11

12 Temperate bacteriophages play an underestimated role in microbial infection and disease progression as they

13 carry genes that promote positive evolutionary selection for the lysogen. Using Biolog phenotype microarrays and

14 comparative metabolite profiling we demonstrate the impact of the well-characterised Shiga toxin-prophage

15 φ24$_B$ on its *Escherichia coli* host MC1061. As a lysogen, the prophage alters the bacterial physiology by increasing

16 the rates of respiration and cell proliferation. This is the first reported study detailing phage-mediated control of

17 the *E. coli* biotin and fatty acid synthesis that is rate limiting to cell growth and antimicrobial tolerance to

18 chloroxylenol and 8-hydroxyquinoline. Distinct metabolite profiles discriminate between MC1061 and the φ24$_B$

19 lysogen in standard culture, and when treated with the 2 antimicrobials. This is also the first reported use of

20 metabolite profiling to characterise the physiological impact of lysogeny under antimicrobial pressure. We

21 propose that temperate phages do not need to carry antimicrobial resistance genes to play a significant role in

22 tolerance to antimicrobials.

23

24 **Introduction**

25 Colonisation by Shiga toxin-encoding *Escherichia coli* (STEC) causes a potentially fatal gastrointestinal infection in

26 humans. There are currently > 500 different characterised STEC serogroups that cause disease including O157:H7

27 and more recently O104:H4 (1, 2). Symptoms of STEC infection can vary from bloody diarrhoea through to

28 haemorrhagic colitis, thrombotic thrombocytopaenic purpura (TTP) and haemolytic-uraemic syndrome (HUS) the

29 latter can be fatal (3, 4). STEC is a zoonotic infection transmitted from an animal reservoir via contaminated food

30   or water (5). Shiga toxins are responsible for the severe downstream sequelae due to high cytotoxicity to human

31   renal microvascular endothelial cells (4, 6). Importantly, the genes encoding Shiga toxin (Stx) are disseminated by

32   temperate bacteriophages.

33   Stx-phages enter one of two replication pathways, a productive lytic life cycle or a more passive

34   lysogenic cycle where the prophage is replicated by the bacterium as any other genetic loci. The lytic-

35   lysogen decision of lambdoid-like bacteriophages is regulated by early gene expression and sequential

36   binding of proteins to a well characterised genetic switch (7-9).

37   The co-evolutionary interaction between a phage and its bacterial host is dynamic, with interplay linked

38   to rounds of inhibition, selection and evolution, often referred to as an 'arms race' (10). Smith et al.,

39   (2007) used a multi-loci PCR typing approach to demonstrate that no 2 Stx phage isolates had the same

40   genotype (11). This heterogeneity is further supported by Bonanno et al. (2016) who identified multiple

41   Stx-phage morphologies not previously reported (12). Stx-phages are closely related to bacteriophage

42   lambda, with a comparable genome organisation. In comparison to lambda, Stx-phages carry

43   significantly larger amounts of DNA (~20-25 Kbp) with up to 73 % of the genome and putative coding

44   genes having no known function when analysed at either the nucleotide or protein level (13).

45   Nevertheless these genes are well conserved across many Stx-phages and thus likely to be important to

46   the biology of the phage or its bacterial host (13). Upon phage infection and conversion to a lysogen,

47   genes that are accessory to the core biology of the phage may offer a selective advantage to the host. Mis-

48   excision, mis-packaging of phage DNA (14) and recombination (15) play a large role in phage genome variation.

49   This may leave phage DNA regions, remnant or cryptic prophages that positively impact on the selection and

50   survival of both the phage and the bacterium (16). This is further supported by the common occurrence of

51   prophage regions, usually multiple, in the chromosomes of many bacterial pathogens (17).

52   There are a number of features of the Shigatoxigenic phage vB_EcoPϕ24$_B$ or ϕ24$_B$ that are particularly

53   relevant to the success and persistence of Stx prophages in *E. coli*. In contrast to the lambda infection

54   model, ϕ24$_B$ can multiply infect a bacterial host (18-20). Stx-phages have been isolated from a wide

55   variety of environments where *E.coli* is present and this has undoubtedly been promoted by the use of

56   an essential outer membrane protein BamA as the adsorption site (21); this interaction is conserved in

57   Stx-phages as the incidence of the tail and host recognition protein is widespread (21). ϕ24$_B$ has also

58   been shown to survive well in compost models (22), also showing infectivity after 30 days in bovine

59   manure and slurry (23). φ24$_B$ is genetically similar to phages isolated from sporadic outbreaks of STEC

60   with high virulence and therefore a good model of the viruses circulating in *E. coli* populations in the

61   environment (13).

62   The ability of lambdoid like phages to increase virulence by carriage of toxins in their accessory genome (24) is

63   well described e.g. the cholera toxin (CTX) carried by *Vibrio cholera* phage (25, 26). In Stx-phage genomes the

64   shigatoxin genes are always located at the same position on the phage genome, upstream of the Q antiterminator

65   gene therefore organisation and gene location is important (27). It has been hypothesised that presence of *stx*

66   also offers selection and stability for the lysogens (28). Colon et al., (2016) observed that Stx-prophages show

67   greater levels of spontaneous induction than lambda but this more readily correlates to Rec dependant and

68   independent control of the CI repressor protein rather than presence or absence of *stx* (29).

69   Other accessory genes that are seemingly superfluous to viral replication have been shown to aid microbial

70   selection against environmental stress. Examples include: antibiotic resistance (30, 31), acid tolerance (32, 33)

71   and polylysogeny (34). Phage gene expression has also been shown to aid adhesion and colonisation, for example

72   the expression of the λ-encoded lom gene promotes adhesion to buccal epithelial cells (35), and the λ-encoded

73   bor confers serum resistance (36). Other phage encoded virulence traits include exotoxin production in *E. coli* (37)

74   and increase in bacterial invasion via *Staphylococcus* phage encoded kinase that influences fibrinolysis (38).

75   Bacteriophage φ24$_B$ has also been shown to encode a mi-RNA in the *lom* region that alters expression of anti-

76   repressor *d-ant* and downstream activity of CI, leading to rapid induction (39). Tree et al., (2014) identified 55

77   prophage regions encoding small regulatory RNA within the Sakai *E. coli* O157:H7 strain (40). These small

78   prophage anti-sRNA had the ability to form complexes or mimic core genome regulatory sRNA to aid selective

79   advantage to the bacterial host in bovine rectal mucus. Stx-phage φ24$_B$ shows 98% sequence homology at the

80   nucleotide level to the remnant Stx2 phage present in the Sakai genome (13).

81   The function of the large numbers of hypothetical proteins encoded by φ24$_B$ and other converting phage is

82   difficult to determine, and a focus of this study, as gene expression or interaction may be specific to an

83   environment or subject to selective pressure. Therefore current approaches *in vitro* using synchronous cultures

84   and standard laboratory conditions to investigate the role of these prophages are critically flawed. The function of

85   these hypothetical gene products and how they impact the host in either an advantageous or deleterious way

86   may be missed. In this study we focus on phage mediated antimicrobial tolerance to antibiotics found in the

87   livestock farm setting which is the primary reservoir of pathogenic shigatoxigenic *E. coli*.

88   Our principal aim was to identify how infection and integration of φ24$_B$ changes the microbial physiology, and

89   how phage conversion aids selection compared to its naïve counterpart. This study demonstrates an increase in

90   cell proliferation in standard culture, respiration activity using the Biolog phenotypic array and antimicrobial

91   tolerance that is not linked to an identifiable resistance gene-cassette. The Biolog phenotypic array is a good

92   tool for rapidly identifying phenotypic changes in the respiration profiles of bacteria (41, 42). This study

93   also presents an untargeted metabolomics approach to reveal key phage-mediated differences in metabolism

94   directly linked to biotin and fatty acid synthesis. Interestingly, we show that integration of φ24$_B$ into its primary

95   integration site located 250 bp upstream of the IntS gene (43) allows converted *E. coli* MC1061 to grow using

96   alternative sources of phosphate compared to the naïve bacterial host. We show for the first time unique changes

97   in bacterial metabolite profiles on phage conversion in response to sub-inhibitory concentrations of antimicrobial

98   agents.

99

100   **Results**

101   **φ24$_B$ integration increases cell proliferation.** Growth rates of bacteria can differ due to a range of environmental

102   parameters. To investigate the impact of φ24$_B$ on *E. coli*, viable cell counts were determined during growth

103   comparing *E. coli* B strain MC1061 to single and double lysogens, the latter integrated into separate locations in

104   the MC1061 chromosome (43). Under standard growth conditions, the single and double lysogens showed

105   significantly higher early growth rates compared to the naïve MC1061 (>200 %, Figure 1). This correlates to an

106   increased doubling time of 17 mins for the single lysogen compared to 20 minutes for the naïve MC1061 and 16

107   mins for the double lysogen. As the cultures reached mid to late exponential growth, the differences in growth

108   rates diminished (Figure 1). Increase in growth rate was restricted to early growth (Figure 1). This was supported

109   by a shorter lag time in the single and double lysogen compared to MC1061 with a 0.5 and 1.8 fold increase

110   respectively in cell number after the first hour of growth. Stationary phase in the double lysogen is achieved

111   earlier compared to MC1061 and the single lysogen as nutrients are utilised rapidly alongside the accumulation of

112   inhibitory components of growth.

113   **φ24$_B$ integration alters utilisation of different mono-phosphates and inability to respire using β   D-Allose.** To

114   explore the single lysogen related differences in cell respiration during growth we used the Biolog Phenotype

115   MicroArray. This determined functional changes in respiration and metabolism resulting from phage conversion

116   over a 48 h period with recordings taken every 15 min. The lysogen acquired the ability to respire and grow

117   utilising uridine-2-monophosphate (U-2-P) when compared to the naïve MC1061 (SI Figure 1, panel A). Phage

118   mediated subversion of pyrimidine and purine synthesis by lytic phages has been previously reported and will be

119   discussed later. Conversely, integration of the phage inhibited the lysogens ability to use D-Allose for respiration.

120   **φ24$_B$ integration alters resistance to osmotic stress or antimicrobials.** Again using the Biolog phenotypic array

121   the single lysogen is able to tolerate a range of antimicrobial agents that have both extracellular and intracellular

122 targets (Figure 2). The respiration curves derived for this experiment are provided in the supplementary

123 information (SI - Figures 1 and 2). Tests showing differences in respiration profile were determined in the

124 presence of 22 antimicrobials and 7 increases in salt concentration (SI Table 2).Of these 29 different tests, the

125 lysogen showed a level of tolerance to 17 antimicrobials (SI Table 2). Data presented in Figure 2 (n=3) are

126 comparisons of the area under the respiration curve illustrating those that were altered significantly. $\phi24_B$

127 infection promotes tolerance to 8-hydroxyquinoline (P <0.000), chloroxylenol (P <0.0037), and cefmetazole (P

128 <0.0026), cefoxitin, (P <0.015) cefomendole (P <0.0239) and amoxicillin (P <0.057). Integration of $\phi24_B$ into the

129 primary site 250 bp upstream of *IntS* inhibits respiration utilising B-D-allose. Lysogeny also limits cell respiration in

130 the presence of oxolinic acid although this is linked to phage induction as the cellular target is DNA gyrase.

131 Inhibition of DNA gyrase has been previously shown to stimulate temperate phages to the lytic life cycle as

132 cellular stress stimulates RecA, lexA and proteolytic cleavage of the repressor protein promoting phage induction

133 (44).

134 **$\phi24B$ integration increases MC1061 tolerance to sub-inhibitory concentrations of chloroxylenol and 8-**

135 **hydroxyquinoline.** To better understand the level of antimicrobial tolerance of the single lysogen, we first

136 determined sub-inhibitory concentrations (SIC) against both MC1061 and the lysogen that reduce cell growth by ~

137 60 %. The antimicrobials chloroxylenol, oxolinic acid and 8-hydroxyquinoline were selected to validate the Biolog

138 data. Prior to comparison, an approximate SIC range was determined for MC1061 utilising each of the 3 test

139 drugs. Figure 3 illustrates increased tolerance in a dose dependent response by the lysogen in the presence of

140 chloroxylenol and 8-hydroxyquinoline. Conversely, the naïve host shows increased tolerance compared to the

141 lysogen in the presence of oxolinic acid. This also offers a positive control for the assay as oxolinic acid targets

142 DNA gyrase and therefore stimulates phage induction (26). Phage induction was confirmed by the presence of

143 free phage compared to the un- induced control (data not shown).

144

145 **Metabolic profiles comparing naïve MC1061 to $\phi24_B$ Lysogen.** We used an untargeted metabolite profiling

146 approach using high resolution LC-MS (≤1 ppm mass accuracy in full scan) to determine metabolic differences

147 between bacterial host and lysogen during growth and when challenged with a sub-inhibitory concentration of test

148 antibiotic. To broadly compare findings, significant metabolic differences ($p < 0.05$) were observed between both

growth phase and antimicrobial challenge. In total, >11K ion features or possible metabolites were determined across all of the different tests performed. Of these 81 showed discrimination between the naïve MC1061 and the φ24$_B$ lysogen that had clean chromatogram peaks and < 5% coefficient variable (CV) (SI table 3). These 81 metabolites that show differences can be further stratified to each test.

The metabolite data were analysed using supervised and non-supervised multivariate analysis. Principal Component Analysis was first employed to visualise trends in the dataset and identify potential outliers. To further interrogate the data, Partial-Least Squared Discriminant Analysis models (PLS-DA) were generated and score plots are shown in (Figure 4 A-C). The PLS-DA models for both hydroxyquinoline and chloroxylenol conditions score plots had good discriminating ability, establishing the metabolic differences between the lysogen and naïve host. During standard growth conditions component 1 failed to discriminate: Q2 -0.556, R2Y 0.262, as R2Y and Q2 <0.5, although certain metabolites showed significant differences between the lysogen and MC1061. The 8-hydroxyquinoline component 1: Q2 0.74, R2Y 0.89 and the chloroxylenol component 1: Q2 0.802, R2Y 0.923 were both discriminatory with an R2Y and Q2 > 0.5. Further model statistics can be found in the supplementary information SI table 5. Stx-phage φ24$_B$ has been previously shown to undergo spontaneous induction (27) and may impact the metabolite profile through sequestration of host function and movement to lysis. We therefore compared the metabolite profiles of both the lysogen and MC1061 with a phage inducing agent, oxolinic acid (DNA gyrase inhibitor). No correlation was seen between metabolite profiles of the lysogen or MC1061 when compared to that of the lysogen undergoing induction with oxolinic acid (data not shown).

φ24$_B$ integration alters the metabolite profile of MC1061 in standard growth conditions. Out of the 81 discriminatory metabolites the standard culture condition had 16 metabolites shown to discriminate between the naïve host and single lysogen. Of these 16 metabolites 4 were found in higher levels in the lysogen. This suggests that the lysogen down regulates certain metabolic functions or is directing metabolism along a different pathway. It is likely to support the change in biology we report in this work and increased rates of early growth by the lysogen.

Early growth in the lysogen demonstrates an observable difference in metabolic profile compared to the naïve MC1061. Under standard growth conditions during early growth, 5 metabolites in total were shown to discriminate between the naïve MC1061 and lysogen. Of these, 1 was higher compared to the naïve control (Figure 3 SI).

176 During stationary phase, in standard growth conditions, only 9 metabolites in total showed significant difference

177 and all were found in lower levels in the lysogen.

178 As phage-mediated metabolic differences are present during standard culture, the differences in metabolite profiles

179 under challenge with sub-inhibitory concentrations of 8-hydroxyquinoline and chloroxylenol were tested (Figure 2

180 B and C). The previous Biolog results showed that the lysogen displays a tolerance to these 2 antibiotics.

181 ***φ24$_B$ integration alters the metabolite profile of MC1061 during growth under sub-inhibitory concentrations of***

182 ***8-hydroxyquinoline.*** Upon treatment with 8-hydroxyquinoline, there were 29 metabolites that showed significant

183 difference between the naïve MC1061 and single lysogen. Of these 29 metabolites, 22 were found in higher levels

184 in the lysogen. Early growth phase in the lysogen demonstrates an observable difference in metabolic change

185 compared to the naïve MC1061. Under 8-hydroxyquinoline stress during early growth, 6 metabolites in total were

186 shown to discriminate between the naïve MC1061 and lysogen. Of these, 5 were higher compared to the naïve

187 control (Figure 3 SI).

188 ***φ24$_B$ integration alters the metabolite profile of MC1061 during growth under sub-inhibitory concentrations of***

189 ***chloroxylenol.*** Under chloroxylenol treatment, 41 metabolites showed significant differences between the naïve

190 MC1061 and lysogen. Of these 41, the lysogen had 22 metabolites with significantly higher levels compared to the

191 naïve host. Early growth phase in the lysogen demonstrates an observable difference in metabolic change compared

192 to the naïve MC1061. Under chloroxylenol stress during early growth, 13 metabolites in total were shown to

193 discriminate between the naïve MC1061 and lysogen. Of these, 9 were higher compared to the naïve control

194 (Figure 3 SI).

195 ***Alteration in metabolomics profile and antimicrobial tolerance is not linked to kanamycin resistance selective***

196 ***marker used to detoxify φ24$_B$.*** The kanamycin gene (*aph3*) used to detoxify the φ24$_B$ phage (18) is used as a

197 selective marker only prior to experimentation. Through these studies there is no discernible metabolic burden or

198 difference seen of encoding *aph3* as there would be a consistency between the metabolic profiles when challenged

199 with the 2 different antimicrobials. The discriminatory metabolites used in this analysis are discreet to the 2

200 antibiotics tested.

201

Characterising the metabolites that discriminate between the naïve MC1061 and ϕ24$_B$ lysogen. The discriminatory metabolites determined from each test were compared with metabolite databases and were putatively identified based on exact mass and empirical formula (LCMS methods section). The identity of each metabolite was confirmed using fragmentation analysis using a secondary MS/MS stage. Identities with fragment similarity were found for 58 of the 81 metabolites discriminating between the naïve and lysogen. We focus here on 6 particular metabolites as they have robust identities from fragmentation patterns, retention times, and low accurate mass error (PPM), relating to known curated bacterial metabolites (Table 4 SI). The 6 metabolites are: hexadecanoic acid (a fatty acid that is utilised in the construction of lipid A), sphinganine (putative kinase), 5-Methyluridine (nucleotide synthesis, specifically pyrimidine), ophthalmic acid (glutathione analogue), pimelic acid and FAPy-Adenine, with PPM error margins of 0 ± 1 (0.17, -0.64, 0.45, 1.31, 0.56 and -1.00, respectively) and therefore most accurate identities in this study.

The lysogen has significantly higher intensity levels of pimelic acid under all tests, specifically during early growth (Figure 5). FAPy-Adenine, a bacterial stress marker (45), is only seen in stressed conditions in these analyses, with the lysogen expressing significantly lower intensity during early growth and higher intensity at stationary phase growth (Figure 5). Hexadecanoic acid is identified in significantly higher abundance under cellular stress of chloroxylenol, and is further increased in the lysogen during early growth ($P = 0.04$). Metabolite sphinganine is present under standard conditions in higher intensity in the naïve MC1061. When challenged with chloroxylenol, intensity levels of sphinganine were undetectable in both naïve and lysogen during early growth. During mid-exponential and stationary phase growth under choloroxylenol test there is $>$ 100 fold increase in intensity of sphinganine in both the naïve and lysogen. 5-Methyluridine is present at stationary phase in all conditions, and is also identified in higher intensity when challenged with both antibiotics. Ophthalmic acid was present at all stages of growth under standard conditions where the lysogen shows lower intensity at early and mid-growth, and higher levels at stationary phase. When treated with either antimicrobial agent, ophthalmic acid was only present at stationary growth, with significantly higher intensity found in the lysogen ($P = 0.001$). During standard culture, there are 16 metabolites responsible for the differences seen between the core metabolic profiles of naïve host and lysogen during the 3 growth phases. Importantly 10 of these, including pimelic acid, are also present when the lysogen is challenged with chloroxylenol and 8-hydroxyquinoline.

In the absence of antibiotics, the metabolite profile shows less discrimination between the lysogen and host at the 3 stages of growth by PLS-DA (Figure 4A). Changes in individual metabolite abundances were measured as before

231 (Figure 4 and 6), and >100 were deemed possible biologically relevant metabolites. From the confirmed

232 compounds, a total of 16 metabolites (SI table 3) were shown to discriminate between MC1061 and the φ24$_B$

233 lysogen.

234 We further analysed these data using Hierarchical cluster analysis (HCA) and Euclidean dissimilarity matrix (DM)

235 to create a heatmap that discriminates between 81 metabolites across all tests in this study (Figure 6). The heatmap

236 was assembled unsupervised and unconstrained yet the metabolic profiles have separated by condition.

237 Figure 6 illustrates differences between the metabolic profiles of the naïve MC1061 and φ24$_B$ lysogen when

238 comparing both test antimicrobials and the standard culture conditions. Firstly there is the greatest dissimilarity

239 when the naïve host or lysogen has been treated with a sub-inhibitory concentration of chloroxylenol. Within this

240 grouping the naïve host shows the greatest difference in profile at stationary phase when treated. The chloroxylenol

241 group is further stratified by whether the phage is present or absent. Presence of the phage offers the most

242 dissimilar metabolic profile under this antimicrobial challenge. Treatment with 8-hydroxyquinoline has less impact

243 on the metabolic profiles, yet the antimicrobial tolerance is still marked. The difference is also less marked as the

244 profiles are stratified by growth phase rather than presence or absence of phage. Importantly in Figure 6

245 differences between the 81 metabolites in the naïve host and lysogen without challenging with an antimicrobial are

246 still apparent.

247 **Discussion**

248 The accessory genome of bacteria promoted through horizontal gene transfer is important in understanding how

249 transposable genetic elements aid selection in the environment. Metagenomics of DNA viruses in environmental

250 and clinical samples has revealed a wide range of antimicrobial resistance genes (ARGs) (46-48). Enault *et al.*,

251 (2016) demonstrate that caution is needed as ARGs are over-estimated and therefore rarely found in phage

252 genomes and that this over-estimation was further supported by functionality (49). We here propose a different

253 mechanism promoted by Stx-phage φ24$_B$, through infection and subversion of the cell physiology, promoting

254 tolerance to sub-inhibitory concentrations of antimicrobials 8-hydroxyquinoline and chloroxylenol. Importantly, we

255 show here that this tolerance is to antimicrobials commonly used in the farming industry globally. DeSmet et al.,

256 (2016) illustrated metabolomic differences during phage infection of *P. aeruginosa* (50), whereas this is the first

257 reported use of a metabolic profiling approach to characterise the impact of temperate phage infection on the

258 physiology of the bacteria under antimicrobial pressure. The impact of prophage should not be underestimated as

10

259 basis for metabolic variation and selection for the bacterial host by heightening or dampening cellular response to

260 stress. With the altered metabolic profile of the φ24$_B$ lysogen and increased levels of biotin concentration and fatty

261 acid intensities it leads to the hypothesis that altered growth and lipids may play a role in altering the cell surface

262 that promotes antimicrobial exclusion.

263 The metabolite pimelic acid is a precursor for the majority of the carbon atoms of biotin (51). Biotin plays a crucial

264 role in cell metabolism via carboxylation and decarboxylation reactions. Beyond its function as a cofactor for

265 carboxylases, biotin also plays a role in gene regulation in mammals (52). Unfortunately the mechanism of its

266 action in *E. coli* is relatively unknown. However it has been shown that the *E. coli* BioC–BioH pathway uses a

267 methylation and demethylation strategy to complete the necessary pimeloyl moiety (51). This methylation

268 approach disguises the biotin synthetic intermediates such that they become substrates for the fatty acid synthetic

269 pathway, and once the pimeloyl moiety is complete it is demethylated (51). We show here that the φ24$_B$ prophage

270 has a significant upregulatory effect on biotin that links to other physiological pathways including fatty acid

271 synthesis (51). Differences in pimelic acid intensities between lysogen and naïve host were greatest during early

272 growth (Figure 5 1A, 2B, and 3A), which correlates with the differences observed in growth rates during the first

273 2.5 hours of culture (Figure 1). This is associated with a ~3 fold increase in the level of biotin present per cell at

274 mid-exponential growth phase (Figure 5 B3), which correlates to metabolite profiling for pimelic acid. This is the

275 first time a phage has been shown to drive the biotin pathway.

276 The Biolog data confirmed significant differences in rates of respiration between the naïve host and lysogen under

277 different nutrient and chemical challenges. Interestingly the φ24$_B$ lysogens acquired the ability to respire using

278 Uridine-2-Phosphate where the AURC is illustrated in Figure 2 A and SI Figure 1. U-2-P is involved in cellular

279 metabolism (including biotin metabolism), nucleotide metabolism, pyrimidine metabolism and pyrimidine

280 catabolism (53). Phages have been shown to subvert purine and pyrimidine synthesis to aid viral construction and

281 proliferation (50, 54). Lysogen mediated differences encoded by φ24$_B$ also supports these numerous studies as

282 metabolomics profiling identifies increased pyrimidine catabolism as 5-methyluridine intensity decreases in the

283 lysogen sample. It has also been previously shown through metagenomic analysis that well adapted phages of

284 *Pseudomonas aeruginosa* in the lung carry genes that are involved with purine, pyrimidine and different phosphate

285 utilisation (55). This is further supported by Chevallereau, *et al*., (2016) who show marked changes in RNA

286 metabolism during bacteriophage infection of *P. aeruginosa* (56). Importantly, not only does φ24$_B$ lysogen show

287 increased pyrimidine utilisation it shows that phages can expand the group of phosphates *E. coli* can use for cell

288 respiration and growth, in this instance U-2-P.

289 Conversely to addition of function, integration of φ24$_B$ into the MC1061 chromosome confers an inability to

290 respire using β-D- allose. The lysogen used in this study has φ24$_B$ inserted into the primary integration site on the

291 *E. coli* genome ~ 250 bp downstream of *intS* (43). In *E.coli* there are 3 genes, alsB, alsA, and alsC, that are linked

292 to the utilisation of D-allose (57), but are disparate (~700 Kbp) from any of the 6 integration sites reported by Fogg

293 et al. (2007) (43). This is significant as it illustrates that integration can yield off target epigenetic effects. This

294 study illustrates that the lysogen associated changes in fatty acid synthesis may exclude D-allose being transported

295 into the bacterial cell.

296 Previous research showed infection with λ increased cell growth by the lysogen under cell

297 starvation/supplementation of glucose in a chemostat culture (58-60). This increase in growth rate is also seen with

298 φ24$_B$ here. Interestingly we see a further increase with infection of a secondary, genetically identical phage. The

299 double lysogen is an identical clone to that reported by Fogg et al., (2007), with phage integrating into the

300 secondary integration site (43). When monitoring growth the single lysogen confers a doubling time of 17 mins

301 compared to 20 mins for the naïve MC1061. This is also combined with shorter lag phases in both the single and

302 double lysogen. It has been previously shown in many bacteria and yeast that augmenting a growing culture with

303 biotin increases cell growth rates (61-65).

304 When stressed with chloroxylenol, a demonstrated increase in lipid biosynthesis occurs in the lysogen presumably

305 through subversion of the biotin pathway. This is supported through identification of higher intensity levels of

306 hexadecanoic acid in the metabolite data. Hexadecanoic acid is involved in the biosynthesis of lipid A, a core outer

307 cell membrane structure (66-68). Changes in hexadecanoic acid in the lipid A structure of *E. coli* have been

308 previously shown to be associated to mutations in the firA gene (67, 69). The firA gene is essential for growth and

309 outer membrane synthesis (70), and has also been shown as essential for rifampicin resistance associated with

310 certain mutations in the β subunit of the RNA polymerase (68). This resistance and increase in hexadecanoic acid

311 associated to the firA gene, shows that manipulation of this specific fatty acid likely improves antibiotic resistance.

312 It is noteworthy that altering cell wall properties can broadly improve drug resistance (71), and the biotin pathway

313 is intrinsically linked to cell wall synthesis and growth (51, 72).

314   The lysogen showed increased tolerance to 8-hydroxyquinoline and chloroxylenol using the Biolog phenotypic

315   array and sub-inhibitory antimicrobial tests. An untargeted metabolomics approach demonstrated that phage

316   conversion offers the bacterial host different metabolic profiles to tolerate the two antimicrobials tested. The

317   tolerance observed also suggests core functional changes allow the cell to resist two disparate antimicrobials. This

318   may suggest that these lysogen associated metabolic differences would likely infer tolerance to other environmental

319   challenges and selective pressures.

320   Firstly, we present a metabolic difference in growth under standard culture conditions between the naïve MC1061

321   and the φ24$_B$ lysogen. From 81 metabolites, 16 were discriminatory between the Lysogen and MC1061 (SI table 3).

322   Pimelic acid is present and constitutively raised after infection by φ24$_B$. We also showed here a difference between

323   metabolites at the 3 key stages of growth. These again differ between the lysogen and MC1061 (Figure 6).

324   Under treatment with chloroxylenol in early growth, increased intensity of hexadecanoic acid was identified,

325   particularly in the lysogen. The metabolite sphinganine was observed in our data, sphinganine plays an essential

326   part in the sphingolipid synthesis pathway (73). In both the lysogen and naïve host there is evidence of higher

327   intensities of a sphinganine under chloroxylenol treatment and at stationary growth in standard conditions (Figure

328   6). In *Shigella* species, a pathway associated with mammalian sphingolipid based rafts has been linked to improved

329   binding and mammalian host cell entry (74).

330   Metabolic differences between the lysogen and naïve bacteria are the most disparate when under challenge of a

331   sub-inhibitory concentration of chloroxylenol, illustrated in the PLS-DA plots (Figure 4) and heatmap (Figure 6).

332   Chloroxylenol is a bactericidal agent and a halophenol that targets microbial membranes (71) with a broad activity

333   as an antimicrobial (75).

334   Tolerance to antimicrobial 8-hydroxyquinoline is also reported here. Interestingly, compared to stress under

335   chloroxylenol, the 8-hydroxyquinoline tested metabolite profile changes less significantly from standard

336   conditions. Furthermore when treated with 8-hydroxyquinoline, the metabolite profile is less pronounced in the

337   lysogen when compared to the chloroxylenol test. 8-hydroxyquinoline is a lipophilic metal-chelator with

338   intracellular targets (76). It inhibits growth by chelating metal ions, e.g. Zn^{2+} on RNA polymerase (77, 78). The

339   changes in the intensity of lipids present at the cell surface, that we previously suggest effect uptake of D-allose,

340   are similarly likely to inhibit levels of these 2 antimicrobials entering the cell.

13

When testing cellular stress it is imperative to find markers of inhibition detailed in the metabolite data. The metabolomic profiles identified 2 discriminatory metabolites that are associated with cellular stress: FAPy-Adenine (45) and ophthalmic acid (79, 80). Our data showed that FAPy-Adenine was only present when cells were challenged by the antimicrobials 8-hydroxyquinoline and chloroxylenol. Interestingly the intensity levels of FAPy-adenine differ greatly depending on the antimicrobial used and also presence or absence of integrated $\varphi24_B$ (Figure 5). In the presence of chloroxylenol the lysogen demonstrates lower intensities of the stress marker (0.56 fold less in early growth phase and 0.37 fold reductions in mid-exponential growth phase, (Figure 5 2a & b)) but higher intensity of pimelic acid compared to MC1061. This strengthens the hypothesis of a biotin related lipid increase or change at the cell surface lowering levels of the drug reaching its intracellular target.

When challenging the culture with 8-hydroxyquinoline, FAPy-adenine intensity increases rapidly, even more so than the naïve host (Figure 5). Again there is an increase in pimelic acid intensity that is ubiquitous to the metabolic profiles in the presence of an integrated $\varphi24_B$, however hexadecanoic acid was undetectable within the cell, which may be associated with the lipophilic nature of the drug. The stress response occurs directly after treating with 8-hydroxyquinoline and likely promotes some cell death. Extracellular lipids released through cell lysis binds the drug, forming a matrix. This therefore would reduce the concentration of the available drug present allowing the bacterial culture to grow.

The second stress marker ophthalmic acid is an analogue of glutathione and a reported marker of oxidative stress (79, 80). Opthalmic acid intensity mirrored the stationary phase levels of FAPy-adenine, across all tests, however it was also present in standard culture conditions in both the early and mid-exponential growth phase cultures. This observation from our metabolomic analysis implies higher oxidative stress in the lysogen at stationary growth, as the data are supported by Desnues et al. (2003) (80). The oxidative stress also correlates with the reduction in growth rate and a reduction in the intensity of pimelic acid.

This study has established that Stx-phage $\varphi24_B$ provides a 'jump start' in early respiration and increased bacterial growth rates. These phage-mediated alterations in bacterial host metabolic profile may offer positive selection for the lysogen. Subversion of the biotin pathway is core to the changes mediated by $\varphi24_B$ as it links to the bacterium becoming able to tolerate chloroxylenol and 8-hydroxyquinoline during early and mid-exponential growth phase. These tolerances are important as both antimicrobials are used globally in livestock farming. Importantly metabolic shift and subversion offers 2 mechanisms of controlling this antimicrobial tolerance through increased biotin and

fatty acid synthesis. With treatment and tolerance to choloroxylenol, alteration in levels of lipid A and presumably other lipids enables exclusion of the drug from entry. Secondly 8-hydroxyquinoline treatment drives early cellular stress, cell death and lysis which increases extracellular lipids that bind free drug, allowing the community to continue to grow.

The mechanism for this is unclear, yet this is importantly linked to subversion of the bacterial cell because no phage encoded metabolites are present. We therefore propose that temperate phages may not carry ARGs but play a larger role interfering with metabolic regulation that alters bacterial sensitivity to antimicrobials.

Materials and Methods

Bacterial strains and growth conditions - Buffer and Agar

All bacterial strains were grown in Lysogeny Broth + 0.01 M $CaCl_2$ (LB). Growth of the MC1061($\phi24_B$:: Kan), a lysogen of the bacteriophage $\phi24_B$::Kan and growth of the MC1061($\phi24_B$:: Cat), a lysogen of the bacteriophage $\phi24_B$::Cat (54) was supplemented with 50 $\mu g.ml^{-1}$ kanamycin (kan) and Chloramphenicol (cat) respectively (55).

Bottom agar plates for plaque assay included LB broth (56)) including 7 % (w/v) grade 1 agar (57). Soft top agar was contained LB broth plus 0.4 % (w/v) grade 1 agar. Unless otherwise stated culture conditions were at 37 °C, and broth cultures were shaken at 200 rpm.

Growth curve of single and double lysogens

A single colony of either naïve MC1061, single or double lysogen was cultured overnight for 18 h (200 rpm). LB with 0.01M $CaCl_2$ (100 ml) was inoculated with 1 % (v/v) of the overnight culture. Samples were taken over a 7 hour period, subject to serial, ten-fold dilutions and spread plated on LB agar plates.

Bacterial phenotypic microarray - Biolog

The Biolog assay utilises a redox dye where a tetrazolium violet salt acts as an electron receptor from the tricarboxylic cycle and reduction to NADH. The transfer alters the clear salt to a purple formazan dye that is inexplicably linked to the cellular activity, specifically cell respiration. An inoculum was taken from an 18 h

394   streaked plate of either MC1061 or φ24$_B$ lysogen, raised through 2 rounds of passage from single colony

395   amplification from cryo-stock. A single colony was added to fluid IF-0 (containing 50 µM leucine due to MC1061's

396   auxotrophy), to a transmittance of 42% T on a Biolog turbidometer in a 20 mm diameter tube as per

397   manufacturer's instructions and used to inoculate Biolog Phenotypic Microarray plates.

398

399   The panel plates used for this study included Biolog plates PM 1-20, which include a range of both metabolic and

400   toxicological additives (see SI). Further details of the components associated with these PM plates can be found at

401   http://www.biolog.com/pmMicrobialCells.html. The Biolog PM plates were grown at 37 °C and monitored using

402   the Omnilog plate reader at 30 min intervals over 47 hours.

403

404   **Sub-inhibitory concentration (SIC) assay**

405   Again as per Biolog assay an inoculum of for the MC1061 or lysogen, for a transmittance of 42 % T was created in

406   the same manner. An identical volume of inoculum was added to an equal volume of antimicrobial (double

407   concentrate) diluted in LB broth. Readings were taken at 0 and 18 hours; plates were incubated at 37 °C.

408

409   **SIC assay – Liquid chromatography mass spectrometry (LCMS) analysis comparing metabolic compounds**

410   **from Naïve host and Lysogens.**

411   Replicated in triplicate therefore n=9 bacterial cultures (10 ml) were grown as previously described under

412   standard growth conditions and challenged with antimicrobials, the cells were harvested at early, mid, and late

413   log phase. The cells were harvested by centrifugation (5,000 rpm for 5 min) and the pellet washed (x3) in ice cold

414   1 x PBS prior to lyophilisation. Lyophilised samples (x3) were pooled, normalised for weight/vol (normalised to 1

415   mg.ml) with methanol and 0.1% formic acid, this was vortexed and then sonicated (Bandelin Sonorex, Sonicator)

416   for 1 hour and centrifuged (5k rpm for 5 mins). The supernatant was recovered and filtered through 0.22 µm

417   pore-sized, nylon filter and injected into the Q-Exactive LC-MS (Thermo-Fisher) after separation on a Phenomenex

418   Gemini column (110A, 150x2mm, 5µm, flow 0.2 ml.min). LCMS mobile phase parameters were: 0-6 mins at 20%

419   ACN, 8 mins 60% ACN, 12 mins 95% ACN, 17 mins 95% ACN, 17.1 -23 mins 5% CAN. MS conditions were: full MS

420   mode, resolution 70, 000, AGC target 1x10^6, maximum IT 200ms, scan range 150-2000, column temperature 35

421   °C. Progenesis QI software was used for raw data analysis; this software provided alignment, peak picking,

422   pairwise statistical analysis and putative metabolite ID based on accurate mass. Metabolites were confirmed by

423   analysing pure standards and MSMS fragmentation analysis run under identical analytical conditions.

424   **Biotin quantification assay**

425   Inoculums were prepared in the same manner as for the SIC and Biolog assays. Optical density values were taken

426   at 0 and 18 h, incubation at 37 °C. The cultures were diluted to the lowest OD_{600} reading to normalise cell number

427   between naïve MC1061 and lysogen. Dilutions of both naïve MC1061 and lysogen were made in LB (1:100 and

428   1:1000). Cells were harvested by centrifugation (5,000 rpm for 5 mins). The biotin assay was completed using the

429   Bio Vision® (Cambridge, UK) Biotin Quantitation Kit (Colorimetric) according to the manufacturer's protocol. In

430   brief, the supernatant was discarded and the pellet re-suspended in 10 µl PBS and heated to 100 °C for 3 min and

431   then immediately placed on ice. Diluted naïve and lysogen cells (10 µl) were added to individual aliquots of Biotin

432   Assay buffer (20 µl) and 300 µl of biotin reaction mix, pre-prepared as described in the Biotin Quantitation Kit

433   protocol (version 7.6), was added to the buffer and cells. The mix was incubated at 21 °C for 15 min. Each sample

434   mix (150 µl) was then pipetted into a microtitre plate and read at 500 nm. A standard curve was prepared as per

435   manufacturer's instructions.

436   **Statistical analysis**

437   To determine statistically significant difference between growth rates of the single and double ϕ24$_B$ lysogen

438   compared to MC1061, paired-sample T-tests in the statistical package SPSS was used. The two tailed p values are

439   given at 95% confidence limits. The statistically significant difference in SIC between lysogen and MC1061 was

440   calculated using an independent t-test, using the SPSS platform (> 95 % confidence limits). The Biolog area under

441   the respiration curve (AURC) for respiration values were calculated using a trapezoid algorithm (58). Statistical

442   significance of area under the respiration curve (AURC) and comparison at a specific time point during mid

443   exponential growth phase was achieved by determining normal Gaussian distribution by parametric analysis and

444   statistical significance identified using an un-paired *t* test (> 95% confidence limits). Metabolomic analysis was

445   carried out primarily by Progenesis QI software, this software provided alignment, peak picking, pairwise

446   statistical analysis and putative metabolite ID based on accurate mass. Further multivariate analysis was

447   performed using SIMCA-P. ID's were obtained through the QI plugin 'Progenesis metascope' and filtered through

448   a range of databases using sdf files (ECMDB, HMDB, small molecules drugs, Biomolecules, analgesics mix, Lipid

449   MBD, Basic lipids, and Yeast DB). A paired sample t test was used to determine statistically significant differences

450   between intensities of metabolites identified during metabolomic analyses (> 95% confidence limits).

665 **Figure Legends**

666

667

668 **Figure 1|** Clustered column graph representing percentage increase in cell proliferation of single ($\phi24_B$::ΔKan,

669 dark grey) and double ($\phi24_B$::ΔKan, $\phi24_B$::ΔCat, light grey) MC1061 lysogens. Cultures were grown at 37 °C

670 (CFU.ml) and samples taken over a 7 hour period including experimental and technical replicates (n=9).

671 Percentage increases or decreases show differences in growth of the lysogens compared to the uninfected

672 MC1061 represented here as 0 on the x axis. Significance threshold *P* values *** <0.001, ** <0.01, * <0.05,

673 significance below the x axis demonstrates greater growth from the Naïve host.

674

675 **Figure 2 | A comparison of Area Under the Respiration Curve (AURC) data from the Biolog bacterial phenotypic**

676 **microarray.** Data plotted shows the addition of supplemented nutrients or chemical challenge showed

677 statistically significant difference in rates of respiration between the lysogen and naïve MC1061 host (for *P* values

678 see SI Table 2). Arbitrary Omnilog fluorescence values (y-axis) show differences between the naïve MC1061 (light

679 grey) host and the lysogen (dark grey) over a 47.5 h time period (n=3). Error bars represent SEM. Graphs A-F show

680 significantly higher amount of respiration of the lysogen compared to the naïve host under the following

681 conditions; (A) U-2-monophosphate, (B) 8-hydroxyquinoline, (C) chloroxylenol, (D) cefoxitin, (E) cefomendole and

682 (F) amoxacillin. Graphs G-I show mean AURC values where growth on different carbon sources or chemical

683 challenge that has a detrimental effect on the respiration of MC1061 when converted by $\phi24_B$, these inculde; (G)

684   -D-Allose, (H) ofloxacin and (I) oxolinic acid.

685

686 **Figure 3| Dose response in growth of both MC1061 (light grey) and the $\phi24_B$ lysogen (Dark grey) to an**

687 **increasing concentration of (A) 8-hydroxyquinoline, (B) chloroxylenol, and (C) oxolinic acid.** Bacterial growth

688 was measured by increase in optical density at 600nm after 18 hours growth at 37°C, as per original Biolog assay.

689 Error bars represent the standard error of the mean (SEM) (n=12). Significance represented by (*P*) thresholds; ***

690 <0.001, ** <0.01, * <0.05.

691

692 **Figure 4| A, B and C: The metabolite profiles of MC1061 versus lysogen and multivariate analysis using partial**

693 **least discriminant analysis (PLS-DA)**. The panels represent score plots from PLS-DA models of: (A) Standard

694 growth conditions, and supplementation with (B) 8-hydroxyquinoline and (C) chloroxylenol, between the naïve

695 host (light grey spot) and lysogen (dark grey spot), the model discriminatory parameters for the PLS-DA analysis

696 are described in the results section and in SI table 5.

697

Figure 5| Biotin concentration, FAPy-Adenine and pimelic acid intensity showing significant biological differences between naïve host and lysogen during growth and antimicrobial challenge. **A1**: Changes in cellular stress marker FAPy-Adenine abundances under the challenge of chloroxylenol at early, mid and stationary growth between the lysogen (dark grey) and naive Host (light grey). **B1**: Average pimelic acid abundance under chloroxylenol at early, mid and stationary growth between the lysogen and naive Host. **A2**: Average FAPy-Adenine abundances under selective pressure of 8-hydroxyquinoline at early, mid and stationary growth between the lysogen and naive MC1061. **B2**: Average pimelic acid abundances under challenge with 8-hydroxyquinoline at early, mid and stationary growth between the lysogen and naive Host. **A3**: Average pimelic acid abundances under standard conditions at early, mid and stationary growth between the lysogen and naive Host. **B3:** Variance in the amounts of Biotin present in samples of $\Phi24_B$ lysogen and MC1061 naïve Host. Error bars derived from standard error of the mean (n=3). Biotin Quantitation test performed using BioVision® quantitation kit (7.5) using a modified protocol. Two tailed significance represented by ******* <0.001, ****** <0.01, ***** <0.05, key: *Inc. = Increase, *expo = exponential growth.

Figure 6| Heatmap generated by metabolic levels of 81 metabolites using HCA and DM Culture conditions and presence or absence of phage can be found alongside each profile (H = 8-hydroxyquinoline, C = chloroxylenol). Each individual tile represents a metabolite. The colour of a given tile denotes higher or lower intensity of the metabolite. The colour scale key is: dark blue: lowest levels; white: mid-point; dark red: highest level. The gradient between these colours represents variation in the levels of the metabolite across the colour scale (putative ID's can be found in SI table 3). Pimelic acid is highlighted across all profiles with a hatched box.
