenic state, and this is further constrained by the sensitivity of the methods used to identify proteins present in low abundance (27). Here we use transcriptome sequencing (RNA-Seq) to produce preliminary gene expression patterns controlled by, or derived from, Stx prophage carriage and determine the influence of one such upregulated operon, glutamic acid decarboxylase (*GAD*), on the acid resistance phenotype that has been associated with disease-causing Shiga-toxicogenic *E. coli*.

MATERIALS AND METHODS

Bacterial strains, growth conditions, and RNA extraction. *E. coli* K-12 strain MC1061 was used in all experiments; naive MC1061 refers to cells that have not been infected with bacteriophage $\phi 24_B::\text{Kan}$ (28), and MC1061($\phi 24_B$) refers to MC1061 lysogens of $\phi 24_B::\text{Kan}$ (see Table S1 in the supplemental material). MC1061 and MC1061($\phi 24_B$) were propagated overnight in three biological replicates (16 h), subcultured (1:10), and grown to mid-exponential phase (optical density at 600 nm [OD₆₀₀] of 0.5). Aliquots (1 ml) were harvested, and RNA was extracted by using the RNeasy minikit from Qiagen according to the manufacturer's instructions. These 6 cultures, 3 MC1061 and 3 MC1061($\phi 24_B$) cultures, were then induced with norfloxacin as described previously (27); briefly, cultures were incubated with norfloxacin (1 $\mu\text{g ml}^{-1}$) for 1 h at 37°C with shaking at 200 rpm, followed by dilution of the cultures 1:10 in fresh lysogeny broth, and allowed to recover at 37°C for 40 min with shaking at 200 rpm. Cells were then collected by centrifugation, and RNA was immediately extracted as described above.

Sequencing of the MC1061($\phi 24_B$) genome. Prior to the RNA-Seq analysis of the four transcriptomes generated in the study, the genome of MC1061($\phi 24_B$) was sequenced, annotated, and deposited, along with the four transcript libraries, in the European Nucleotide Archive. The genome assembly consists of 5,027,118 bp in 15 scaffolds.

The *E. coli* MC1061($\phi 24_B$) genome was obtained through whole-genome shotgun pyrosequencing by generating a standard DNA mate-pair library with an 8-kb insert size, using a 454 preparation kit (Roche Applied Sciences, Indianapolis, IN). The genomic DNA (gDNA) sample was sequenced with a GS-FLX system using Titanium chemistry (454 Life Sciences, Roche Applied Sciences). The 454 reads were assembled with Newbler (August 2010 R&D version of GSAssembler; Roche Applied Sciences). The final assembly was annotated on the RAST (Rapid Annotation Using Subsystem Technology) server (29). To improve the quality of the prophage sequence within the lysogen, the 57,677-bp genome of $\phi 24_B$ (GenBank accession number [HM208303.1](https://www.ncbi.nlm.nih.gov/nuclink/1208303.1)) was used to replace the lower-quality prophage sequence residing in the lysogen genome sequence between bp 3129539 and 3186979 (57,440 bp) to form a hybrid genome. All the subsequent analyses and RNA-Seq mapping were done by using the hybrid genome. To compensate for the coordinate numbering following the creation of the hybrid sequence, 236 bp (57,677 bp – 57,440 bp – 1 bp = 236 bp) were added at the starting and ending coordinates of each gene from the original assembly after bp 3186979, while 3,129,538 bp (3,129,539 bp – 1 bp = 3,129,538 bp) were added at the starting and ending coordinates of each gene from the $\phi 24_B$ prophage genome.

Preparation and sequencing of cDNA libraries. The quantity and quality of harvested RNA were assessed on an Agilent 2100 bioanalyzer using an RNA 6000 Nano Chip kit from Ambion. Equal amounts of RNA were pooled from each biological triplicate to produce four libraries (naive cultures, naive cultures treated with norfloxacin, lysogen cultures, and

lysogen cultures treated with norfloxacin). rRNA was depleted from the total RNA samples by using the MICROBExpress bacterial RNA enrichment kit according to the manufacturer's instructions, and the resulting mRNA quantity and quality were evaluated on an Agilent 2100 bioanalyzer using an RNA 6000 Nano Chip kit from Ambion. The RNA was then randomly fragmented by incubation with RNase III (Applied Biosystems) at 37°C for 10 min, recovered by using the RiboMinus concentration module (Invitrogen), and assessed for quantity and size distribution on a bioanalyzer using the RNA 6000 Pico Chip (Agilent). The processed RNA fragments were hybridized and ligated to the adapters from the SOLiD small RNA expression kit (Ambion), and reverse transcription was performed by using ArrayScript reverse transcriptase (Ambion). The resulting cDNA was purified by using the MinElute PCR purification kit (Qiagen). Size selection of cDNA (100 to 200 bp) was performed by using Novex 6% Tris-borate-EDTA (TBE)-urea gels (Invitrogen). The harvested DNA was amplified by using components from the SOLiD small RNA expression kit (Ambion) according to the manufacturer's instructions, and the products were purified by using the PureLink PCR microkit (Invitrogen).

Data processing and gene expression analysis. RNA samples as cDNA were sequenced on an ABI SOLiD sequencing platform using v4 chemistry. More than 8×10^6 high-quality, single-end, 50-bp color-space reads were generated per sample. The reads were analyzed by using the ABI BioScope v1.3 whole-transcriptome analysis (WTA) pipeline. The WTA pipeline first aligned the reads onto the *E. coli* lysogen sequence [MC1061($\phi 24_B$)] and reported the alignments as a BAM file (30). WTA was then used to enumerate reads aligning to each genomic feature in the lysogen genome. Each defined genomic feature was subsequently assigned a tag count, which is the total number of alignments that pass the stringency filters. Finally, the WTA pipeline was used to calculate the normalized level of expression of each genomic feature by using RPKM (reads per kilobase of exon model, per million mapped reads) values (31).

Statistical analysis was performed on normalized read counts for all four samples by using the R platform. The DESeq package was used to analyze differential gene expression across the four libraries (32). The script used in the analysis uses the command `cds<-estimateVarianceFunctions(cds, method = "blind")`, as recommended in the DESeq manual (32), for processing of samples that are pools and therefore not replicated: `table<-read.table("LN.txt", header = T)`, `conds<-factor(c["L," "N"])`, `cds<-newCountDataSet(table, conds)`, `cds<-estimateSizeFactors(cds)`, `cds<-estimateVarianceFunctions(cds, method = "blind")`, `res<-nbinomTest(cds, "L," "N")`, and `write.table(res, file = "LNres.txt", sep = "\t")`.

Hierarchical cluster analysis was performed on the base 2 logarithm of gene read counts by using the "qplots" packages in Bioconductor (34).

Arabinose induction of phage transcriptional regulators. The $\phi 24_B$ genes encoding the regulators CI, CII, and CIII were amplified from MC1061($\phi 24_B$) DNA by using the appropriate PCR primers (see Table S2 in the supplemental material). *cI* was purified and digested with the NcoI and SalI endonucleases. The arabinose-inducible plasmid pBAD/Myc-His (see Table S1 in the supplemental material) was digested with the same enzymes, and both products were cloned to create p $\phi 24_B$ -cI. A construct bearing both *cII* and *cIII* was made by PCR using the primers *cII_cIII_phusion* and *cIII_Sal I* (see Table S2 in the supplemental material), digested with NcoI and SalI, and cloned into pBAD/Myc-His to create p $\phi 24_B$ -cIIcIII. MC1061 and MC1061($\phi 24_B$) competent cells were transformed with each of the plasmid constructs, and transformants were selected on LB agar (LBA) containing ampicillin (100 $\mu\text{g ml}^{-1}$).

MC1061 and MC1061($\phi 24_B$) cultures bearing p $\phi 24_B$ -cI or p $\phi 24_B$ -cIIcIII were grown at 37°C to an OD₆₀₀ of ~0.4, when expression of the cloned phage genes was stimulated by the addition of arabinose (0.01% [wt/vol]), and the cultures were further incubated for 1 h. Production of CI, CII, and CIII was confirmed by SDS-PAGE and Western blot analyses (data not shown).

Acid resistance assay. Eight independent cultures of MC1061, MC1061 (ϕ 24_B), MC1061/p ϕ 24_B-cI, MC1061/p ϕ 24_B-cIIcIII, MC1061(ϕ 24_B)/p ϕ 24_B-cI, and MC1061(ϕ 24_B)/p ϕ 24_B-cIIcIII were grown at 37°C with shaking to an OD₆₀₀ of ~0.4. The expression of CI, CII, and CIII was induced with arabinose as described above. After 1 h of incubation with arabinose, each culture was diluted 1:10 in fresh LB at pH 2.5 and pH 7.5 and incubated again at 37°C for 2 h. Aliquots of 50 μ l from each culture were harvested in triplicate before and after incubation at pH 2.5 and pH 7.5 and serially diluted, and colony counts on LBA were determined. Survival curves were produced for each biological replicate, and statistical analysis was performed by using one-way analysis of variance (ANOVA) followed by a Tukey *post hoc* test; *P* values of <0.05 were considered to be statistically significant.

Relative RT-qPCR. RNA samples for reverse transcription-quantitative PCR (RT-qPCR) were prepared, independently, as described above, from three biological replicates of MC1061 and MC1061 (ϕ 24_B) cultures. Three biological replicates of MC1061/p ϕ 24_B-cI, MC1061/p ϕ 24_B-cIIcIII, MC1061(ϕ 24_B)/p ϕ 24_B-cI, and MC1061(ϕ 24_B)/p ϕ 24_B-cIIcIII cultures were also propagated overnight (16 h), subcultured (1:10), and grown until they reached an OD₆₀₀ of ~0.4; arabinose (0.01% [wt/vol]) was added to stimulate protein production; and cultures were grown for a further hour. RNA was treated with Turbo DNase (Ambion, TX, USA) according to the manufacturer's instructions. The absence of DNA was verified by qPCR, and the amount of RNA was quantified by using the Nanodrop ND-1000 spectrophotometer (Thermo Fisher Scientific). Each RNA sample (1,000 ng) was reverse transcribed by using random hexamers (Bioline, London, United Kingdom) and the cDNA synthesis kit from Bioline (London, United Kingdom).

RT-qPCR was performed by using a StepOnePlus real-time PCR system (Applied Biosystems); each reaction mixture consisted of 100 ng of cDNA, a 1 \times SensiFAST SYBR Hi-ROX kit (Bioline, London, United Kingdom), and 200 nM specific primers in a 20- μ l reaction mixture. The amplification cycling conditions were as follows: an initial denaturation step at 95°C for 2 min, followed by 39 cycles of denaturation at 95°C for 5 s, annealing at 55°C for 10 s, and extension at 72°C for 5 s. A melting curve analysis was performed for each amplification reaction, with a temperature gradient of 0.1°C from 55°C to 95°C. No-template controls were included in every experiment. The $2^{-\Delta\Delta CT}$ method (35) was used to calculate relative gene expression levels by using the *pdxA* (4-hydroxythreonine-4-phosphate dehydrogenase) (GenBank accession number NP_414594.1) and *rraB* (RNase E inhibitor) (accession number NP_418676.1) genes as endogenous reference genes. The endogenous reference genes were chosen from among those genes that showed no changes in expression levels across the four samples in the RNA-Seq experiment. All primers used for RT-qPCR are listed in Table S2 in the supplemental material; the efficiency of each primer pair was determined by running calibration curves, in triplicate, against 6 10-fold dilutions (starting with 100 ng) for the PCR amplicons of each target gene that had been cloned into the PCR-Blunt vector (Invitrogen, Paisley, United Kingdom) and linearized with NcoI (NEB, Herts, United Kingdom). Technical replicates were run for every sample, and means were calculated. Statistical analysis was performed on *gadC*, *gadE*, and *gadX* expression data by using one-way ANOVA with a *post hoc* Tukey test. A two-sample *t* test was used to analyze the expression data for the following genes, selected because they have unique sequences amenable to qPCR: *mgo* (GenBank accession number NP_416714.1), *cyaA* (accession number NP_414966), *aceE* (accession number NP_414656.1), *cI* (accession number ADN68413.1), *cro* (accession number ADN68414.1), *vb_24B_19c* (accession number ADN68433.1), *vb_24B_25* (unannotated coding DNA sequence located between nucleotides 33819 and 33905; accession number HM208303.1), *vb_24B_28* (accession number ADN68449.1), and *vb_24B_30* (accession number ADN68451.1). *P* values of <0.05 were considered to be statistically significant.

Nucleotide sequence accession numbers. The genome sequences of MC1061(ϕ 24_B) along with the four transcript libraries were deposited in the European Nucleotide Archive, and the accession numbers can be found under BioProject record number PRJEB9491.

TABLE 1 Summary of cDNA sequencing output

Sample	Reads generated (bp)	% mapped reads	% uniquely mapped reads ^a	Coverage (Mb)
MC1061(ϕ 24 _B)	82,804,709	58.29	37.51	2,228.74
MC1061	86,132,244	64.7	45.83	2,632.59

^a Zero mismatches.

RESULTS

cDNA sequence output. The transcriptomes of naive *E. coli* and isogenic Stx phage lysogen cultures were sequenced. mRNA-derived cDNA libraries were generated from pools comprised of three independent cultures for the following four states: mid-exponential-phase naive and ϕ 24_B lysogen cultures and norfloxacin-treated naive and ϕ 24_B lysogen cultures. This enabled sampling of both the stable and induced lysogen transcriptomes for comparison with the naive *E. coli* host transcriptome with and without norfloxacin treatment. Reads (82.8 million to 87.3 million; 50 bp in length) were obtained from each of the four pooled samples, with 57 to 65% of reads mapping to the *E. coli* MC1061 genome with or without the ϕ 24_B prophage incorporated at the primary insertion site (36). A summary analysis of the cDNA sequence output is presented in Table 1.

Gene expression in response to norfloxacin treatment and expression of ϕ 24_B bacteriophage genes. Prophage gene expression analysis must take account of the effect of ongoing spontaneous induction of the prophage in the bacterial lysogen culture, which may occur at rates as high as 1:1,000 cells. We have demonstrated that this can be achieved by using comparative data sets generated by exogenous prophage induction, as previously demonstrated with RT-qPCR gene expression profiling (27). MC1061 and MC1061(ϕ 24_B) samples treated with norfloxacin, to activate the lytic cycle via the SOS response, were included here to enable us to properly identify gene expression changes that can be ascribed to prophage carriage on the *E. coli* chromosome. Additionally, and of particular interest to this study, by using these controls, we were able to identify phage-carried genes that are potentially expressed during the lysogenic cycle.

The overall pattern of gene expression in response to norfloxacin treatment is depicted in Fig. S1 in the supplemental material and can be summarized as a significant upregulation of genes for DNA repair and iron and phosphate acquisition concomitant with a downregulation of genes and operons involved in carbon and nitrogen metabolism, energy generation, and motility (see Table S3 in the supplemental material). Upregulation of the iron and phosphate acquisition operons/genes has been linked to prophage carriage by a previous microarray-based study of Stx phage ϕ Min27 lysogens (24). In that microarray study, controls for the effect of spontaneous prophage induction were not included, and our data indicate that comparative upregulation in a lysogen culture is actually due to large gene expression changes in the small subset of the population undergoing spontaneous induction (see Table S3 in the supplemental material). The impact of significant gene expression profile changes on the small subset of cells in a lysogen culture undergoing spontaneous induction was described previously for *E. coli* populations harboring the ϕ 24_B prophage (27).

There is always a basal level of expression of bacteriophage genes associated with the lytic phage replication cycle in any lysogen culture due to some proportion of that culture undergoing spontaneous induction (27). In order to establish whether a phage gene is truly expressed during lysogeny or as part of the lytic cycle, it is necessary to examine the expression of the gene upon induction. Here the expression levels of 68 of the 93 $\phi 24_B$ genes increased >20-fold upon prophage induction into the lytic cycle, although for 17 of these genes, DESeq analysis did not classify the upregulation as significant (see Table S4 in the supplemental material). The expression levels of 14 genes were unaltered, and these genes include *cl*, responsible for the maintenance of the lysogenic state; *int*, the phage integrase which has been shown to be uncoupled from the phage regulatory network in $\phi 24_B$ (37); *bor*, characterized in bacteriophage lambda (38); *stk*, a serine-threonine kinase; and 10 genes of unknown function (see Table S4 in the supplemental material), 2 of which, *vb_24B_13c* and *res*, were previously shown to be expressed in *E. coli* $\phi 24_B$ lysogens (27).

Four phage genes (*vb_24B_19c*, *vb_24B_25*, *vb_24B_28*, and *vb_24B_30*) were selected to validate the RNA-Seq data. The regulatory genes *cl* and *cro* were included as controls, and relative RT-qPCR was performed as described in Materials and Methods. These data are presented in Fig. 1A. In accordance with data from the transcriptomic analysis, expression levels of *cl*, *vb_24B_19c*, *vb_24B_28*, and *vb_24B_30* did not change significantly, while the expression level of *vb_24B_25* showed a significant 10-fold increase upon induction (*P* value of <0.05). The latter expression level is far short of the increase of >60-fold (*P* value of <0.005) for *cro*, the control for gene expression linked to bacteriophage induction. This qPCR-derived value for *cro* is in agreement with the 45-fold increase observed in the RNA-Seq data (see Table S4 in the supplemental material).

Gene expression changes associated with Stx prophage carriage. Comparison of the MC1061 and MC1061($\phi 24_B$) transcriptomes revealed that the majority of bacterial expression changes detected are likely to be simply a consequence of the SOS response occurring in the MC1061($\phi 24_B$) sample (see Table S3 in the supplemental material). In most cases, the decreased gene expression in the lysogen can be ascribed to spontaneous bacteriophage induction. However, there were several genes that appear to be truly downregulated in the lysogen, i.e., due to phage carriage. *mgo* encodes a malate:quinone oxidoreductase that was downregulated 5-fold in the lysogen sample but showed slightly increased expression levels in both lysogen and naive samples treated with norfloxacin (Table 2). Similarly, the expression levels of *aceEF* were significantly decreased (Table 2); *aceEF* encode two of the subunits that form pyruvate dehydrogenase, the enzyme that provides acetyl coenzyme A (acetyl-CoA) for the tricarboxylic acid cycle (39, 40). The expression level of the gene encoding the third subunit of pyruvate dehydrogenase, *aceK*, was reduced 1.7-fold. The expression level of the *cyoABCDE* operon was also found to be reduced in the lysogen; these genes encode the subunits of the cytochrome *b* oxidase, one of the three major terminal oxidases in the aerobic respiratory chain of *E. coli*. These observations based on RNA-Seq analysis of pooled samples require independent verification, and this is supplied by the RT-qPCR data for *aceK*, *mgo*, and *cyoA* (see Fig. S2 in the supplemental material), which support the RNA-Seq observations.

Among the lysogen-upregulated genes were operons encoding type I fimbriae and the GAD acid stress island (Table 2). The *fim*

operon comprises 9 genes, 7 of which (*fimACDEFGI*) showed significantly increased expression in the lysogen. The genes comprising the GAD acid stress island control the glutamate-dependent acid resistance mechanism in *E. coli* (41–43). The *gadAB* genes encode two glutamate decarboxylases that, together with *gadC*, comprise the structural genes of the GAD operon. Expression of the *gadABC* genes is under the control of the global regulator *gadE* and two additional regulators, *gadX* and *gadW*. All of these genes were significantly upregulated in the lysogen (Table 2).

Increased acid resistance of MC1061($\phi 24_B$). Among the data in Table 2, the 3- to 5-fold-increased expression levels of components of the GAD system, which controls acid resistance in *E. coli*, are particularly striking. Acid resistance is a well-studied feature of the biology of *E. coli* O157 (43), and the low infective dose characteristic of this pathogenic serotype is thought to be related to its ability to survive passage through the stomach. To assess whether $\phi 24_B$ imparts increased acid resistance to the lysogen via upregulation of the GAD system, both MC1061 and MC1061($\phi 24_B$) were incubated at pH 2.5 for a period of 2 h at 37°C, and survival was determined (Fig. 2). The rate of survival of the lysogen MC1061($\phi 24_B$) under acidic conditions was reproducibly ~3-fold higher than that of the naive strain, MC1061 (*P* value of <0.05). In order to determine if phage regulator proteins that control phage gene transcription (CI, CII, and CIII) were involved in activating the GAD system, the genes for these proteins were cloned into MC1061, which was then subjected to a 2-h pH 2.5 challenge after induction of gene expression. The cloning vector was an arabinose-inducible expression plasmid modified to harbor either the *cl* gene or both the *cII* and *cIII* genes, p $\phi 24_B$ -*cl* or p $\phi 24_B$ -*cIIcIII*, respectively. CI is the transcriptional repressor that maintains lysogeny (44). CII is a transcriptional regulator crucial to the lysis-lysogeny decision during the early stage of the phage life cycle, and it is rapidly degraded by the bacterial FtsH protease (44–46). The CIII protein acts by inhibiting FtsH, indirectly protecting CII from degradation (45).

MC1061 harboring p $\phi 24_B$ -*cl* possessed the same acid survival phenotype as that of naive cells (Fig. 2). In contrast, the MC1061 clone expressing both CII and CIII was more acid resistant than the lysogen (Fig. 2). In order to determine the impact of CII-CIII expression on *gadE*, *gadX*, and *gadC*, the regulators of the acid resistance GAD system in *E. coli*, RT-qPCR data were generated by using MC1061 and MC1061($\phi 24_B$) mid-exponential-phase cultures. The relative expression levels of *gadE*, *gadX*, and *gadC* were calculated by using the naive MC1061 sample as the calibrator (Fig. 1B). The *gadX* expression level was significantly higher in the MC1061($\phi 24_B$) samples than in the MC1061 samples (*P* value of <0.05), but this gene exhibited a very similar relative expression profile in all other constructs and strains (Fig. 1B). The expression of *gadE* was also increased in MC1061($\phi 24_B$) samples with respect to MC1061; however, there was no significant effect on *gadE* expression due to the presence of CI or CII-CIII in MC1061. There was a reduction in *gadE* expression in MC1061($\phi 24_B$)/p $\phi 24_B$ -*cl* and an increase in expression in MC1061($\phi 24_B$)/p $\phi 24_B$ -*cIIcIII* compared to MC1061($\phi 24_B$) (Fig. 1B). Interestingly, the most pronounced effect was observed for *gadC* expression. There was a very significant difference between the MC1061($\phi 24_B$) and MC1061 samples (*P* value of <0.01), but expression was significantly reduced by the production of CI in MC1061($\phi 24_B$), while the production of CII-CIII maintained high levels of *gadC* expression (Fig. 1B). GadC is one of the proteins directly involved in acid

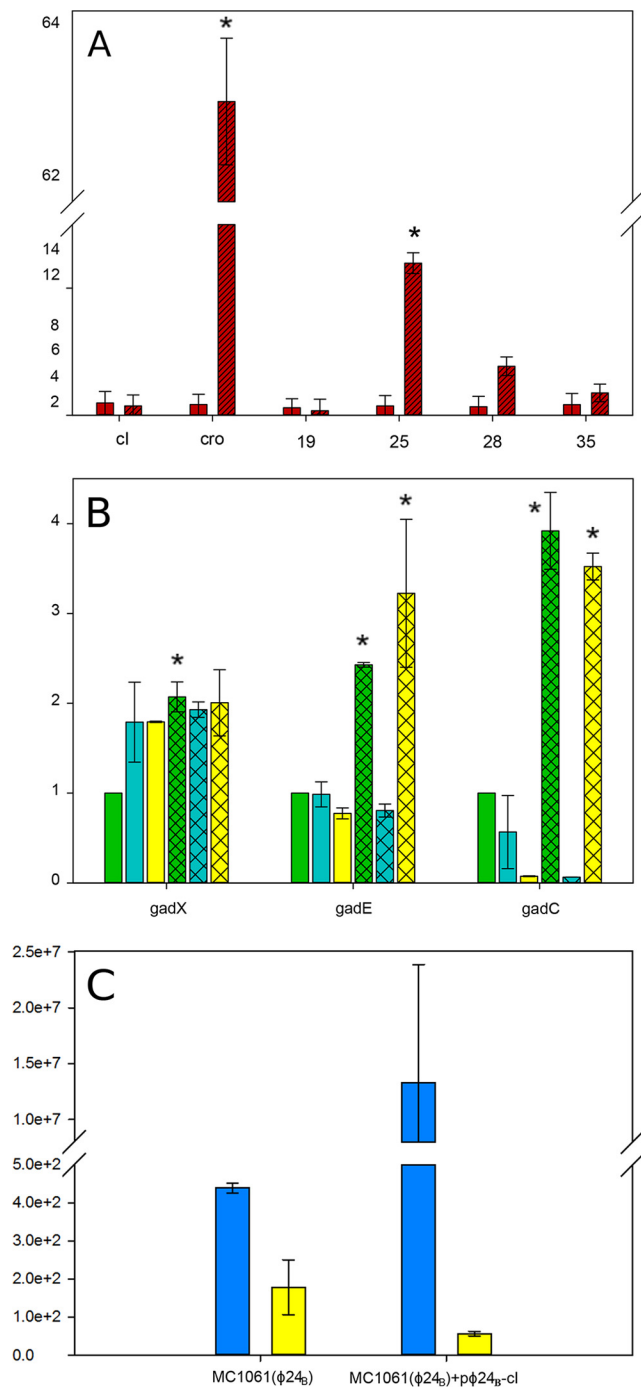

FIG 1 (A) Fold changes in expression of the $\phi 24_B$ genes *cI*, *cro*, *vb_24B_19c*, *vb_24B_25*, *vb_24B_28*, and *vb_24B_30* determined by RT-qPCR. Solid red bars, MC1061($\phi 24_B$); hatched red bars, induced MC1061($\phi 24_B$). Error bars represent standard errors of the means ($n = 3$). * represents statistically significant values in a two-sample *t* test (P value of <0.05). (B) *gadX*, *gadE*, and *gadC*. Expression levels were normalized against the values for the endogenous reference genes *pdxA* and *rraB*. Solid green bars, MC1061; hatched green bars, MC1061($\phi 24_B$); solid blue bars, MC1061/p $\phi 24_B$ -cI; hatched blue bars, MC1061($\phi 24_B$)/p $\phi 24_B$ -cI; solid yellow bars, MC1061/p $\phi 24_B$ -cIIcIII; hatched yellow bars, MC1061($\phi 24_B$)/p $\phi 24_B$ -cIIcIII. Error bars represent standard errors of the means ($n = 3$). * represents statistically significant values compared to MC1061, as determined by one-way ANOVA with a *post hoc* Tukey test (P value of <0.05). (C) Expression levels of the $\phi 24_B$ genes *cI* (blue) and *cII* (yellow) in MC1061($\phi 24_B$) and MC1061($\phi 24_B$)/p $\phi 24_B$ -cI after incubation with 0.01% arabinose. Error bars represent standard errors of the means ($n = 3$).

resistance (membrane transporter of glutamate) rather than functioning as a regulator.

In bacteriophage lambda, CII binds to a well-defined sequence, a tetranucleotide repeat (TTGCN₆TTGC) flanking the -35 region of the promoters for P_{RE} , P_I , and P_{aQ} , controlling the ability of lambda to establish CI production and to express integrase and the anti-Q transcript, respectively (47–49). In $\phi 24_B$, there is a single nucleotide change in this repeat in the same locations, but the GAD operon had no matches to either of the CII binding sequences, suggesting that the substantial effect of CII $_{\phi 24B}$ on acid resistance is pleiotropic.

The confounding issue with CII increasing acid resistance is that CI (repressor) should turn off all CII expression in the lysogen. We determined the levels of the *cII* transcript in MC1061($\phi 24_B$) cultures by RT-qPCR and demonstrated that measurable numbers of transcripts were present, corroborating our RNA-Seq data (Fig. 1C). We then measured the levels of the *cII* transcript in MC1061($\phi 24_B$)/p $\phi 24_B$ -cI cultures grown in the presence of 0.01% arabinose by RT-qPCR and demonstrated a 3-fold decrease in *cII* transcript levels (Fig. 1C). These data, combined with the observations that the CI expression level is very low (Fig. 1A) in the lysogen and that it is known that the operator binding sites in $\phi 24_B$ and related phages like 933W are missing or reside in the *cI* open reading frame (50, 51), support our contention that CII is present and active in the lysogen. Furthermore, we were able to reestablish acid sensitivity in the $\phi 24_B$ lysogen by overexpressing *cI* (Fig. 2); overexpression of *cI* has also been shown to abolish CII downregulation of a type III secretion system in a Shiga-toxicogenic *E. coli* lysogen (EDL933W) (25). We made a $\phi 24_B$ lysogen of strain TUV93-0 (EDL933 with both Shiga-toxicogenic phages removed) and compared the acid resistances of the naive and lysogen strains. We were able to replicate our observations with MC1061; i.e., the levels of acid resistance were 4-fold higher in the lysogen and >4 -fold higher in a TUV93 lysogen (data not shown).

DISCUSSION

Sequencing of the transcriptomes of *E. coli* MC1061 and MC1061($\phi 24_B$) is an invaluable general tool to discern the impact that a bacteriophage can have on its host transcriptome as well as to determine which bacteriophage genes are expressed during the lysogenic state.

Shiga toxin-encoding lambdoid phages were discovered in 1983 (52), and while their contribution to the pathogenic profile of Shiga-toxicogenic *E. coli* has been well documented, their impact on the biology of the *E. coli* host has not been fully characterized. A microarray-based comparison of gene expression levels in a naive strain and a strain harboring a Shiga-toxicogenic phage (ϕ Min27) identified groups of genes that were up- or downregulated (24), among them the GAD operon, also identified here as being particularly responsive to lysogeny. We describe the application of RNA-Seq technology to the relative quantification of gene expression in naive and lysogenic *E. coli* strains, addressing genes carried by both the $\phi 24_B$ phage and the host and crucially correcting for transcriptional changes that are due to phage induction via the SOS response. It is important to differentiate gene expression patterns that are due to spontaneous induction in a lysogen culture from the carriage and expression of the prophage genes *per se*. Hence, here we can identify genes involved in iron acquisition, phosphate metabolism, carbohydrate metabolism,

TABLE 2 Bacterial genes differentially expressed between MC1061 and MC1061(ϕ 24_B) before norfloxacin treatment^a

Gene	Function ^b	Fold change	P value
Genes downregulated in MC1061(ϕ 24 _B)			
<i>cyoB</i>	Cytochrome O ubiquinol oxidase	3.41	0.001
<i>cyoA</i>	Cytochrome O ubiquinol oxidase	3.78	0.000
<i>cyoC</i>	Cytochrome O ubiquinol oxidase	3.12	0.001
<i>cyoD</i>	Cytochrome O ubiquinol oxidase	3.12	0.002
<i>cyoE</i>	Heme O synthase, protoheme IX farnesyltransferase	2.1	0.022
<i>aceE</i>	Pyruvate dehydrogenase E1 component	3.24	0.001
<i>aceF</i>	Pyruvate dehydrogenase E2 component	2.40	0.011
Genes upregulated in MC1061(ϕ 24 _B)			
<i>hdeA</i>	Chaperone HdeA	3.004	0.038
<i>hdeD</i>	Membrane transporter, H-NS repressed	3.127	0.044
<i>rpoS</i>	Sigma transcription factor controlling a regulon of genes required for protection against external stresses	3.427	0.021
<i>gadA</i>	Glutamate decarboxylase	3.558	0.043
<i>gadB</i>	Glutamate decarboxylase	3.133	0.030
<i>gadC</i>	Probable glutamate/gamma-aminobutyrate antiporter	3.414	0.021
<i>gadE</i>	Transcriptional activator	5.989	0.032

<i>fimF</i>	Minor component of type 1 fimbriae	6.543	0.028
<i>fimA</i>	Major subunit of type 1 subunit fimbriae	19.451	0.000
<i>fimC</i>	Required for biogenesis of type 1 fimbriae	17.396	0.000
<i>fimD</i>	Type 1 fimbria anchoring protein involved in export and assembly of <i>fimA</i> fimbrial subunits across the outer membrane	11.850	0.000
<i>fimE</i>	Type 1 fimbria regulatory protein	21.938	0.022
<i>fimG</i>	Type 1 fimbria adapter subunit	9.526	0.014
<i>fimI</i>	Type 1 fimbria protein	20.345	0.000

^a Excludes ϕ 24_B genes that are presented in Table S4 in the supplemental material.

^b HTH, helix-turn-helix.

and anaerobic respiration (see Table S3 in the supplemental material) that are in this category, although further analysis is required to confirm their role in the SOS response.

Bacteriophage lambda carries *lom* and *bor*, two genes that are expressed in *E. coli* and enhance the lysogen's adhesion to epithe-

FIG 2 Survival of MC1061, MC1061/p ϕ 24_B-cl, MC1061/p ϕ 24_B-clcIII, MC1061(ϕ 24_B), MC1061(ϕ 24_B)/p ϕ 24_B-cl, and MC1061(ϕ 24_B)/p ϕ 24_B-clcIII after incubation in LB at pH 2.5. Error bars represent standard errors of the means ($n = 8$). * represents statistically significant values compared to MC1061, as determined by one-way ANOVA with a *post hoc* Tukey test (P value of <0.05).

lial cells and resistance to immune cell attack (38, 53). These genes are also carried by ϕ 24_B, and expression by the lysogen was previously described as being constitutive and uncoupled from the phage regulatory network (27). The RNA-Seq data here fully support that conclusion. The phenomenon represented by prophage-controlled acid resistance, i.e., the control of host cell genes by phage regulators resulting in the alteration of a fitness/virulence trait, was described previously (24), but the mechanism by which the prophage effects this change is addressed here. Our data (from RNA-Seq, RT-qPCR, and acid resistance assays) have demonstrated that the phage-encoded CII transcriptional activator controls the acid response in the lysogen. There are four distinct acid resistance mechanisms described for *E. coli* (54, 55), and the glutamate-dependent acid resistance system is the most efficient of the four. GAD has long been recognized as a virulence factor in EHEC that contributes to its low infective dose by helping it survive exposure to pHs as low as 1.5 (56, 57).

CII from 933W has also been assigned a role in controlling, specifically decreasing, the expression of a type III secretion system, another virulence factor of EHEC (25), while prophages that encode regulators that upregulate type III secretion have also been found (58). The CII protein of ϕ 24_B shares significant homology with the CII protein of 933W. However, these two proteins differ at their carboxyl termini (Fig. 3). In fact, the carboxyl terminus of ϕ 24_B shares considerable homology with CII encoded by bacteriophage lambda; this shared sequence is in fact the domain that targets CII for destruction by the cellular protease FtsH. Thus, the

FIG 3 Shared homology across CII proteins from three lambdoid phages. The T-Coffee multialignment program hosted by the EBI (<http://www.ebi.ac.uk/Tools/msa/tcoffee/>) was used to analyze homology shared between CII proteins from phages lambda, 933W, and ϕ 24_B. The CII proteins encoded by the Stx phages 933W and ϕ 24_B share significant levels of homology, except for their C termini. The C-terminal residues shared between proteins encoded by lambda phage and ϕ 24_B (highlighted by a bracket) serve as the FtsH recognition site and therefore control the half-life of CII.

CII proteins of ϕ 24_B and 933W would be expected to share similar transcriptional regulatory functions without sharing susceptibility to FtsH destruction, while the CII protein encoded by lambda should not have the same phenotypic effects.

The impact of CII expression and its control of the survival of Stx phage lysogens in transit through the gastric system still need to be addressed through animal experimentation, but our data suggest that CII will directly improve the survival of *E. coli* in the acidic environment of the stomach. Significantly, we were able to introduce ϕ 24_B into an *E. coli* O157-derived strain and demonstrate increased acid resistance in the lysogen. Our data point to the fact that the Stx phages themselves directly contribute to the fitness of their lysogens and that it is not simply the carriage of *stx* genes that provides a selective advantage for the dissemination and host range expansion that has been seen since the first *E. coli* O157:H7 outbreak in 1982.

ACKNOWLEDGMENTS

This work was funded by a United Kingdom Biotechnology and Biological Sciences Research Council (BBSRC) grant (reference number BB/I013431/1).

We thank David Gally for providing the TUV93-0 strain used in this study, Ben Libberton for helpful discussions on statistical analyses, and Alastair Darby and Sam Haldenby for helpful bioinformatics discussions and suggestions.
