25 **Abstract**

26

27 Limiting similarity theory predicts that competing species must segregate along one or more
28 dimensions of their ecological niche in order to coexist. However, balancing the costs and
29 benefits of moving the position along specific niche axes becomes harder with decreasing
30 breadth of tolerance, and increasing community complexity. In predator communities,
31 interspecific interactions are influenced by a diversity of factors; therefore the behavioural
32 patterns of composing species will differ due to locally adapted interactions.

33 We deployed 32 - 41 camera-traps in five study areas distributed across the Iberian Peninsula to
34 investigate the temporal relations within mesocarnivore communities in SW Europe. The
35 selection for a period of the diel cycle and plasticity in activity patterns was evaluated, using the
36 Jacobs selection index (JSI) and the coefficient of activity overlap (Δ_1). Furthermore, we
37 investigated whether temporal shifts can facilitate coexistence by reducing activity overlap.
38 Overall, seven species of mesocarnivores were detected and were assigned into one of three
39 behaviourally distinct groups: diurnal ($JSI_{\text{day}} \geq 0.8$), strictly nocturnal ($JSI_{\text{night}} \geq 0.8$) and
40 facultative nocturnal species ($0.4 \geq JSI_{\text{night}} > 0.8$). Most species included in the two latter groups,
41 while strongly bound to nighttime, exhibited substantial flexibility within their preferred activity
42 periods allowing them to locally adapt their foraging strategies (intraspecific $\Delta_1 = 0.70 - 0.77$).
43 The mean Δ_1 values obtained from all pairwise comparisons in each sampling campaign was
44 negatively correlated with the number of carnivore species with ≥ 10 detections ($r = -0.76$, $p =$
45 0.02). Our results suggest that temporal segregation is likely to play an important role in
46 facilitating mesocarnivore coexistence, especially with increasing community complexity.
47 Moreover, while some overlap in activity patterns is inevitable, most species activity peaks were
48 asynchronous. These results contribute for understanding the dynamics and behavioural

49 strategies of coexisting mesocarnivores, crucial for forecasting the possible outcomes of
50 conservation or management actions.

51 **Introduction**

52

53 A population of a given species can be ecologically described by its position along a set of
54 dimensions ordering environmental variables (Schoener 1974), thus occupying a specific
55 ecological niche (Hutchinson 1957). MacArthur and Levins' (1967) limiting similarity theory
56 predicts that there is a threshold of niche similarity between sympatric species under which
57 stable coexistence is allowed. This means that competing species must segregate, at least
58 partially, along one or more dimensions of their ecological niche (Hardin 1960; MacArthur and
59 Levins 1967; Szabó and Meszeéna 2006). Alternatively to this kind of displacement, limiting
60 theory predicts that depending on the competitive abilities of the species involved, competition
61 would be reflected in their population numbers (Abrams 1983). Schoener (1974) found that the
62 separation among species niches is generally multidimensional, and two is the most common
63 number of dimensions separating species. Despite being regarded as the least important of the
64 three main niche axes - spatial, temporal and resource exploitation - , the temporal niche axis is
65 particularly relevant in the case of predator species as they often segregate across the diel cycle,
66 promoting coexistence (e.g. Di Bitetti *et al.* 2009; Harrington *et al.* 2009; Wang and Fisher
67 2012). Further, the presence of competitors frequently influences activity patterns through
68 interference competition, which is expected to be stronger whenever similarity in other niche
69 dimensions and body mass are high (Schoener 1974; Linnell and Strand 2000; Donadio and
70 Buskirk 2006; Ritchie and Johnson 2009). However, a species activity pattern along the diel
71 cycle is not only regulated by competition. It is internally regulated by each specie's endogenous
72 clock (Kronfeld-Schor and Dayan 2003) and by external abiotic and biotic factors which, in the
73 case of predator species, are strongly constrained by the accessibility to preys, that often have

74 their own well defined activity patterns (Halle 2000; Arias-Del Razo *et al.* 2011). Biological and
75 ecological similitudes bind mesocarnivore species, making this group particularly interesting for
76 addressing community functioning studies (Roemer, Gompper, and Valkenburgh 2009). The
77 ecological interactions within a carnivore community should vary as a result of several factors
78 such as community structure, species plasticity and bottom-up and top-down control effects
79 (Linnell and Strand 2000; Elmhagen and Rushton 2007; Ritchie and Johnson 2009; Elmhagen *et*
80 *al.* 2010). A consequence of such complexity is that mesocarnivore communities with similar
81 species composition may differ in their internal organization, niche relations and behavioural
82 patterns relative to species interactions. Different guild compositions and structures should result
83 into different interspecific relations among its composing species, and potentially drive their
84 positions along specific niche axes to change from one area to another. In the presence of
85 competition for a position in a specific niche axis, a subordinate competitor is either plastic
86 enough to displace its position along that axis or will change along some other axis to further
87 reduce niche overlap. However, resource partitioning is a community wide phenomenon and the
88 interactions involved are complex. Therefore, the analysis and interpretation of such interspecific
89 relations require a holistic approach (Schoener 1974; Ritchie and Johnson 2009).

90 Southwestern (SW) European mesocarnivore communities include a total of seven species,
91 which not all occur in sympatry or coexist spatially within their distribution areas by result of
92 ecosystem disruption, habitat fragmentation, direct persecution or other historical factors
93 (Cabral *et al.* 2005; Palomo, Gisbert, and Blanco 2007). For example, the pine marten (*Martes*
94 *martes*) distribution is restricted to the northern fringe of the Iberian Peninsula (López-Martin
95 2007), and the Egyptian mongoose (*Herpestes ichneumon*) to the Mediterranean bioclimatic
96 region (Palomares 2007). In SW European mesocarnivore communities, the potential for

97 exploitation and/or interference competition exists among several species pairs along various
98 niche dimensions due to above-mentioned high diversity of mesocarnivore community
99 structures' that can be found.

100 Here, we analyze data on the diel activity of mesocarnivores of several areas and bioclimatic
101 regions in SW Europe. We aimed to evaluate the level of plasticity of the species that compose
102 these mesocarnivore communities in their activity patterns and whether ecological shifts along
103 the temporal axis could promote coexistence by reducing the overlap in activity periods with
104 competitors.

105

106 **Methods**

107 *Study areas*

108 The Iberian Peninsula (IP) is included in two biogeographical regions: the Mediterranean region,
109 which occupies roughly 2/3 of the southwestern IP; and the Atlantic region, which is restricted to
110 the northern fringe and extends towards the Pyrenees (European Environmental Agency 2012).

111 In order to obtain data from the mesocarnivore communities of both bioclimatic regions, five
112 study sites were selected, distributed across the IP (Fig. 1): the Guadiana Valley Natural Park
113 (GVNP) and the Peneda-Gerês National Park (PGNP), located in Portugal; and the Cabañeros
114 National Park (CNP), the Sierra de Andújar Natural Park (SANP) and the Muniellos Natural
115 Reserve (MNR), located in Spain. GVNP, CNP and SANP are located in the Mediterranean
116 region, and have a Mediterranean pluviseasonal continental bioclimate (Rivas-Martínez, Penas,
117 and Díaz 2004). Scrublands are mainly associated with steeper slopes, elevation ridges and main
118 water bodies, and are dominated by *Pyro-Quercetum rotundifoliae* and *Myrto communis-Quercro*
119 *rotundifoliae* series and other subserial stages (Rivas-Martinez 1981; Costa *et al.* 1998). At CNP

120 and GVNP, areas with gentler slopes are mainly occupied by cereal crops and a savannah-like
121 system, with holm oak trees (*Quercus rotundifolia*) scattered within a grassland matrix (García-
122 Canseco 1997). At the SANP, areas with gentler slopes are rather dominated by Stone pine
123 (*Pinus pinea*) and Maritime pine (*Pinus pinaster*) forests with and without understorey (Gil-
124 Sánchez, Ballesteros-Duperón, and Bueno-Segura 2006). Human access is highly restricted at
125 CNP and SANP, for conservation purposes. However, at GVNP hunting activity is extremely
126 important in this region and about 86% of the land is included in hunting estates.

127 The PGNP and MNR are located in the Atlantic region, and have a temperate oceanic
128 submediterranean bioclimate (Rivas-Martínez *et al.* 2004). The landscapes consist of
129 mountainous agricultural–forest mosaic, where mountain tops are mostly dominated by
130 scrublands with Ericaceae, *Ulex* sp. and Betulaceae habitats, and mountain slopes and valleys are
131 essentially dominated by oligotrophic oak forests (dominated by *Quercus* sp., *Betula* sp. and
132 *Fagus* sp.). Pastures, agricultural fields and small villages are found scattered through the
133 landscape, mainly along valleys and lower altitude locations (Prieto and Sánchez 1996; Carvalho
134 and Gomes 2004). High levels of tourist visitation (namely hikers) also characterize the PGNP
135 study area, which are mainly focused in the warmer months and in the main valley. Human
136 access is limited inside the integral reserve of MNR, and is restricted to 20 persons per day along
137 a specific trail. The neighboring areas also included in the study area have relatively low
138 disturbance (mainly hikers), which is mainly concentrated in the summer months.

139 A study area of approximately 6000ha within each of the study sites was selected, based on
140 criteria of ecosystem conservation status and logistic factors. The only exception was the SANP
141 study area, where we were only allowed to work in an area of 2700ha.

142

143 *Field sampling*

144 All study areas were sampled in two seasons: non-breeding (Jul-Oct), when the offspring of most
145 medium-sized carnivores from that year become independent; and breeding season (Feb-Apr),
146 during these species' breeding season (Blanco 1998).

147 Data collection was obtained by camera-trapping methods, and followed the sampling scheme
148 and trap sites selection described by Monterroso, Alves, and Ferreras (2011). Briefly, 32 to 41
149 cameras were uniformly spaced in each study area following a grid-sampling scheme, where
150 distance between camera traps was approximately 1.4 km apart, promoting spatial independence.

151 The exception was SANP, where only 20 cameras were placed due the smaller size of this area.

152 Two camera-trap models were used: Leaf River IR5 (LeafRiver OutDoor Products, Taylorsville,
153 Mississippi, USA) and ScoutGuard SG550V (HCO OutDoor Products, Norcross, Georgia,
154 USA), which have trigger times of 0.9 and 1.3 seconds, respectively. Cameras were mounted on
155 trees approximately 0.5 – 1.0m off the ground and set to record time and date when triggered.

156 We programmed cameras with the most sensitive sensor setting, to fire a burst of three photos
157 when triggered and with the minimal delay time possible (<1 min), to maximize the number of
158 photos taken per captured individual. Camera-traps were maintained in the field for a minimum
159 period of 28 days and were inspected for battery and memory card replacement every 7 to 14
160 days. If there was evidence that a camera trap was not working during the entire sampling period,

161 we considered the effective sampling period as the time frame between camera setting (or the
162 previous inspection) and the date of the last photograph taken. A combination of carnivore

163 attractants was used in order to incite animals' curiosity and thus increase detection probabilities.

164 The attractants used were Lynx urine, obtained from captive specimens of Eurasian lynx (*Lynx*
165 *lynx*) and Iberian lynx (*Lynx pardinus*), and Valerian extract solution, as suggested by

166 Monterroso *et al.* (2011) for Iberian carnivore sampling. Attractants were placed in the field at a
167 distance of 2-3 m from the camera-traps, and were deployed in perforated separated containers
168 (plastic or PVC), at a distance of 10-15 cm from each other and approximately 30 cm above the
169 ground. Five to 10 mL of each attractant were sprayed into a cotton gaze, held inside each
170 container. Attractants were re-baited every 7 to 14 days. When multiple photographs of the same
171 species were taken within a 30-minute interval we considered them as a single capture event to
172 ensure capture independence (unless animals were clearly individually distinguishable; Davis,
173 Kelly, and Stauffer 2011).

174 Target species consisted of all mammalian carnivore species with mean body weight between 1.0
175 and 7.0kg (i.e. all mesocarnivore species): the red fox (*Vulpes vulpes*), the European wildcat
176 (*Felis silvestris*), the stone marten (*Martes foina*), the pine marten (*Martes martes*), the Eurasian
177 badger (*Meles meles*), the common genet (*Genetta genetta*) and the Egyptian mongoose
178 (*Herpestes ichneumon*). We also included the Iberian lynx because of its reported physical and
179 spatial interactions with several species of mesocarnivores (Palomares *et al.* 1996, 1998;
180 Palomares and Caro 1999) (table 1).

181 Cats detected by camera trapping were identified as wildcats (*F. s. silvestris*) or domestic cats (*F.*
182 *s. catus*) by the most diagnostic phenotypic traits, particularly tail shape and colour pattern, and
183 lateral coat pattern (Ragni and Possenti 1996; Spassov *et al.* 1997; Kitchener *et al.* 2005).

184 Whenever it was visible, the extent of the dorsal stripe was also used. Individuals that did not
185 display these characteristics, considered diagnostic of wildcats, were considered domestic cats.

186 Domestic cats were only detected in GVNP study area at only few sites, and with few detections.

187 Furthermore the levels of admixture found in putative wildcats were low in GVNP (Oliveira *et*
188 *al.* 2007) providing further confidence in the genetic integrity of the detected wildcats. In areas

189 of co-occurrence, the distinction between pine and stone martens was also assessed by evaluating
190 several (not always all) morphological traits and coat patterns, namely leg size, over and
191 undercoat color, bib shape, color and contour, ear size, color and shape (Blanco 1998, López-
192 Martin 2007, Reig 2007, Wilson and Mittermeier, 2009). All photos of martens were subjected
193 to a blind identification procedure by three experienced researchers (PM, PF and PCA).
194 Identification to the species level was only considered when consensus was achieved. All
195 remaining photos were only identified to the genus level.

196

197 *Assessment of diel activity patterns and species plasticity*

198 The independent detection records for each target species were regarded as a random sample
199 from the underlying continuous temporal distribution that describes the probability of a
200 photograph being taken within any particular interval of the day (Ridout and Linkie 2009). The
201 probability density function of this distribution (i.e. activity pattern; Linkie and Ridout 2011)
202 was estimated nonparametrically using kernel density (Ridout and Linkie, 2009), considering
203 only cases with ≥ 10 detections.

204 In order to evaluate the plasticity of the diel distribution function for each species, pairwise
205 comparisons of activity patterns for all study areas and seasons combinations were performed by
206 estimating the coefficient of overlap Δ_1 , as suggested by Ridout and Linkie (2009) and Linkie
207 and Ridout (2011) for small sample sizes. The coefficient of overlap ranges from 0 (no overlap)
208 to 1 (complete overlap), and is obtained taking the minimum of the density functions of the two
209 cycles being compared at each time point. The precision of this estimator was obtained by
210 computing a standard deviation from 500 bootstrap samples. These analyses were performed
211 using R software (R Development Core Team 2008). The R code used to estimate overlap

212 coefficients was that provided by Ridout and Linkie (2009). As we sampled all study areas
213 around the equinoxes (autumn and spring), we assumed that daylight length would not change
214 significantly and therefore no standardizations were performed with respect to sunrise and sunset
215 times. The evaluation of Δ_1 values, and consequent definition of “high” or “low” overlap
216 between two distinct activity patterns is largely subjective. For that reason, within the scope of
217 our analysis, we defined “low”, “moderate” or “high” activity overlap values with respect to the
218 overall pairwise comparisons performed. Hence, compared activity patterns with Δ_1 values \leq
219 50th percentile of our sample were considered as “low overlap values”. Activity patterns with
220 50th percentile $< \Delta_1 \leq$ 75th percentile were considered “moderate overlap values”, and $\Delta_1 >$ 75th
221 were defined as “high overlap values”.

222 Because the coefficient of overlap is purely descriptive, i.e. does not provide a threshold value
223 below which two activity patterns might be significantly different, we used the Mardia-Watson-
224 Wheeler test (MWW test; Batschelet 1981) to compare the distribution of detections across the
225 diel cycle for all sampling campaign pairs (Gerber, Karpanty, and Randrianantenaina 2012;
226 Brook, Johnson, and Ritchie 2012). This test pools the samples together and sorts them into
227 increasing angles. They are then evenly distributed around the diel cycle by calculating a
228 uniform score (or circular rank). If the distributions of the samples are identical then the new
229 uniform scores for the samples should be evenly interspersed around the diel cycle, and their
230 resultant vector lengths R should be short and similar. Any significant difference between the R s
231 will lead to a large W test statistic and rejection of the null hypothesis of identical distributions
232 (Kovach 2011). Only distributions with ≥ 10 detections were considered (Gerber *et al.* 2012).
233 These analyses were performed using the software Oriana v. 4.01 (Kovach 2011).
234 In order to evaluate each species strength of selection for diel period, four periods of the diel

235 cycle where considered: Day - defined as the period enclosed between 1h after sunrise and 1h
236 before sunset; Night - between 1h after sunset and 1h before sunrise; Dawn - between 1h prior
237 and 1h after sunrise, and Dusk - between 1h prior and 1h after sunset (Lucherini *et al.* 2009;
238 Gerber *et al.* 2012; Foster *et al.* 2013). Species selection for each period of the diel cycle was
239 evaluated using the modified Ivlev's selectivity index (Ivlev 1961), adapted by Jacobs (1974),
240 hereafter JSI. This index is broadly applied in ecological studies to evaluate selection for various
241 types of resources (e.g. Palomares *et al.* 2000; Blanco-Garrido *et al.* 2007; Monterroso *et al.*
242 2011). Using bootstrap resampling (500 replicates) (Manly 1997) and recalculating the JSI for
243 each bootstrap sample, we determined the average JSI index and 95% confidence intervals for
244 each period and species. We then considered each diel period as positively (or negatively)
245 selected whenever the 95% CI of the JSI was positive (or negative) and did not overlap zero (i.e.
246 used as expected by chance).

247

248 *Temporal segregation among species*

249 For each sampling campaign (study area \times season) the temporal segregation between coexisting
250 mammalian carnivores was evaluated by comparing the distribution of their activity records
251 along the diel cycle. This comparison was performed using the coefficient of overlap Δ_1 (Ridout
252 and Linkie 2009) between pairs of species, as described above. The significance of the
253 differences in the diel activity patterns between coexisting pairs of mesocarnivores was evaluated
254 using multiple comparison MWW tests (Batschelet 1981). Multiple comparison MWW tests
255 were controlled for type I errors using the Bonferroni correction by adjusting the significance
256 level (alpha): dividing the type I error (0.05) by the number of tests (McDonald 2009). Data are
257 presented as mean \pm SE, unless explicitly stated.

258

259 **Results**

260 *Camera-trapping results and species detected*

261 A total of 1514 independent detections allowed species level identification of mammalian
262 carnivores from 9955 effective trap-days (905 ± 75 trapping days/campaign). Overall, we
263 obtained 99 detections (24.8 ± 14.9 detections/campaign) of unidentified taxonomic origin,
264 corresponding to 1.2% of all animal records. The range of target species detected in each study
265 area and season did not vary greatly, especially within bioclimactic region. European wildcats,
266 Eurasian badgers, stone martens and common genet were detected in all study areas. The
267 Egyptian mongoose was only detected at CNP and GVNP, the Iberian lynx was only detected at
268 SANP and the pine marten was only detected at PGNP and MNR. Reliable discrimination
269 between stone and pine martens was not possible in nine (19.6%) and three (9.4%) of the
270 detections in MNR, during nonbreeding and breeding seasons, respectively. Neither was it
271 possible in 14 (46.7%) and eight (17.8%) marten detections for the same seasons at PGNP. In
272 spite of some consistency in composition, community structure varied across sampling
273 campaigns (table 3, Appendix Table S1, Supporting information). Several target species were
274 detected in the distinct sampling campaigns, but with insufficient data for estimating their
275 activity patterns: the red fox in MNR during nonbreeding season; the European wildcat in CNP,
276 MNR, PGNP in both seasons and SANP during nonbreeding season; the stone marten in MNR in
277 both season, in PGNP during nonbreeding season and in SANP during breeding season; the
278 common genet in MNR and SANP in both seasons, in GVNP during nonbreeding season, and in
279 PGNP during breeding season; the Eurasian badger in MNR in both seasons, in GVNP and
280 PGNP during breeding season, and in SANP during nonbreeding season; the Egyptian mongoose

281 at CNP during breeding season . The European wildcat was detected in all sampling campaigns
282 except at SANP during breeding season, however sufficient number of records was only obtained
283 at GVNP for both seasons.

284 Domestic carnivores were rarely detected over the course of the sampling campaigns, and the
285 low number of detections prevented the estimation of these species' activity patterns.

286 In total, dogs (*Canis familiaris*) were detected six times. They were detected in all study areas,
287 except in CNP, and only at one camera-trapping station per study area. Domestic cats were only
288 detected at GVNP at three camera-trapping stations out of 32 (9.4%) in only seven occasions out
289 of 41: three during the non-breeding and four during the breeding season.

290

291 *Species plasticity and selection for diel period*

292 Mean coefficients of overlap were similar across species: $0.70 \leq \Delta_1 \leq 0.77$ (table 1, Appendix
293 Table S1, Supporting information). However, MWW tests revealed that the red fox was the only
294 species that showed statistically different use of the diel cycle between several pairs of sampling
295 campaigns (table 1, Appendix Table S1, Supporting information). The Egyptian mongoose was
296 only detected during daytime. Regardless, significant differences were detected in their patterns
297 of activity between both seasons (table 1). The remaining species revealed some consistency in
298 their use of the diel periods between sampling campaigns, but displayed some plasticity in the
299 way they used their preferred activity periods, as suggested by asynchronous peaks between
300 sampling campaigns and some MWW tests, despite lack of statistical significance ($0.1 \leq p \leq 0.5$;
301 Figs. 2 and 3; Appendix Table S1, Supporting information).

302 Most carnivore species detected in Iberian communities revealed strong signals of preference for
303 the nighttime period (table 2, Appendix Table S2, Supporting information). Stone martens,

304 genets and Eurasian badgers, revealed a particularly strong selection for the nighttime, with
305 mean JSI_{night} values ≥ 0.80 (Appendix Table S2, Supporting information). However, their
306 preferred period at night varied between study areas and seasons, as suggested by the mean Δ_1
307 values ≤ 0.75 (table 1). The activity of stone martens varied from bimodal (during breeding
308 season) to unimodal pattern, with peaks at different periods of the nighttime (mainly during non-
309 breeding season; Figs. 2 and 3). Similarly, the activity patterns of common genets varied from
310 nearly constant during nighttime, to unimodal or bimodal pattern. The Eurasian badger varied
311 from marked bimodal to a unimodal pattern with an activity peak occurring between 22h00 and
312 24h00 (at CNP, during breeding season). These species consistently avoided daytime (mean
313 JSI_{day} values ≤ -0.95), but their activity could be extended towards the periods of dim light,
314 although with less intensity. Although preferring the nighttime, red foxes, European wildcats,
315 pine martens and Iberian lynx, may also be active in the remaining periods of the diel cycle
316 (table 2, Appendix Table S2, Supporting information). A common pattern detected in red foxes,
317 European wildcats and pine martens was an overall tendency for diurnal activity to be less
318 pronounced in the non-breeding season, as supported by and average strength of selection for
319 daytime of -0.85 ± 0.06 and -0.53 ± 0.08 for the non-breeding and the breeding season,
320 respectively. However, Iberian lynx did not exhibit such a tendency (table 1, Appendix Table S2,
321 Supporting information).

322 The Egyptian mongoose is the only species with marked diurnal behaviour (JSI_{day} values ≥ 0.80),
323 however its activity pattern differed between the non-breeding and breeding periods, as
324 supported by the $\Delta_1 \approx 0.75$ and significant MWW test (Appendix Table S1, Supporting
325 information). A detailed description of the temporal plasticity of each species can be found in
326 Appendix S3 of the Supporting information.

327
328 *Temporal segregation among species*
329 Mean Δ_1 values obtained in interspecific pairwise comparisons were of 0.61 ± 0.03 (mean \pm SE),
330 and the 50 and 75 percentiles of that distribution were 0.66 and 0.76, respectively, being
331 therefore considered as the thresholds between “low”, “moderate” and “high activity overlap.
332 Several species pairs revealed significant segregation in their use of the diel cycle (table 3).
333 However, the degree of segregation of each species’ pair was not constant across study areas or
334 seasons. The mean Δ_1 values obtained from all pairwise comparisons in each sampling campaign
335 was negatively correlated with the number of carnivore species with ≥ 10 detections (Spearman
336 rank correlation -0.76, $p = 0.018$), suggesting that the level of circadian segregation increases
337 with community diversity. Mean Δ_1 values between coexisting mesocarnivores were
338 significantly higher (Wilcoxon test, $p < 0.01$) in non-breeding season ($\Delta_{1\text{Non-breeding}} = 0.72 \pm 0.08$)
339 than in breeding season ($\Delta_{1\text{breeding season}} = 0.65 \pm 0.05$). However, no significant differences were
340 found between the mean Δ_1 values between mesocarnivores’ diel activity in the Mediterranean
341 vs. Atlantic region (Kruskal-Wallis test, $p = 0.33$).
342 The level of segregation between each species pairs was not constant across study areas. For
343 instance, the diel activity patterns of red foxes and stone martens revealed significant differences
344 in 3 out of 5 (60%) pairwise comparisons, and mean Δ_1 values were low: 0.65 ± 0.03 (table 3).
345 The mean activity overlap between red foxes and common genets was moderate ($\Delta_1 = 0.75 \pm$
346 0.06), and their patterns were only statistically different during breeding season, at CNP and
347 GVNP (table 3). Despite the activity patterns of red foxes and badgers were significantly
348 different during the non breeding season at CNP and GVNP, their activity was largely
349 asynchronous, as supported by a mean Δ_1 of 0.63 ± 0.03 .

350 As expected from its diurnal behaviour, the activity pattern of the Egyptian mongoose was
351 significantly different from that of all other carnivore species in both seasons (table 3), and Δ_1
352 values were very low (range $\Delta_{1\text{Non-breeding season}} = 0.07 - 0.20$; range $\Delta_{1\text{Breeding season}} = 0.09 - 0.41$).
353 Several other statistically different activity patterns were detected in other species pairs, although
354 less consistently (see table 3).
355 Iberian lynx were only detected at SANP, and their activity patterns were not statistically
356 different from that of red foxes in any of the seasons ($W_{\text{Non-breeding season}}=3.12$; $p=0.21$; $W_{\text{Breeding season}}=0.56$; $p=0.76$). Similarly, no circadian segregation was detected between the Eurasian
357 badger and neither of the other coexisting carnivores in breeding season (table 3). Coefficients of
358 activity overlap were always above or close to 0.70. The only species which provided enough
359 detections for activity pattern analysis in MNR study area were the pine marten in both seasons
360 and the red fox in spring. During spring season, the unimodal nocturnal pattern of red foxes
361 contrasted with the slightly bimodal pattern of pine martens (Fig. 3). Regardless, no significant
362 differences were detected by MWW test ($W=4.87$; $p=0.09$) and the activity overlap Δ_1 was 0.79
363 ± 0.09 .
364
365 Despite the preference of most species for the nighttime period, a sequential use of the diel cycle
366 was observed in several study areas and both seasons, as suggested by the observed asynchrony
367 between the activity peaks of different coexisting mesocarnivores (Fig. 2). An area-by-area
368 detailed description of the temporal segregation among species can be found in Appendix S4 of
369 the Supporting information.

370

371 **Discussion**

372 *Species plasticity*

373 With the exception of the Egyptian mongoose, which strongly selected daytime, all studied
374 mammalian carnivore species revealed preference for the nighttime period. However, in spite of
375 this preference we could clearly define two groups of species from a behavioural point of view:
376 strictly and facultative nocturnal species. The first group includes species that reveal particularly
377 strong selection indices towards nighttime ($JSI_{\text{night}} > 0.80$), with little activity during the twilight
378 periods, and strong avoidance of daytime. The stone marten, common genet and Eurasian badger
379 exhibited such activity patterns, irrespective of study area, season or bioclimatic region. Despite
380 being described as mainly nocturnal (Posillico, Serafini, and Lovari 1995; Herr 2008; López-
381 Martín, Ruiz-Olmo, and Cahill 2008; Wilson and Mittermeier 2009), the stone marten has been
382 reported to have occasional activity bouts during daytime or twilight (Posillico *et al.* 1995; Herr
383 2008; López-Martín *et al.* 2008). Similarly, common genets and Eurasian badgers have been
384 reported to be predominantly (Camps 2008) or exclusively (Palomares and Delibes 2000;
385 Kowalczyk, Jedrzejewska, and Zalewski 2003; Wilson and Mittermeier 2009) nocturnal,
386 although some occasional exceptions can be found in the literature (e.g. Rodríguez, Franquelo,
387 and Delibes, 1996). However, while strongly bound to the nighttime, stone martens, common
388 genets and Eurasian badgers exhibited some plasticity within this preferred period. Neither of
389 these species showed a uniform activity pattern at night, nor was the activity pattern constant
390 across study areas, seasons or bioclimatic regions. Other studies have found Eurasian badgers to
391 uniformly use the nighttime period (Kowalczyk *et al.* 2003) or varying between continuous and
392 intermittent (Zabala *et al.* 2002; Goszczynski *et al.* 2003). Common genets have been found to
393 have more intense activity in the first half of the night (Palomares and Delibes 2000; Camps
394 2008). The activity peak of stone martens occurred later in the night in Luxembourg (Herr 2008),
395 while the activity of a radiotracked individual in NE Spain peaked between 18h00 and 24h00,

396 during non-breeding season (López-Martín *et al.* 2008). Our results suggest that, in spite of the
397 rigidity of the endogenous regulation of the nighttime/daytime activity, stone martens, common
398 genets and Eurasian badgers can locally adapt their strategies in response to environmental cues,
399 possibly to maximize foraging efficiency and reduce the chances for agonistic encounters.

400 The facultative nocturnal group included the red fox, European wildcat, pine marten and Iberian
401 lynx. These species positively selected nighttime, but also use, in average, the twilight periods as
402 expected by chance. Furthermore, while exploring daytime less than expected by chance these
403 species do not strictly avoid it. Previous studies on red foxes have reported significant daytime
404 activity (Sunquist 1989; Cavallini and Lovari 1991, 1994; Travaini *et al.* 1993), suggesting some
405 flexibility in their activity patterns, facilitating access to their their main prey (Ables 1969;
406 Cavallini and Lovari 1991) or avoidance of the most risky periods of the day (Doncaster and
407 Macdonald 1997; Adkins and Stott 1998). The European wildcat and the pine marten exhibit
408 comparable plasticity in their diel activity structure. Overall, 21% of all our wildcat detections
409 were diurnal. This is in accordance with previous studies which found that European wildcats
410 can be active over 20% of the daytime (Urrea 2003; Monterroso 2006; Germain, Benhamou, and
411 Poulle 2008). Equivalent activity patterns have been described for both pine martens and Iberian
412 lynx (Zielinski, Spencer, and Barrett 1983; Clevenger 1993; Beltrán and Delibes 1994; Fedriani,
413 Palomares, and Delibes 1999; Zalewski 2000).

414 No seasonal differences were detected in the pattern of daytime activity of Iberian lynx. This is
415 in accordance with what has been observed in the Doñana population (Fedriani *et al.* 1999).

416 However red foxes, European wildcats and pine martens revealed a tendency for diurnal activity
417 to be less pronounced in the non-breeding season. This observation contrasts with previous
418 studies which suggest that mesocarnivores are active for less time and are more nocturnal during

419 the breeding season (Posillico *et al.* 1995; Zielinski 2000; Zalewski 2000; Kowalczyk *et al.*
420 2003). Behavioural strategies are influenced by a combination of intrinsic and extrinsic factors,
421 including ambient temperature (Liberek 1999; Zalewski 2000; Weir and Corbould 2007). The
422 climate in the IP is characterized by mild winters, even in the Atlantic region, where the average
423 temperature ranges from $0.8 \pm 3.5^{\circ}\text{C}$ to $23.9 \pm 2.5^{\circ}\text{C}$ (Hijmans *et al.* 2005). However, the
424 ambient temperature often rises above 35°C in the Mediterranean region during the warmer
425 seasons (Rivas-Martínez *et al.* 2004; Hijmans *et al.* 2005). This could lead to thermoregulatory
426 stress, inhibiting activity during midday. This could help explain the reduction in activity at
427 midday by Egyptian mongooses (at GVNP) and during daylight hours by most other
428 mesocarnivores at the Mediterranean study sites in non-breeding season (Fig. 2).

429 The pine marten, which only occurs in the Atlantic region of Iberian Peninsula (López-Martin
430 2007), is not affected by the severe summers of the continental Mediterranean climate.

431 Therefore, it should be able to explore the daytime period during non-breeding season. However,
432 this pattern was not observed (Fig. 3). The increased accessibility to small mammals could be
433 related to the observed levels of nocturnal activity (Monterroso *et al.* 2013). An analysis of the
434 pine martens' feeding ecology in PGNP and MNR has shown that they prey frequently on small
435 mammals, especially during non-breeding season ($\text{FO} = 90.80 \pm 2.11$; Rebelo 2013). Human
436 disturbance also affects animals activity, and other studies have shown that predators exhibit
437 behavioural responses to the patterns of human disturbance (Kitchen, Gese, and Schauster 2000;
438 Muhly *et al.* 2011; Kight and Swaddle 2011). Although we could not test its effect, it is possible
439 that seasonal differences in tourism-related human presence (namely by hikers, supported by
440 park visitation rates), could also contribute to the more nocturnal pattern during non-breeding
441 season.

442

443 *Temporal segregation*

444 According to the competitive exclusion principle (Hardin 1960) we would expect that
445 segregation along the temporal axis would be an effective behavioural response favouring
446 coexistence among mammalian carnivores, especially when they are forced to overlap in other
447 niche dimension (Lucherini *et al.* 2009; Di Bitetti *et al.* 2009; Gerber *et al.* 2012).
448 Our results suggest that competition among mesocarnivores might be minimized by segregation
449 along the diel cycle. At GVNP and CNP, where mesocarnivore communities appeared to be
450 more complex, mean activity overlap was low (mean $\Delta_1 = 0.57 \pm 0.04$) when compared to the
451 results obtained in other studies using similar methods (Ridout and Linkie 2009; Linkie and
452 Ridout 2011; Wang and Fisher 2012; Foster *et al.* 2013), even when excluding the strictly
453 diurnal Egyptian mongoose (mean $\Delta_1 = 0.63 \pm 0.04$). Moreover, nearly 60% of all possible
454 pairwise comparisons revealed significant differences in activity patterns (table 3). Additionally,
455 the activity peaks of most coexisting mesocarnivores in these study areas were, at least partially
456 asynchronous. In Southwestern Europe European rabbits, which are more abundant in the
457 Mediterranean region, are among the most profitable prey for mammalian mesocarnivores (Malo
458 *et al.* 2004; Díaz-Ruiz *et al.* 2013). Whenever rabbit abundance is low (mainly in the Atlantic
459 region), rodents take its place as the preferred prey of many mammalian mesocarnivores
460 (Lozano, Moleón, and Virgós 2006; Zhou *et al.* 2011). In our study areas, European rabbits
461 exhibit peaks of activity on the twilight periods while rodents were mainly nocturnal
462 (Monterroso *et al.* 2013). The combined activity patterns of rodents and rabbits provide
463 continuous mammalian prey availability from before sunset to after sunrise, potentially allowing

464 mesocarnivores to segregate within a relatively long period while maintaining access to prey
465 (Monterroso *et al.* 2013).

466 In cases when asymmetrical competition occurs, the subordinate species adjusts its behaviour to
467 minimize agonistic encounters with the superior competitor (Palomares *et al.* 1996; Azlan and
468 Sharma 2006; Harrington *et al.* 2009). Where Iberian lynx occur, they have the ability to
469 structure mesocarnivore communities through top-down regulation of subordinate competitors
470 (Palomares *et al.* 1996; Fedriani *et al.* 1999), which often takes the form of intraguild predation
471 (Palomares and Caro 1999). Historically Iberian lynx was widespread in SW Iberia, but it is
472 currently absent from most of its historical range, which includes GVNP and CNP (Sarmiento *et*
473 *al.* 2009; Gil-Sánchez and McCain 2011). However, it is the dominant competitor within the
474 carnivore community at SANP. There, in spite of the high risks that encounters with Iberian lynx
475 pose to the integrity of red foxes, no significant differences were observed between the activity
476 patterns of these two species. This could be related to a spatial avoidance of red foxes of those
477 areas with higher probability of lynx encounter, as seems to be supported by camera-trapping
478 results (Monterroso 2013). Similar findings were described by Fedriani *et al.* (1999) who
479 suggested that red foxes avoided lynx predation by habitat segregation during activity periods. In
480 other systems, coexistence between a superior and subordinate competitors have been sustained
481 by spatio-temporal adjustments in the behaviour of the latter (Azlan and Sharma 2006;
482 Harrington *et al.* 2009; Brook *et al.* 2012).

483 The outcome of agonistic encounters in mutual reciprocal interactions is less certain (Donadio
484 and Buskirk 2006). In those cases, the most flexible species should more easily shift their
485 behavioural patterns promoting coexistence (Di Bitetti *et al.* 2010). Along the temporal
486 dimension, cathemerality could provide enough plasticity for the adjustment of a species activity

487 patterns to local conditions to increase its fitness and reduce competition (Lucherini *et al.* 2009;
488 Di Bitetti *et al.* 2009; Gerber *et al.* 2012). Our results support that the Iberian lynx, red fox, pine
489 marten and European wildcat exhibit such characteristics, and suggest that temporal segregation
490 plays an important role in facilitating mesocarnivore coexistence, especially with increasing
491 community complexity.

492 Overall, we obtained low detection rates in both Atlantic study areas, especially at MNR where
493 meaningful activity was only recorded for pine martens and red foxes. In these areas, European
494 rabbits are very scarce (Monterroso *et al.* 2013), therefore mammalian prey is mostly restricted
495 to rodent species, which are phylogenetically bound to nocturnal activity (Roll, Dayan, and
496 Kronfeld-Schor 2006). However, in these study areas a variety of alternative food resources,
497 such as fruits and invertebrates are seasonally widely available (Prieto and Sánchez 1996;
498 Carvalho and Gomes 2004). It has been suggested that the strength of the interactions between
499 competing species is linked to the availability of a shared resource (Valeix, Chamaillé-Jammes,
500 and Fritz 2007). Most mesocarnivores with significant activity detected by camera-trapping in
501 this ecoregion are feeding generalists (table 1), but with significant consumption of rodents
502 (Marinis and Masseti 1995; Virgós, Llorente, and Cortés 1999; Zhou *et al.* 2011; Díaz-Ruiz *et al.*
503 2013), which is reflected by the high synchrony between their activity and that of rodents
504 (Monterroso *et al.* 2013). However, the activity strategies of each mesocarnivore species varied
505 between sampling campaigns, especially at PGNP where activity overlap decreased from the
506 non-breeding (mean $\Delta_1 = 0.89 \pm 0.00$) to the breeding season (mean $\Delta_1 = 0.57 \pm 0.04$). This could
507 be related with access to feeding resources, which are highly available during the non-breeding
508 season, and of limited access during the breeding season (Humphries *et al.* 1996; Fedriani and
509 Delibes 2009; Monterroso *et al.* 2013).

510

511 *Conclusions*

512 Interspecific relations between mesopredators are not constant, resulting in non-equilibrium,
513 where changing resource availability might cause shifts in the relative fortunes of the species
514 concerned (Linnell and Strand 2000). With this work we provide an insight into the temporal
515 functioning of mesocarnivore communities in SW European ecosystems. We identified three
516 clear groups of species among Iberian mesocarnivores: strictly nocturnal, facultative nocturnal
517 and diurnal animals, with the latter group consisting of only one species, the Egyptian mongoose.
518 In spite of the constraints imposed by their endogenous regulation on when to be active, all
519 species exhibited substantial flexibility within their preferred activity periods. This fact facilitates
520 segregation within their own endogenous boundaries enabling them to concentrate activity bouts
521 on the most beneficial periods, maximizing resource acquisition (Monterroso *et al.* 2013, Rebelo
522 2013). Spatial interference as well as exploitative competition for shared resources, have been
523 already advocated in several species pairs in southern European mesocarnivore communities
524 (Palomares *et al.* 1996; Fedriani *et al.* 1999; Barrientos and Virgós 2006; Zabala, Zuberogoitia,
525 and Martínez-climent 2009). Our results suggest that temporal partitioning is likely to play an
526 important role in facilitating mesocarnivore coexistence, especially with increasing community
527 complexity. However, and given that interspecific interactions between species and within guilds
528 are multidimensional, further work simultaneously evaluating the interspecific relations along
529 several niche axes among Iberian mesocarnivores could provide vital information for
530 conservation planning and for the understanding of the full implications of predators interspecific
531 interactions.

532

533 **Aknowledgements**

534 This work was partially supported by a PhD grant from the Fundação para a Ciência e a
535 Tecnologia (FCT) to P.M. (SFRH/BD/37795/2007) and two research projects, one from the
536 Spanish National Plan (project ref: CGL2009-10741) funded by the Spanish Ministry of Science
537 and Innovation and EU-FEDER funds, and another one from the Spanish Organismo Autónomo
538 Parques Nacionales (project ref: OAPN 352/2011). We thank Pedro Rebelo, Ana Serronha,
539 António Rebelo, António Lages, Pedro Moreira, Ricardo Silva, Rafaela Carreira, Jesús Caro,
540 Francisco Díaz-Ruiz for their assistance during the fieldwork. We acknowledge the staff from
541 Cabañeros National Park, especially Angel Gómez, the staff from Vale do Guadiana Natural
542 Park, Peneda-Gerês National Park and Muniellos Natural Reserve for their support during data
543 collection. We also thank the Iberian lynx Life project team: Miguel Ángel Simón, José María
544 Gil-Sánchez, Germán Garrote for all their help and information supplied on Sierra de Andújar
545 Natural Park.

546

547 **Ethical standards**

548 This work was performed in compliance with current Portuguese and Spanish legislation, and
549 follows the European Union's recommendations regarding animal welfare (permit PP1104.03 by
550 the Castilla La-Mancha University ethics committee). All procedures were carried out with
551 appropriate permits, by the concerned institutions.

552

842 **Figures**

843

844 **Fig. 1** - Location of the study areas: MNR - Muniellos Natural Reserve; PGNP - Peneda-Gerês
845 National Park; GVNP - Guadiana Valley Natural Park; CNP - Cabañeros National Park; SANP -
846 Sierra de Andújar Natural Park.

847

848 **Fig. 2**. - Diel activity patterns of target mammalian carnivores in the Mediterranean region study
849 areas: CNP - Cabañeros National Park; GVNP - Guadiana Valley Natural Park; SANP - Sierra
850 de Andújar Natural Park. Red fox (solid line), European wildcat (dashed line), stone marten
851 (dotted line), common genet (dotdash line), Eurasian badger (long dash line), Egyptian
852 mongoose (long dotdash line) and Iberian lynx (grey dashed line). Vertical dashed lines represent
853 sunrise and sunset times, respectively.

854

855 **Fig. 3**. - Diel activity patterns of target mammalian carnivores in the Atlantic region study areas:
856 MNR - Muniellos Natural Reserve; PGNP - Peneda-Gerês Natural Park. Red fox (solid line),
857 stone marten (dotted line), common genet (dotdash line), pine marten (long dash, short blank
858 line). Vertical dashed lines represent sunrise and sunset times, respectively.

859 Table 1. Description of target species, average body mass (kg), described distribution and feeding specialization, and mean coefficient
 860 of overlap (Δ_1 ; mean \pm SE) and Mardia-Watson-Wheeler (MWW) test between the activity patterns of each species across all
 861 sampling areas and seasons (only for cases when the number of detections was ≥ 10). N - Number of pairwise comparisons.

862

Species	Mean body mass (kg)	European distribution	Feeding specialization	N	Δ_1	MWW test	
						W	p
<i>Vulpes vulpes</i>	6.0 ¹	Pan-European	Generalist ⁹	36	0.73 \pm 0.01	86.72**	<0.01
<i>Felis silvestris</i>	4.7 ³	Pan-European	Facultative specialist ¹¹	1	0.70	5.06	0.08
<i>Lynx pardinus</i>	10.5 ²	South Iberian Peninsula	Specialist ¹⁰	1	0.73	0.59	0.74

868 Table 2. Mean Jacobs Selectivity Index (JSI) and 95% confidence intervals, for each of the defined periods of the diel cycle: Night,
 869 Dawn, Day and Dusk. Significant selection was considered whenever the 95% confidence interval of the JSI did not overlap zero (i.e.
 870 used as expected by chance).

<i>Species</i>	<i>JSI_{Night}</i>	<i>JSI_{Dawn}</i>	<i>JSI_{Day}</i>	<i>JSI_{Dusk}</i>
<i>Vulpes vulpes</i>	0.59 [0.41; 0.77]*	-0.34 [-0.71; 0.04]	-0.74 [-0.92; -0.56]*	-0.14 [-0.43; 0.15]

874 Table 3. Coefficient of overlap (Δ ; mean \pm SD) and Mardia-Watson-Wheeler test (W) between the activity patterns of coexisting
 875 carnivore species in all study areas, during non-breeding (NB) and breeding (B) seasons (only for species with ≥ 10 detections). MNR
 876 data is not presented due to the low number of mesocarnivore species with ≥ 10 detections.
