18

19 **Abstract**

20 Sour gas represents about 43 % of the world's natural gas reserves. The sustainable use of this  
21 fossil fuel energy entails the application of CO<sub>2</sub> Capture and Storage (CCS) technologies. The  
22 Chemical Looping Combustion (CLC) technology can join the exploitation of the energy  
23 potential of the sour gas and the CO<sub>2</sub> capture process in a single step without the need of a  
24 sweetening pre-treatment unit. In this work, a total of 60 hours of continuous operation with  
25 sour gas and H<sub>2</sub>S concentrations up to 15 vol. % has been carried out in a 500 W<sub>th</sub> CLC unit,  
26 from which 40 corresponded to a Cu-based oxygen carrier (Cu<sub>14</sub>γAl) and 20 to a Fe-based

27 material (Fe<sub>20</sub>γAl). This is the first time that so high H<sub>2</sub>S concentrations are present in a fuel to  
28 be burnt in a CLC process. The Cu<sub>14</sub>γAl oxygen carrier seems to be no recommendable for the  
29 combustion of sour gas because, although all the H<sub>2</sub>S is burnt to SO<sub>2</sub>, copper sulfides were  
30 formed at all combustion conditions. In contrast, the Fe<sub>20</sub>γAl oxygen carrier presented an  
31 excellent behavior with no agglomeration problems and maintaining the reactivity of the fresh  
32 material. The sour gas (CH<sub>4</sub>, H<sub>2</sub>, and H<sub>2</sub>S) was completely burnt, and neither SO<sub>2</sub> was released  
33 in the AR nor iron sulfides were formed at usual CLC operating conditions. These tests  
34 demonstrated the possibility to use sour gas in a CLC process with 100% CO<sub>2</sub> capture without  
35 any SO<sub>2</sub> emissions to the atmosphere.

39

#### 40 **1. Introduction**

41 Natural gas is a combustible mixture of hydrocarbon gases, being CH<sub>4</sub> the most abundant  
42 compound, usually between 70 to 90 vol.% . Other light hydrocarbons such as C<sub>2</sub>H<sub>6</sub>, C<sub>3</sub>H<sub>8</sub> and  
43 C<sub>4</sub>H<sub>10</sub> are present in the gaseous mixture in variable concentrations up to 20 vol.%. This fuel gas  
44 is usually considered as sour gas if the H<sub>2</sub>S content exceeds 5.7 milligrams of H<sub>2</sub>S per cubic  
45 meter of natural gas (Katz et al., 1959), which is equivalent to approximately 4 ppm by volume  
46 under standard temperature and pressure. However, the composition of sour gas can vary widely  
47 depending on the extraction location, and wells with H<sub>2</sub>S contents in the tens of percentage  
48 range are found (Hammer et al., 2006). According to Lallemand et al. (2012) a typical sour gas  
49 would contain about 10 vol.% H<sub>2</sub>S, and high-sour and super-sour gases are considered those  
50 fuels with H<sub>2</sub>S contents ≈ 20 vol.% and > 30 vol.%, respectively. Sour gas also contains  
51 significant amounts of other acid gas such as CO<sub>2</sub> that can reach contents higher than 10 vol.%.  
52 The presence of H<sub>2</sub>S in natural gas poses Health and Safety Environmental (HSE) problems due  
53 to the high toxicity of H<sub>2</sub>S which makes necessary special operating procedures to ensure

54 worker safety during drilling and in production operations. Furthermore, the presence of H<sub>2</sub>S  
55 and CO<sub>2</sub> can affect negatively to the economic value of the gaseous fuel due to the additional  
56 costs required for special materials compatible with these corrosive compounds and for the  
57 natural gas sweetening unit necessary to remove them previous to commercialize the natural gas  
58 (Romano, 2007).

59 It is probed that the natural gas is continuously increasing its role in meeting the world energy  
60 demand. According to the International Energy Agency (IEA, 2013), about 43% of the world's  
61 natural gas reserves are sour gas sources, which revealed the great relevance of this type of fuel  
62 in the present and future energy scenario. The exploiting of the energy potential of sour gas  
63 entails the application of CO<sub>2</sub> Capture and Storage (CCS) technologies since the CO<sub>2</sub> content in  
64 this fuel can be appreciable as it was previously mentioned. Globally, the proven and probable  
65 sour gas resources have an estimated potential of 4 trillion m<sup>3</sup> of net natural gas and 15000 Mt  
66 of associated CO<sub>2</sub> (Burgers et al., 2011).

67 Direct combustion of sour gas with a high H<sub>2</sub>S content produces a high SO<sub>2</sub> concentration in the  
68 flue gas. The separation of SO<sub>2</sub> from the other components of the flue gas implies significant  
69 costs due to the large volumes of gas to be treated, making this option economically not viable.  
70 Thus, H<sub>2</sub>S should be removed from sour gas previously to its combustion. Usually, the process  
71 of H<sub>2</sub>S removal from natural gas, i.e., the sweetening process, is usually performed by an amine  
72 gas treatment process (Maddox, 1974). The waste gas stream obtained from the sweetening  
73 process is commonly known as acid gas.

74 Because the removal of H<sub>2</sub>S from natural gas requires additional expenses concerning extra  
75 units for acid gas enrichment, other novel technologies such as the Controlled Freeze Zone<sup>TM</sup>  
76 (CFZ) gas treatment technology (Parker et al., 2011) or Chemical Looping Combustion (CLC)  
77 have emerged in the last years as potential single step separation processes of CO<sub>2</sub>, H<sub>2</sub>S and  
78 other contaminants from a sour gas stream without the use of sorbents or absorbents.

79 The Chemical Looping Combustion technology would join the exploiting of the energy  
80 potential of the sour gas and the CO<sub>2</sub> capture process in a single step. Figure 1 shows the  
81 technology train to deal with sour gases through CLC.

82 CLC is a combustion technology based on the transfer of oxygen from air to fuel by means of a  
83 solid oxygen carrier which is continuously circulating between two interconnected fluidized bed  
84 reactors, the air reactor (AR) and the fuel reactor (FR) (Adánez et al., 2012). When a  
85 carbonaceous fuel is considered to be burnt, in a first step the fuel is oxidized in the FR to CO<sub>2</sub>  
86 and H<sub>2</sub>O by a metal oxide (Me<sub>x</sub>O<sub>y</sub>) which is reduced to a metal (Me) or reduced form (Me<sub>x</sub>O<sub>y-1</sub>).  
87 A highly concentrated stream of CO<sub>2</sub> is obtained after water condensation and purification. In a  
88 second step, the metal or reduced metal oxide is oxidized with air in the AR regenerating the  
89 material for a new cycle.

90 The objective in a CLC process that uses sour gas as fuel is to generate a highly concentrated  
91 stream of CO<sub>2</sub> and SO<sub>2</sub> in the FR, avoiding as much as possible the release of sulfur in the AR  
92 stream. The SO<sub>2</sub> produced in the FR can be separated at a lower cost since the volumetric flow  
93 of the flue gases is seven times less than by means of direct combustion in the burner-boiler,  
94 resulting in significantly smaller post-treatment units. Shell Global Solutions International BV  
95 company has developed a patent (Mirfenderski and Sprachmann, 2013) where sour gas is used  
96 as fuel for thermal energy conversion without the need of a sweetening pre-treatment utilizing  
97 the high caloric content of burning H<sub>2</sub>S, with improved capture of the produce SO<sub>2</sub>, whilst  
98 maintaining the CO<sub>2</sub> inherent separation characteristics of CLC. The captured SO<sub>2</sub> may be sent  
99 to a next destination such as e.g. a sulfuric acid plant, a sulfur recovery plant, liquid SO<sub>2</sub>, or  
100 even injection of the CO<sub>2</sub>/SO<sub>2</sub> mixture.

101 The selection of the oxygen carrier for a particular CLC process depends on the type of fuel, the  
102 operating conditions to be adopted, the cost and the lifetime of the material, environmental  
103 aspects, etc. In addition, the resistance to sulfur is a crucial aspect to be considered when sour  
104 gas is used. ICB-CSIC research group studied the behavior of four highly reactive oxygen  
105 carriers in a 500 W<sub>th</sub> continuous CLC unit regarding the presence of H<sub>2</sub>S in the gaseous fuel.  
106 These oxygen carriers were based on Ni (García-Labiano et al., 2009), Mn (Cabello et al.,  
107 2014b), Fe (Cabello et al., 2014a) and Cu (Forero et al., 2010) oxides. The material based on  
108 nickel oxide was not suitable to be used for the CLC process with H<sub>2</sub>S-containing fuels, at  
109 concentrations higher than 100 vppm, since deactivation of the oxygen carrier took place at all

110 operating conditions by  $\text{Ni}_3\text{S}_2$  formation. Regarding the Mn-based oxygen carrier, in the form of  
111 a perovskite ( $\text{CaMn}_{0.9}\text{Mg}_{0.1}\text{O}_{3-\delta}$ ), the addition of  $\text{H}_2\text{S}$  caused a negative effect on its behavior for  
112 the CLC process in terms of agglomeration problems, deactivation and loss of oxygen  
113 uncoupling capacity. Thermodynamic analyses conclude that manganese sulfides are not found  
114 as predominant sulfur species during the interaction of Mn-based oxygen carriers with sulfur  
115 (Jerndal et al., 2006; Wang et al., 2005). The poisoning of this perovskite by  $\text{H}_2\text{S}$  addition was  
116 not due to the presence of manganese oxide within its structure, but due to the presence of Ca  
117 that could form certain undesired compounds such as  $\text{CaSO}_4$  and  $\text{CaS}$ .

118 Fe- and Cu-based oxygen carriers presented a good CLC performance using fuels containing  
119  $\text{H}_2\text{S}$  (Cabello et al., 2014a; Forero et al., 2010). In the case of the Fe-based oxygen carrier, the  
120 presence of  $\text{H}_2\text{S}$  in the fuel gas did not affect the behavior of the material independently of the  
121 amount of sulfur present in the fuel stream. Iron sulfides were not formed, the redox reactivity  
122 was maintained during operation and high combustion efficiencies were obtained with and  
123 without sulfur presence. Regarding the Cu-based oxygen carrier, the presence of  $\text{H}_2\text{S}$  did not  
124 produce the deactivation of the material working at oxygen carrier-to-fuel ratios,  $\phi$ , above 1.5.  
125 At these conditions, complete combustion of fuel was achieved and the great majority of the  
126 sulfur fed into the system ( $\approx 95$  vol. %) was released in the gas outlet stream of the FR as  $\text{SO}_2$ .  
127 For  $\phi$  values lower than 1.5, the formation of copper sulfide,  $\text{Cu}_2\text{S}$ , was detected, and the  
128 oxygen carrier was deactivated. However, this material was completely regenerated in a  $\text{H}_2\text{S}$ -  
129 free atmosphere.

130 It must be remarked that the maximum  $\text{H}_2\text{S}$  content in all the above works was 3400 vppm.  
131 However, the amount of  $\text{H}_2\text{S}$  in sour gas sources can be very elevated, being increased several  
132 orders of magnitude (Katz et al., 1959). As above mentioned, the composition of sour gas can  
133 vary widely depending on the extraction location, and wells with  $\text{H}_2\text{S}$  contents in the tens of  
134 percentage range can be found (Hammer et al., 2006; Lallemand et al., 2012). The presence of  
135 sulfur in the fuel can affect to the quality of the concentrated  $\text{CO}_2$  stream obtained or to the  
136 admissible emission of pollutants if it is released as  $\text{SO}_2$  in the FR or AR, respectively. In

137 addition, the possible poisoning of the oxygen carrier by sulfur becomes crucial when using  
138 sour gas as fuel because metal sulfides formation decreases the oxygen carrier reactivity,  
139 oxygen transport capacity and fuel conversion potential.

140 Based on previous experience, the objective of this work was to analyze the behavior of two  
141 materials based on Cu and Fe, respectively, during sour gas combustion in a 500 W<sub>th</sub> CLC unit  
142 in presence of high H<sub>2</sub>S concentrations, up to 15 vol. %. The influence of H<sub>2</sub>S concentration on  
143 the gas products distribution, sulfur splitting between FR and AR and oxygen carrier  
144 deactivation were investigated. Furthermore, the evolution of the main oxygen carrier properties  
145 during the time of operation was also analyzed.

146

## 147 **2. Experimental section**

### 148 **2.1 Oxygen carrier materials**

149 A Cu- and a Fe-based oxygen carriers were prepared at ICB-CSIC by the incipient impregnation  
150 method using  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> as support. These materials were designated as Cu14 $\gamma$ Al and Fe20 $\gamma$ Al  
151 oxygen carrier respectively. The CuO content in the Cu14 $\gamma$ Al oxygen carrier particles was 14.2  
152 wt.%, whereas the Fe<sub>2</sub>O<sub>3</sub> content in the Fe20 $\gamma$ Al material was 20.4 wt.%. The corresponding  
153 oxygen transport capacities, R<sub>OC</sub>, were 2.9 and 2.0 %, respectively. The method of preparation  
154 and the main physical and chemical properties of both materials were deeply explained by  
155 Adánez et al. (2006) and Gayán et al. (2012).

### 156 **2.2 ICB-CSIC-g1 facility**

157 Sour gas combustion tests were carried out in the ICB-CSIC-g1 facility (500 W<sub>th</sub>). Figure 2  
158 shows a schematic diagram of the unit after the modifications made for safe operation with high  
159 H<sub>2</sub>S concentrations. The atmospheric chemical-looping combustor prototype was composed of  
160 two interconnected fluidized-bed reactors, the air reactor and the fuel reactor, separated by a  
161 loop seal, a riser for solids transport to the fuel reactor, a cyclone and a solid valve to control the  
162 solids fed to the fuel reactor. An important feature of the prototype was the possibility to control  
163 and measure the solids circulation rate at any moment through the solids valves located above

164 the FR. Moreover, the prototype allowed the collection of solid material samples from the AR  
165 or the FR at any moment for further characterization. A detailed description of the installation  
166 can be found elsewhere (García-Labiano et al., 2009; Forero et al., 2010).

167 The CLC unit was modified by including three mass flow controllers for H<sub>2</sub>S, H<sub>2</sub> and H<sub>2</sub>O. The  
168 synthetic sour gas was fed at the bottom of the reactor. This made necessary the use of a special  
169 distributor plate manufactured in Kanthal APM. H<sub>2</sub> was also added to avoid H<sub>2</sub>S decomposition  
170 in the feeding line. Furthermore, to avoid corrosion problems with reactor alloys some steam  
171 was also included in the feeding gas stream. Two scrubbers containing a saturated solution of  
172 sodium carbonate were located in the gas outlet streams of the FR and AR reactors to keep the  
173 emissions below the Health, Safety and the Environment (HSE) limits. Furthermore, a special  
174 installation for gas leakage detection was included in the CLC unit. This security system is  
175 composed by three gas detectors, a control unit and two electronic valves. Two gas detectors  
176 (one for H<sub>2</sub>S and another one for SO<sub>2</sub>) were located inside the cupboard covering the CLC plant,  
177 and an additional H<sub>2</sub>S gas detector was installed outside near the plant. The gas detectors were  
178 configured for 5 vppm alarm. All the detectors were connected to the control unit. If a gas  
179 leakage was detected, several alarms were switched on and the relays of the control unit acted  
180 on the electronic valves. In such case, the H<sub>2</sub>S flow was closed and the line was flushed with N<sub>2</sub>.

181 Some specific analyzers for sulfur compounds were placed at the outlet streams of the AR and  
182 FR. A non-dispersive infrared (NDIR) analyzer (Siemens Ultramat U22) was used to detect the  
183 SO<sub>2</sub> concentration obtained at the AR gas outlet stream. Different solutions were used for on-  
184 line gas concentration determination downstream the FR: a) a NDIR analyzer to measure the  
185 SO<sub>2</sub> concentration, and b) a gas chromatograph (Varian 3400-CX GC) equipped with a  
186 PORAPAK-Q packed column and a sulfur-specific Flame Photometric Detector (FPD) for the  
187 SO<sub>2</sub> determination at low concentrations, and with a Thermal Conductivity Detector (TCD) for  
188 SO<sub>2</sub> concentrations above 1 vol.%. In this way, it was also possible the detection of the different  
189 gaseous sulfur compounds that can appear in the FR such as H<sub>2</sub>S, SO<sub>2</sub>, COS, CS<sub>2</sub>, etc. The  
190 chromatograph was calibrated in the range 0-2000 vppm for H<sub>2</sub>S and 0-20 vol. % for SO<sub>2</sub>. It  
191 must be remarked that only the SO<sub>2</sub> concentration data corresponding to the NDIR analyzer will

192 be showed in Section 3 of this paper. Furthermore, the sulfur mass balances that appear in  
193 Sections 3.1.3 and 3.2.3 were carried out considering the aforementioned data.

### 194 **2.3 Testing conditions**

195 The total solids inventory in the system was the same for both oxygen carriers, 1.2 kg  
196 approximately, of which 0.3 and 0.5 kg were in the FR and AR, respectively. A total operation  
197 time of 60 hours of continuous operation with sour gas and different H<sub>2</sub>S concentrations up to  
198 15 vol. % were carried out in the 500 W<sub>th</sub> CLC unit, from which 40 hours corresponded to the  
199 Cu-based oxygen carrier and 20 hours to the Fe-based material. The temperatures used in the  
200 CLC unit were different for the sour gas combustion tests depending on the oxygen carrier used.  
201 In the case of the Cu<sub>14</sub>- $\gamma$ Al material, the temperatures in the FR and AR were 1073 K and 1123  
202 K respectively. On the other hand, the Fe-based oxygen carrier was subjected to higher  
203 temperatures: 1173 K in the FR and 1223 K in the AR. The gas flows fed to the reactors were  
204 identical for all sour gas combustion tests. The inlet gas flow in the FR was 191 L<sub>N</sub>/h (0.1 m/s at  
205 1173 K). The AR was fluidized with air, which was divided into the primary air, added from the  
206 bottom bed (720 L<sub>N</sub>/h), and the secondary air, added at the top of the bubbling bed to help  
207 particle entrainment in the riser (150 L<sub>N</sub>/h). Nitrogen was also used to fluidize the bottom loop  
208 seal (37.5 L<sub>N</sub>/h).

209 Tables 1 and 2 shows a summary of the main variables used in the sour combustion tests carried  
210 out with the Cu-based and Fe-based materials respectively. The oxygen carrier-to-fuel ratio,  $\phi$ ,  
211 which was defined as the ratio between the oxygen supplied and the oxygen needed to  
212 stoichiometrically react with the fuel flow, was calculated by Eq. (1) as follows:

$$213 \quad \phi = \frac{F_{MeO}}{b \cdot F_{Fuel}} \quad (1)$$

214 where F<sub>MeO</sub> is the molar flow rate of the metal oxide. F<sub>MeO</sub> can be calculated considering both  
215 the solid flow rate (measured by means of a diverting solids valve located below the cyclone,  
216 see Figure 2) and the metal oxide content of the oxygen carrier. F<sub>Fuel</sub> is the inlet molar flow rate  
217 of the fuel in the FR. The parameter b is the stoichiometric coefficient of the fuel gas and  
218 depends on the oxygen carrier used during combustion tests (Cu-based or Fe-based oxygen

219 carrier) and on the fuels present in the sour gas composition ( $\text{CH}_4$ ,  $\text{H}_2\text{S}$ , and  $\text{H}_2$ ). This parameter  
220 was determined as a function of the solids circulation rate,  $f_s$ . A value of  $\phi = 1$  corresponds to  
221 the stoichiometric MeO amount needed for complete conversion of the sour gas to  $\text{CO}_2$ ,  $\text{SO}_2$ ,  
222 and  $\text{H}_2\text{O}$ .

223 Regarding the combustion tests conducted with the  $\text{Cu}_{14-\gamma}\text{Al}$  material, test Cu1 corresponded to  
224 the reference test carried out without  $\text{H}_2\text{S}$  addition. Tests Cu2-Cu4 were performed the first days  
225 of operation with sulfur addition. During these tests, the  $\text{H}_2\text{S}$  concentration was low, reaching  
226 values up to 3 vol. %. Tests Cu5-Cu6, Cu7-Cu9 and Cu10-Cu12 corresponded to  $\text{H}_2\text{S}$   
227 concentrations of 5, 10 and 15 vol. %, respectively. For each  $\text{H}_2\text{S}$  concentration tested in the  
228 CLC unit, several  $\text{CH}_4$  contents were used. The variation of concentration of both compounds  
229 allowed us to check the behavior of the oxygen carrier under different oxygen carrier-to-fuel  
230 ratios. At the end of the experimentation, a total of 40 hours of continuous operation with  $\text{H}_2\text{S}$   
231 feeding was reached.

232 Finally, test Cu13 was carried out with a new batch of oxygen carrier particles selecting the  
233 same operating conditions as in test Cu5, but replacing  $\text{N}_2$  for  $\text{CO}_2$  as gas balance. This  
234 atmosphere would better represent the atmosphere existing in a FR where only fuel is added. It  
235 must be remarked that the CLC unit of ICB-CSIC is limited by the AR design up to  $500 W_{\text{th}}$ .  
236 This fact makes necessary to use some gas as balance that it is introduced together with the fuel.  
237 In the case of the Fe-based oxygen carrier, most of the tests were carried out using  $\text{CO}_2$  as  
238 diluting agent. Tests Fe1-Fe4 corresponded to experiments with 10 vol.%  $\text{CH}_4$ , 5 vol.%  $\text{H}_2$  and  
239 increasing amounts of  $\text{H}_2\text{S}$  from 0 up to 15 vol.%. Tests Fe5-Fe8 were carried out at a higher  
240  $\text{CH}_4$  content (20 vol.%) and increasing amounts of  $\text{H}_2\text{S}$  (up to 15 vol.%). It must be remarked  
241 that in tests Fe7 and Fe8 the  $\phi$  value was very low. After that, it was decided to repeat test Fe6  
242 in order to check if repetitive results were obtained. Finally, tests Fe10 and Fe11 were  
243 performed at the same operating conditions as in tests Fe6 and Fe1, but replacing the  $\text{CO}_2$  gas  
244 balance by  $\text{N}_2$ . These last tests were carried out to check again if the variation of gas affected to

245 the obtained results. At the end, 20 hours of continuous operation were performed with the  
246 Fe<sub>2</sub>O<sub>3</sub> oxygen carrier.

247

### 248 3. Results

#### 249 3.1 Tests of sour gas combustion with the Cu<sub>2</sub>O oxygen carrier

##### 250 3.1.1 Thermodynamic calculations for copper materials

251 A thermodynamic study was carried out using the HSC Chemistry 6.1 (2008) software to  
252 determine the fate of sulfur when Cu-based oxygen carriers are used in a CLC plant with sour  
253 gas. This program obtains the equilibrium composition by using the method of minimization of  
254 the Gibbs free energy of the system for a fixed mass balance, at constant pressure and  
255 temperature.

256 The calculations were performed considering CuO as oxygen carrier and typical sour gas  
257 compositions. Figure 3 shows the thermodynamic equilibrium of the compounds existing in the  
258 FR for two sour gas compositions, (sour gas 1: 99.5 vol.% CH<sub>4</sub> - 0.5 vol.% H<sub>2</sub>S, and sour gas 2:  
259 85 vol.% CH<sub>4</sub> - 15 vol.% H<sub>2</sub>S) as a function of the oxygen carrier-to-fuel ratio,  $\phi$ , and at 1073 K.  
260 The reactions considered between the fuel (CH<sub>4</sub> + H<sub>2</sub>S) and the active phase of the oxygen  
261 carrier are the following depending on the value of parameter  $\phi$ :

266 The values obtained from the thermodynamic analysis were expressed as the volumetric  
267 percentage of gas product composition for sour gas combustion and as the molar percentage of  
268 sulfur species present in the products in relation to the sulfur fed into the system. At  $\phi$  values  
269 above 1, complete combustion of fuel gas to CO<sub>2</sub>, H<sub>2</sub>O and SO<sub>2</sub> was achieved (see Equations 2  
270 – 5). The unique stable sulfur compound at these conditions was SO<sub>2</sub>. If the oxygen carrier-to-  
271 fuel ratio decreased below 1, unreacted H<sub>2</sub> and CO appeared and reached a maximum when H<sub>2</sub>O

272 and CO<sub>2</sub> concentrations are zero. Below that point, CH<sub>4</sub> appeared as an unreacted gas.  
 273 Moreover, different solid and gaseous sulfur species, mainly Cu<sub>2</sub>S and H<sub>2</sub>S, appeared at sub-  
 274 stoichiometric conditions as a function the oxygen present in the system. The concentration of  
 275 H<sub>2</sub>S and Cu<sub>2</sub>S in equilibrium depended on the H<sub>2</sub> concentration through reaction (6):

277 It can be observed that the amount of Cu<sub>2</sub>S in equilibrium increased with the H<sub>2</sub>S content in the  
 278 sour gas. Thermodynamic calculations made at different temperatures from 973 to 1273 K  
 279 showed similar results.

280 The above results were obtained considering CuO as the only active copper-based specie  
 281 present in the oxygen carrier particles. However, XRD characterization showed that Cu14-γAl  
 282 material was composed by CuO and a spinel-structure CuAl<sub>2</sub>O<sub>4</sub> due to the interaction between  
 283 the active phase (CuO) and support (γ-Al<sub>2</sub>O<sub>3</sub>) (Adánez et al., 2006). The distribution between  
 284 CuO and CuAl<sub>2</sub>O<sub>4</sub> in the oxygen carrier depends on several factors but the presence of CuAl<sub>2</sub>O<sub>4</sub>  
 285 can be as high as 75 % during usual operation. Experience on previous works carried out at  
 286 ICB-CSIC indicated that both compounds were able to react with fuel gases, i.e., the spinel  
 287 phase was also reducible by the fuel gas (de Diego et al., 2004, 2005, 2007).

288 The reduction reactions that take place in the FR between CuAl<sub>2</sub>O<sub>4</sub> and the combustible fraction  
 289 of sour gas are the following:

294 The oxidation in the AR happens through reactions (11) and (12):

297 The same thermodynamic calculations as in the previous case with CuO were performed  
 298 considering CuAl<sub>2</sub>O<sub>4</sub> as oxygen carrier. In this case CuAl<sub>2</sub>O<sub>4</sub> data given from Jacob and Alcock

299 (1975) were used to carry out the thermodynamic analyses. The obtained results were identical  
300 with both Cu-based compounds, CuO and CuAl<sub>2</sub>O<sub>4</sub>, as it can be observed in Figure 3.

### 301 **3.1.2 Combustion tests in the ICB-CSIC-g1 facility**

302 To evaluate the suitability of the Cu<sub>14</sub>- $\gamma$ Al material for sour gas combustion, some experimental  
303 tests were performed in the 500W<sub>th</sub> CLC unit. The combustion efficiency, the sulfur splitting  
304 between reactors, and the reactivity of fresh and after-used particles were analyzed for each  
305 experiment.

306 In test Cu1, without H<sub>2</sub>S addition, full combustion of CH<sub>4</sub> to CO<sub>2</sub> and H<sub>2</sub>O was obtained. This is  
307 the usual behavior of this Cu-based material at the operating conditions used here. The absence  
308 of carbon formation in the oxygen carrier particles was maintained during the whole  
309 experimentation.

310 During the first 2 hours of operation with sulfur addition (3000 vppm) in test Cu2, no SO<sub>2</sub> was  
311 detected at the outlet gas stream of the FR or AR. After that, almost all the sulfur fed to the  
312 installation was detected as SO<sub>2</sub> at the gas outlet stream from the FR.

313 During tests Cu3 and Cu4, CH<sub>4</sub> was fully burnt to CO<sub>2</sub> and H<sub>2</sub>O. CO, H<sub>2</sub>, and H<sub>2</sub>S were never  
314 detected in the FR stream. The latter compound was mainly transformed into SO<sub>2</sub> through  
315 reactions (4), (5), (9) and (10). In addition, variable amounts of SO<sub>2</sub> (up to 300-400 vppm) were  
316 found at the outlet of the AR.

317 During tests Cu5 and Cu6, with a sulfur content of 5 vol.% H<sub>2</sub>S in the feeding gas, the SO<sub>2</sub>  
318 concentration at the outlet gas stream from the FR was maintained quite constant during all the  
319 operation time with values close to the sulfur fed. However, the amounts of SO<sub>2</sub> detected at the  
320 outlet of the AR increased, reaching values up to 2000 vppm (5720 mg/Nm<sup>3</sup>) in test Cu5. In test  
321 Cu6, CH<sub>4</sub> concentration was decreased, which corresponded to an increase in the value of the  
322 parameter  $\phi$ . The response to this change in the gas product distribution was very quick in both  
323 reactors, with slightly increasing the SO<sub>2</sub> concentration in the FR and decreasing in the AR up  
324 to values of 100-200 ppm (286-572 mg/Nm<sup>3</sup>). To corroborate if this change could be attributed  
325 to the change in the value of  $\phi$ , the conditions of test Cu5 were again reestablished, and the

326 previous values were again reached. This fact demonstrated a relation between the oxygen  
327 carrier-to-fuel ratio and the SO<sub>2</sub> concentration obtained at the outlet of the AR, in such a way  
328 that the SO<sub>2</sub> concentration was higher as lower was the φ value. A similar behavior was found  
329 when the solids circulation rate was varied.

330 A possible explanation to this phenomenon may be that some Cu<sub>2</sub>S was formed inside the FR  
331 through reaction (6), being favored when more metallic copper was present in this reactor, that  
332 is, when the circulation rate or the φ value were lower. The Cu<sub>2</sub>S transported to the AR could be  
333 partially burnt to SO<sub>2</sub> according to reaction (13):

335 As an example of the sour gas combustion tests, Figure 4 shows the gas composition obtained at  
336 the outlet of the FR and AR for the tests Cu7-Cu9 corresponding to 10 vol.% H<sub>2</sub>S in the gas  
337 feeding. It was observed the same relation between parameter φ and the SO<sub>2</sub> concentration  
338 obtained at the outlet of the AR as in tests Cu5 and Cu6, i.e., the SO<sub>2</sub> concentration was higher  
339 as lower was the value of the parameter φ. Again, it was possible that some Cu<sub>2</sub>S could be  
340 formed in the lower zone of the fluidized bed, which was partially released in the AR as SO<sub>2</sub>  
341 and some was being accumulated in the particles.

342 In the lower part of Figure 4 a graph showing the instantaneous sulfur mass balance was added.  
343 This mass balance, expressed as mol of sulfur per hour, includes the sulfur fed to the system, the  
344 sulfur detected at the outlet of the FR and AR, and the total sulfur in the gas phase leaving both  
345 reactors. The difference between the sulfur fed and the total sulfur detected in the gas phase at  
346 the exit of the FR and AR could be due to experimental errors or to formation of copper sulfides  
347 in the oxygen carrier particles.

348 In the experimental tests Cu10-Cu12 performed with the highest concentration of H<sub>2</sub>S, i.e., 15  
349 vol.%, it was found again the same relation between the SO<sub>2</sub> released in the AR and the  
350 parameter φ. However, these tests showed the lowest emissions of sulfur in the gas phase among  
351 all the tests, which indicated that there were more sulfides formed or more experimental errors  
352 in the measurements. It must be considered that tests Cu10-Cu12 correspond to the most

353 extreme conditions, with the highest H<sub>2</sub>S concentration, and when the particles have already  
354 been subjected to almost 40 hours of continuous operation with some sulfur accumulated inside  
355 the particles, as it will be showed later (see Section 3.1.4). Nevertheless, agglomeration was  
356 never detected in the CLC unit using this oxygen carrier. The presence of sulfur inside the  
357 particles did not alter their properties regarding agglomeration because they were prepared  
358 under the guidelines proposed by de Diego et al. (2005) to avoid this problem in copper-based  
359 oxygen carriers.

360 After test Cu12, the whole solids inventory was replaced by a new batch of particles and an  
361 additional test, test Cu13, was carried out at the same operating conditions as in test Cu5 but  
362 using CO<sub>2</sub> instead of N<sub>2</sub> as gas balance. This test was performed to analyze the effect of the  
363 reacting atmosphere on the behavior of the oxygen carrier during sour gas combustion. The  
364 results obtained in terms of gas product distribution and sulfur mass balance were similar to the  
365 obtained in test Cu5 which indicated that the gas balance atmosphere had a negligible effect on  
366 the material performance.

### 367 **3.1.3 Sulfur mass balance**

368 A sulfur mass balance was performed to the different tests carried out in the CLC unit with the  
369 Cu<sub>14</sub>Al material. Sulfur splitting between reactors and the possible formation of copper  
370 sulfides in the oxygen carrier particles were analyzed. Figure 5 shows this balance in terms of  
371 percentage of sulfur released in both FR and AR. It can be observed that most of the sulfur  
372 appeared as SO<sub>2</sub> in the FR, and a minor part (less than 13 wt.%) in the AR. It can be also  
373 noticed that there was an amount of sulfur that was not detected in the gas phase. This amount  
374 was high in some tests, which cannot be only attributed to experimental errors. It was concluded  
375 that some sulfur was accumulated in the oxygen carrier, as it will be demonstrated in the next  
376 characterization section. It must be remarked the behavior of the material during the first  
377 experiment with sulfur addition (test Cu2), where there was an important accumulation of sulfur  
378 inside the oxygen carrier particles since only a 23 % of the sulfur fed was released as SO<sub>2</sub> in the  
379 FR. Also, it is remarkable the results obtained in tests Cu10-12 which presented the lowest  
380 sulfur emissions in the gas phase, both in FR and AR. These tests correspond to the most

381 extreme conditions, with the highest H<sub>2</sub>S concentration, and after 35 hours of continuous  
382 operation.

383 According to the thermodynamic data showed in section 3.1.1, and considering that the tests  
384 were always carried out at  $\phi$  values above 1, no copper sulfides should be formed at any of the  
385 operating conditions used during the experimental work. However, it is necessary to take into  
386 consideration that inside the FR fluidized bed could be a reducing zone with possible high CO  
387 and H<sub>2</sub> concentrations and considerable presence of metallic copper that could be responsible of  
388 the copper sulfides formation (Forero et al., 2010), see reaction (6). To confirm this possibility,  
389 a solid characterization to samples extracted from the system at different times was carried out.

#### 390 **3.1.4 Characterization of the oxygen carrier**

391 Samples of Cu<sub>14</sub>Al material were extracted from the FR and AR at the end of each  
392 experimental test for solid characterization. Table 3 shows the main characteristics of those  
393 samples.

394 XRD characterization showed the main compounds existing in the samples extracted from the  
395 AR. The equipment used was a X-ray diffractometer Bruker AXS D8 Advance with Bragg-  
396 Brentano geometry configuration, Cu K $\alpha$  radiation and equipped with secondary graphite  
397 monochromator. Different crystalline species, such as Al<sub>2</sub>O<sub>3</sub>, CuAl<sub>2</sub>O<sub>4</sub> and CuO, were detected.  
398 Regarding stable sulfur phases, no copper sulfides were detected in any case. However, it is  
399 reasonable to think that the amounts of copper sulfides were below the detection limit of the  
400 apparatus (5 wt.%). To check the presence of sulfur in the oxygen carrier particles at lower  
401 amounts, the samples were analyzed by ultimate analysis in a Thermo Flash 1112. From this  
402 characterization technique, important amounts of sulfur were detected, which are showed in  
403 Table 3. Considering Cu<sub>2</sub>S as the unique copper sulfide possible at the experimental conditions  
404 used in the tests, the content of this compound in the samples was calculated. It seems that the  
405 Cu<sub>2</sub>S content depends on the operation conditions and it can be concluded that sulfur was being  
406 accumulated along time in the oxygen carrier particles during the sour gas combustion tests.

407 The presence of sulfur inside the particles was also detected by SEM-EDX. The equipment used  
408 was a scanning electron microscope (SEM) ISI DS-130 coupled to an ultra-thin window PGT

409 Prism detector for energy-dispersive X-ray (EDX). Figure 6 illustrates a SEM image of a cross-  
410 section of an oxygen carrier particle after 40 h of sour gas combustion inside the CLC  
411 prototype. It can be observed that a significant presence of sulfur was detected in those areas  
412 where metallic copper was accumulated.

413 Finally, the reactivity of the oxygen carrier particles along the time of operation was determined  
414 in a TGA CI Electronics type, described elsewhere (Abad et al, 2011), using CH<sub>4</sub> as reducing  
415 gas. It was observed in Figure 7 that samples lost some oxygen transport capacity and reactivity.  
416 Nevertheless, the reactivity until 40 % of solid conversion was maintained high. In this point it  
417 must be highlight that the  $\phi$  values used in the CLC unit were in the range from 1.3 to 3.7,  
418 corresponding to variations of solid conversion below 0.6 in most of the experiments. By this  
419 reason, a decrease in the CH<sub>4</sub> conversion along time was not noticed during combustion tests.  
420 However, it is expected that reactivity decreases below acceptable values for long operating  
421 times as the existing in CLC units at industrial scale. The SO<sub>2</sub> concentrations at the outlet of the  
422 AR corresponded to values measured at the operating conditions used in the tests. When these  
423 values were normalized to an excess of 6 vol.% O<sub>2</sub>, the SO<sub>2</sub> emissions were always higher than  
424 200 mg/Nm<sup>3</sup>, the EU emissions limit for boilers higher than 200 MW<sub>th</sub>. Considering the above  
425 data and the confirmed accumulation of sulfur in the oxygen carrier particles as Cu<sub>2</sub>S, the use of  
426 Cu-based oxygen carriers for sour gas combustion with high H<sub>2</sub>S concentrations is not  
427 recommended.

## 428 **3.2 Tests of sour gas combustion with the Fe<sub>20</sub>Al oxygen carrier**

### 429 **3.2.1 Thermodynamic calculations for iron materials**

430 Similar calculations to the previously ones were performed for Fe-based materials.  
431 Thermodynamic calculations of different sour gas compositions were carried out in a range of  
432 temperature from 1073 K to 1373 K. Figure 8a shows the thermodynamic equilibrium existing  
433 at 1223 K, for a sour gas composed by 85 vol.% CH<sub>4</sub> and 15 vol.% H<sub>2</sub>S, as a function of the  
434 oxygen carrier-to-fuel ratio,  $\phi$ , when the redox pair considered is Fe<sub>2</sub>O<sub>3</sub>-Fe<sub>3</sub>O<sub>4</sub>. In this case, a

435 value of  $\phi = 1$  corresponds to the stoichiometric amount of  $\text{Fe}_2\text{O}_3$  needed for a full conversion of  
436 the fuel ( $\text{CH}_4 + \text{H}_2\text{S}$ ) to  $\text{CO}_2$ ,  $\text{SO}_2$ , and  $\text{H}_2\text{O}$  through reactions (14) and (15).

439 Thermodynamic results are expressed as the volumetric percentage of gas composition and as  
440 the molar percentage of sulfur species present in the products in relation to the sulfur fed into  
441 the system. Furthermore, Figure 8a includes the different iron species in equilibrium at the  
442 different  $\phi$  values considered. At  $\phi$  values above 1, complete combustion of the fuel gas mixture  
443 to  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , and  $\text{SO}_2$  was achieved. Again, the unique stable sulfur compound working with  
444 Fe-based oxygen carriers was  $\text{SO}_2$ , similarly to the case with the Cu-based oxygen carrier. At  
445 sub-stoichiometric conditions,  $\text{CO}_2$  and  $\text{H}_2\text{O}$  concentrations decreased as the amount of oxygen  
446 provided by the active Fe-based specie was reduced. On the contrary,  $\text{H}_2$  and  $\text{CO}$  concentrations  
447 progressively increased reaching their maximum values when the iron oxide was fully reduced  
448 to metallic iron. Finally, at very low  $\phi$  values, lower than 0.1, unreacted  $\text{CH}_4$  appeared in the  
449 equilibrium while the amounts of  $\text{CO}$  and  $\text{H}_2$  dramatically decreased. Different solid and  
450 gaseous sulfur species can appear at  $\phi$  values below 1 depending on the oxygen available in the  
451 system. The main iron sulfide present was the  $\text{Fe}_{0.877}\text{S}$  and always appeared some  $\text{H}_2\text{S}$  in  
452 equilibrium. Small amounts of  $\text{S}_2(\text{g})$  were also found at  $\phi$  values close to 1.

453 However, a special case corresponds to Fe-based oxygen carriers prepared by impregnation on  
454  $\text{Al}_2\text{O}_3$ . In this case, iron aluminate ( $\text{FeAl}_2\text{O}_4$ ) can be formed as reduced compound allowing  
455 complete combustion of gas to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  (Abad et al., 2007; Cabello et al., 2014a; Gayán et  
456 al., 2012; Leion et al., 2008), and increasing three times the oxygen transport capacity of the  
457 oxygen carrier in comparison with the redox pair  $\text{Fe}_2\text{O}_3$ - $\text{Fe}_3\text{O}_4$ . Additional thermodynamic  
458 calculations including  $\text{Al}_2\text{O}_3$  as solid phase were performed using the HSC Chemistry 6.1  
459 program. Figure 8b shows the results corresponding to sour gas containing 15 vol.%  $\text{H}_2\text{S}$ . In this  
460 case, a value of  $\phi = 1$  corresponds to the stoichiometric amount of  $\text{Fe}_2\text{O}_3$ , supported on  $\text{Al}_2\text{O}_3$ ,

461 needed for full conversion of the fuel (CH<sub>4</sub>+H<sub>2</sub>S) to CO<sub>2</sub>, SO<sub>2</sub> and H<sub>2</sub>O when the redox pair  
462 considered is Fe<sub>2</sub>O<sub>3</sub> (Al<sub>2</sub>O<sub>3</sub>) - FeAl<sub>2</sub>O<sub>4</sub>.

465 The gas product distribution and the sulfur species at  $\phi$  values higher than 1 were the same as in  
466 the previous case when the redox pair Fe<sub>2</sub>O<sub>3</sub>- Fe<sub>3</sub>O<sub>4</sub> was considered: full combustion of fuel gas  
467 to CO<sub>2</sub>, H<sub>2</sub>O, and SO<sub>2</sub> as the unique sulfur compound present in the system. At sub-  
468 stoichiometric conditions, unreacted H<sub>2</sub> and CO appeared reaching their maximum values when  
469 the equilibrium Fe-FeAl<sub>2</sub>O<sub>4</sub> was found. In this case, CO<sub>2</sub> and H<sub>2</sub>O were not present in the gas  
470 equilibrium. CH<sub>4</sub> appeared as an unreacted gas at very low  $\phi$  values when hematite was fully  
471 reduced to metallic iron. Interesting results were obtained at sub-stoichiometric conditions  
472 regarding sulfur species present in the reaction products. In this case, formation of iron sulfides  
473 were only possible at very low values of  $\phi$  ( $\phi < 0.4$ ), with most of the sulfur appearing as H<sub>2</sub>S.  
474 This can be considered as a remarkable result and even more if we consider that the  
475 transformation Fe<sub>2</sub>O<sub>3</sub> (Al<sub>2</sub>O<sub>3</sub>) - FeAl<sub>2</sub>O<sub>4</sub> supposes to increase three times the oxygen transport  
476 capacity with respect to the use of the pair Fe<sub>2</sub>O<sub>3</sub>-Fe<sub>3</sub>O<sub>4</sub>. Thermodynamic calculations made at  
477 temperatures from 1073 to 1373 K and sour gas with different H<sub>2</sub>S contents showed similar  
478 results.

### 479 **3.2.2 Combustion tests in the ICB-CSIC-g1 facility**

480 The behavior of the Fe-based oxygen carrier in sour gas atmospheres with high H<sub>2</sub>S  
481 concentrations was analyzed in the ICB-CSIC-g1 facility under continuous operating  
482 conditions. Table 2 shows the combustion tests carried out and the experimental conditions  
483 used.

484 During tests Fe1-Fe4, with a CH<sub>4</sub> concentration of 10 vol.%, neither CO nor H<sub>2</sub> was detected in  
485 the gas outlet stream from FR and full combustion of CH<sub>4</sub> to CO<sub>2</sub> and H<sub>2</sub>O was obtained with  
486 100 % of carbon capture. Reactions (16) and (18) were considered to take place in the FR:

488 In addition, neither CO nor CO<sub>2</sub> was detected in the AR in any of the tests, which means that no  
489 carbon was ever formed during fuel combustion in the FR. In the AR, the oxidation of the  
490 material took place through reaction (19):

492 Taking into account the results of previous works (Cabello et al., 2014, Gayán et al., 2012), this  
493 is the usual behavior of this Fe-based material at the operating conditions used when no H<sub>2</sub>S  
494 was fed into the combustor.

495 Regarding the combustion of the H<sub>2</sub>S fed to the CLC system during tests Fe2-Fe4, it must be  
496 remarked the very good behavior obtained with this oxygen carrier. All the H<sub>2</sub>S was burnt by  
497 the oxygen carrier through reaction (17) and the SO<sub>2</sub> concentration obtained at the outlet of the  
498 FR was very close to the one corresponding to full combustion of H<sub>2</sub>S. No SO<sub>2</sub> was released in  
499 the AR in any of the operating conditions.

500 Due to the excellent results obtained in tests Fe1-4, the CH<sub>4</sub> concentration was increased up to  
501 20 vol.% in tests Fe5-Fe9 to analyze the oxygen carrier behavior when the parameter  $\phi$  took  
502 lower values (see Table 2). The results obtained in these tests are showed in Figure 9.

503 Test Fe5 corresponded to the reference test without H<sub>2</sub>S addition and a CH<sub>4</sub> concentration of 20  
504 vol.%. In this case, the combustion of CH<sub>4</sub> was almost complete because a very small amount of  
505 unreacted CH<sub>4</sub> (< 0.8 vol.%) appeared at the outlet stream from the FR. Furthermore, neither H<sub>2</sub>  
506 nor CO was detected. During test Fe6, full H<sub>2</sub>S combustion to SO<sub>2</sub> and almost full combustion  
507 of CH<sub>4</sub> to CO<sub>2</sub> and H<sub>2</sub>O was achieved in the FR. However, an increase in the H<sub>2</sub>S concentration  
508 up to 15 vol.% (test Fe8) produced a decrease in the percentage of SO<sub>2</sub> obtained in the FR in  
509 relation to the H<sub>2</sub>S fed. Furthermore, some unconverted CH<sub>4</sub> appeared in the FR and increasing  
510 amounts of SO<sub>2</sub> appeared in the AR. This last fact could be as a consequence of the iron sulfides  
511 formed in the FR through reaction (20) that could be burnt in the AR according to reaction (21)  
512 due to the low  $\phi$  values (1.5 and 1.3, respectively) used in these tests.

515 As it was mentioned in Section 3.2.1, thermodynamic calculations showed that  $\text{Fe}_{0.877}\text{S}$  was the  
516 only stable sulfide that could be formed at  $\phi$  values lower than 0.4, through the reaction (20).  
517 Nevertheless, in order to facilitate the adjustment of the chemical reactions, FeS has been  
518 considered as the stable iron sulfide instead of the  $\text{Fe}_{0.877}\text{S}$  compound.

519 Comparing the  $\phi$  values needed to boost thermodynamically the formation of iron sulfides with  
520 the ones used in the CLC plant during the experimental campaign, it could be concluded that  
521 iron sulfides should be not formed in any case at usual operating conditions.

522 After that, conditions corresponding to test Fe6 were reestablished in test Fe9 to evaluate if iron  
523 sulfides were reversible when the amount of oxygen available for combustion increased. In this  
524 case,  $\text{CH}_4$  concentration at the outlet of the FR decreased, i.e., the combustion behavior of the  
525 oxygen carrier particles was improved, and more sulfur, in the form of  $\text{SO}_2$ , was detected at the  
526 outlet of the FR in relation to the amount fed into the CLC system. These results indicated that  
527 the possible iron sulfides formed at reducing conditions were reversible and no accumulation in  
528 the particles was produced. The regeneration of the iron sulfides would be carried out in the FR  
529 by the reverse of reaction (20), that is, by reaction of the iron sulfide with the steam existing in  
530 the environment. The amount of  $\text{H}_2\text{S}$  produced would be further burnt by normal reaction with  
531 the oxygen carrier to release  $\text{SO}_2$ , see reaction (17).

532 The conclusion obtained after these tests revealed that the CLC unit must be operated at  $\phi$   
533 values higher than 1.5 to obtain full combustion of  $\text{H}_2\text{S}$  to  $\text{SO}_2$  in the FR, and therefore to avoid  
534 iron sulfides formation and  $\text{SO}_2$  emissions at the AR outlet stream.

535 Finally, in tests Fe10 and Fe11 the  $\text{CO}_2$  used as balance in the previous tests was replaced by  
536  $\text{N}_2$ . The results obtained during test Fe10 indicated that the gas atmosphere had no influence  
537 over the combustion process and sulfur distribution behavior. Test Fe11 was performed without  
538  $\text{H}_2\text{S}$  feeding in a  $\text{N}_2$  atmosphere to check if the oxygen carrier particles maintained their  
539 reactivity after iron sulfides formed during test Fe8 and later regeneration. The results obtained  
540 during this new reference test were very satisfactory considering that almost full  $\text{CH}_4$   
541 combustion was again achieved.

### 3.2.3 Sulfur mass balance

With the above experimental data, a sulfur mass balance was carried out to the different sour gas combustion tests. Figure 10 shows this balance expressed in terms of molar percentage of sulfur considering the amounts released as SO<sub>2</sub> both in the FR and in the AR. It can be observed that in tests Fe2-Fe4 and Fe6-Fe7, all the sulfur detected appeared as SO<sub>2</sub> in the FR, and the mass balances closed within 8 % of deviation. This deviation could be due to experimental errors or to some sulfur accumulation in the oxygen carrier particles as iron sulfides. Only in test Fe8, corresponding to a very low oxygen-carrier-to fuel ratio ( $\phi = 1.3$ ), some SO<sub>2</sub> was detected in the AR. Furthermore, during this test the total amount of sulfur detected in the gas phase was lower than in the previous tests. This result would indicate a zone of operating conditions which favored the formation of iron sulfides. Finally, in tests Fe9 and Fe10, more amount than the corresponding to the sulfur fed was obtained at the outlet of the FR, which indicated the regeneration of the oxygen carrier by the disappearance of the iron sulfides formed.

### 3.2.4 Characterization of the oxygen carrier

Different samples of the Fe<sub>20</sub>γAl oxygen carrier were extracted from the FR and AR during the 20 hours of continuous operation for further solid characterization. Table 4 shows the main characteristics of those samples.

Powder XRD patterns showed the main crystalline phases existing in the fresh and used samples extracted from the AR at different times of operation. The fresh material was composed by Fe<sub>2</sub>O<sub>3</sub> and α-Al<sub>2</sub>O<sub>3</sub>, and this structure was maintained along operation. Iron sulfides were not detected in any case, which could be due to the detection limit of the apparatus. To evaluate the presence of sulfur inside the samples, used particles were subjected to ultimate analyses with a Thermo Flash 1112 analyzer. Sulfur was only detected in the samples extracted after test Fe8 where only the 76 wt.% of the sulfur fed was released in the gas phase, and some SO<sub>2</sub> was detected in the AR. Nevertheless, the amount of sulfur was very low. No sulfur was found in the samples of subsequent tests, which meant that the iron sulfides formed had disappeared and the material was completely regenerated.

570 The presence of sulfur in the Fe-based oxygen carrier particles was also analyzed by SEM-EDX  
571 techniques. Figure 11 shows a SEM image of the cross-section of oxygen carrier particles  
572 extracted from the CLC unit after test Fe8. The SEM-EDX analysis revealed a small amount of  
573 sulfur in the material.

574 Finally, thermogravimetric experiments were performed to fresh and after-used particles in  
575 order to determine the initial reactivity of this material and its evolution during operation in the  
576 continuous CLC unit. The reduction reactivity of the particles was analyzed using CH<sub>4</sub> as  
577 gaseous fuel. As it can be observed in Figure 12, the samples maintained their reactivity after 20  
578 hours of operation, even in the presence of H<sub>2</sub>S concentrations as high as 15 vol.%.

579

#### 580 **4. Conclusions**

581 A total of 60 hours of continuous operation with sour gas and different H<sub>2</sub>S concentrations up to  
582 15 vol. % has been carried out in the ICB-CSIC-g1 facility (500 W<sub>th</sub>), from which 40  
583 corresponded to a Cu-based oxygen carrier and 20 hours to a Fe-based material.

584 During the sour gas combustion tests with the Cu<sub>14</sub>γAl material, stable operation was achieved  
585 with no agglomeration problems. This oxygen carrier was able to burn completely a synthetic  
586 sour gas. Sulfur was mainly released as SO<sub>2</sub> in the FR, although some amounts were also  
587 released in the AR. As a general rule, the SO<sub>2</sub> concentration in the AR decreased as higher was  
588 the oxygen carrier-to-fuel ratio,  $\phi$ . Nevertheless, with the operating conditions selected during  
589 this experimental work it was not possible to reach in this reactor SO<sub>2</sub> emissions lower than 200  
590 mg/Nm<sup>3</sup>, the EU limit of emissions for boilers higher than 200 MW<sub>th</sub>. Furthermore, Cu<sub>2</sub>S was  
591 formed at all operating conditions, being accumulated during operation. Therefore, it was  
592 concluded that Cu-based oxygen carriers were not adequate for sour gas combustion in a CLC  
593 process.

594 On the contrary, the behavior of the Fe-based oxygen carrier during the sour gas combustion  
595 tests was very satisfactory. The Fe<sub>20</sub>γAl material was able to burn completely the sour gas at  
596 usual oxygen-carrier-to fuel ratios. The high reactivity of the fresh material was maintained

597 throughout all the operation time even in the presence of high H<sub>2</sub>S concentrations. Furthermore,  
598 neither SO<sub>2</sub> was released in the AR nor iron sulfides were formed at oxygen carrier-to-fuel  
599 ratios higher than 1.5. Therefore, it is concluded that this Fe-based material is very adequate for  
600 the combustion of sour gas, even with high H<sub>2</sub>S content, allowing CO<sub>2</sub> capture without any SO<sub>2</sub>  
601 emissions to the atmosphere.
