20

21   **Abstract** European rabbits *Oryctolagus cuniculus* are a keystone species in Iberian

22   Mediterranean ecosystems. Studies over the past few decades have revealed drastic

23   declines in many rabbit populations. However, the reliability of methods for estimating

24   rabbit abundance, particularly when at low numbers, is not well understood. Further,

25   better standardization of these methodologies would allow abundance estimates to be

1

1   more reliably compared between areas and periods. Consequently, we compared several

2   frequently used methods of estimating rabbit abundance and assessed the advantages

3   and disadvantages of each. During the summers of 2008 and 2009, in 11 localities of

4   central-southern Spain we undertook (a) driving transect counts of rabbits, either at dusk

5   or at night, (b) linear transects on foot recording rabbit signs, (c) cleared-plot pellet

6   counts at permanent plots, and (d) standing crop counts, both with and without habitat

7   stratification. Density estimated at night from driving transects using the Distance

8   Sampling method (the reference method against which all other indices were

9   compared), varied from 0 to 2.69 rabbits ha^{-1}. Most pellet-count indices were

10   significantly related to the reference method. In particular, cleared-plot pellet counts in

11   permanent plots corrected for pellet persistence showed the best correlation with the

12   reference method. In contrast, latrine counts were not related to the reference method

13   index, and we recommend against their use. A standard methodology based on cleared-

14   plot pellets counts could be used to monitor rabbit abundance on a large scale,

15   particularly where there is an urgent need for management and conservation of rabbits,

16   and their associated endangered predators.

19

20   **Introduction**

21   European rabbits *Oryctolagus cuniculus* are a key species in Iberian Mediterranean

22   ecosystems (Delibes-Mateos et al. 2007; Valverde 1967), being consumed by more than

23   40 predator species (Delibes and Hiraldo 1981; Delibes-Mateos et al. 2008a). Rabbits

24   also act in this area as ecosystem engineers, because of their effect in vegetation

25   (creation of open areas, preservation of plant species diversity, increased plant growth

1   by inducing soil fertility), but also because they provide feeding resources (latrines) for

2   many invertebrate species, and nest sites and shelter (burrows) for vertebrates and

3   invertebrates (Delibes-Mateos et al. 2008a; Gálvez et al. 2009). Rabbits are also a

4   popular small game species (Angulo and Villafuerte 2003). Although considered

5   harmful pest species in other parts of the world (Lees and Bell 2008; Thompson and

6   King 1994; Williams et al. 1995), European rabbits are only regarded as an agricultural

7   pest in a few localized areas in Spain (Barrio et al. 2010b; Ríos 2010). Rabbit numbers

8   on the Iberian peninsula have declined over recent decades, due mainly to habitat loss

9   (Delibes-Mateos et al. 2010) and the occurrence of two viral diseases, myxomatosis

10   during the 1950s (Muñoz 1960) and rabbit hemorrhagic disease (RHD) at the end of the

11   1980s (Villafuerte et al. 1995). Since the RHD outbreak in Doñana National Park

12   (southwestern Spain), rabbit numbers have declined by an estimated 90% (Moreno et al.

13   2007). Most populations in Spain have continued to decline (Delibes-Mateos et al.

14   2008b), resulting in significant economic and ecological consequences for Iberian

15   Mediterranean ecosystems (Delibes-Mateos et al. 2008a). Monitoring rabbit populations

16   is currently a major challenge for conservation, making the development of widely

17   applicable and reliable monitoring methods particularly important (Delibes-Mateos et

18   al. 2009). For instance, the Iberian lynx (*Lynx pardinus*) is a critically endangered

19   predator specialist on rabbits (Ferreras et al. *in press*) and it has been calculated that the

20   autumn mean rabbit density required for Iberian lynx residence is 1 rabbit ha^{-1}, while

21   the spring mean rabbit density required for reproduction is 4.6 rabbits ha^{-1} (Palomares et

22   al. 2001). Hence, large and cost-effective spatial monitoring projects to select areas

23   suitable for lynx re-establishment are dependent on reliable and easy-to-perform indices

24   of rabbit abundance (Ferreira and Delibes-Mateos *in press*).

1   Direct and indirect methods are currently used to estimate rabbit abundances and

2   population trends. Direct methods are based on surveys or counts of the animals, while

3   indirect methods are based on the monitoring of animal signs. One of the most

4   commonly used direct methods is counting individuals along linear transects, which can

5   provide absolute estimates of density (Barrio et al. 2010a; Martins et al. 2003;

6   Palomares 2001; Palomares et al. 2001) by using the Distance Sampling method

7   (Buckland et al. 1993). The accuracy of this method is dependent on several

8   assumptions (e.g., objects on the line or point are detected with certainty, objects do not

9   move, measurements are exact; Thomas et al. 2010) and these may not always be met.

10   A considerable sampling effort is also required to obtain sufficient number o sightings

11   to reliably estimate density in low density populations (Newey et al. 2003). One

12   alternative to the Distance Sampling method is the kilometric abundance index

13   (sightings km^{-1}; Beltrán 1991; Moreno et al. 2007; Williams et al. 2007), which is

14   correlated with population density (Barrio et al. 2010a; Palomares et al. 2001) and

15   provide data for a range of abundances. Rabbit counts have also several drawbacks (see

16   e.g., Martins et al. 2003; Twigg et al. 1998; Villafuerte et al. 1993). Other direct

17   methods used to estimate densities are based on live trapping, mostly by means of

18   capture-recapture (e.g., Ballinger and Morgan 2002; Marchandeau et al. 2006) and the

19   minimum number of individuals known to be alive (MNA, King and Wheeler 1985;

20   Wood 1988).

21   Indices from rabbit signs are alternatives to direct methods. Indices based on

22   counts of warrens are widely used (Myers et al. 1975) and can be corrected for distances

23   traversed during these counts (Palomares 2001). Pellet counts per unit area can also be

24   used to estimate abundance (Cabezas and Moreno 2007; Delibes-Mateos et al. 2008b;

25   Moreno and Villafuerte 1995), as can latrines per unit of distance (Calvete et al. 2006).

1   The standing crop count method involves counting pellets during only one visit,

2   enabling a large area to be sampled. Nevertheless, to estimate absolute densities it is

3   necessary to correct for defecation rates and pellet persistence (Putman 1984). The

4   cleared-plot count method involves counting pellets that accumulate over a period of

5   time in plots from which pellets had been previously removed (e.g., Palomares 2001). It

6   is important to identify the period during which pellet accumulation and persistence is

7   highest in order to reduce the zero counts in low density populations and the effect of

8   pellet decay in pellet counts. This method is time consuming and labor intensive and it

9   is necessary to optimize the time of visits (Massei et al. 1998). This method can provide

10   reliable estimates of abundance when animal densities are low (Murray et al. 2002), a

11   situation limiting the accuracy of other methods. Other signs, such as scrapes and

12   tracks, are rarely used to obtain indices of rabbit abundance (but see Twigg et al. 2001).

13   Studies monitoring the abundance and trends of rabbit populations in the Iberian

14   Peninsula have used most of the methods described above (Calvete et al. 2006; Delibes-

15   Mateos et al. 2008b; Moreno et al. 2007; Williams et al. 2007). Unfortunately, due to

16   the variety of methods used, it is not always possible to compare results (i.e. rabbit

17   abundances) among studies (Delibes-Mateos et al. 2009). Several studies have

18   attempted to standardize methodologies by comparing indices with a reference method,

19   which provides less biased estimates of population size and absolute densities, often

20   using live trapping indices (Ballinger and Morgan 2002; Marchandeau et al. 2006;

21   Wood 1988). However, the high costs in human effort, time and logistical resources

22   prevent the use of live trapping in wide-scale studies, in many localities and in

23   medium/long-term monitoring programs. As a result most studies have been based on

24   rabbit counts (Barrio et al. 2010a; Myers et al. 1975; Palomares 2001; Palomares et al.

25   2001), though as the same methods are not simultaneously performed in the same study

1 areas, the optimal method for specific conditions and objectives is unclear. Moreover,

2 fewer studies have used a wider approach than using a locality scale. We therefore

3 sought to compare several commonly used methods, and assessed the advantages and

4 disadvantages of each. We propose common and comparable methodologies for

5 assessing rabbit abundances according to the objectives and scale of each study.

6

7 **Material and methods**

8 **Areas and periods of study**

9 Field work was performed in 11 localities of central-southern Spain (Fig. 1), with

10 different rabbit abundances but similar habitat structures and climate. All localities had

11 a Mediterranean climate, characterized by wet, mild winters and warm, dry summers

12 with marked drought periods. Habitats were composed mainly of Mediterranean

13 scrubland, pastures, croplands, 'dehesas' (savanna-like formations that combine

14 pastures with intermittent cereal cultivation in park-like oak woodlands; Blondel and

15 Aronson 1999) and tree plantations. We used the same methods (Table 1, further details

16 below) to estimate rabbit abundance in each locality during the summers (June–August)

17 of 2008 (localities 1–8) and 2009 (localities 9–11). For some indices (density estimates

18 at night, DEN-N; kilometric abundance index at night, KAI-N; cleared-plot pellet

19 counts corrected and uncorrected by persistence, COR and UNC respectively, see below

20 and Table 1) and localities (1–8), data were also collected in the winter–spring

21 (December-May) seasons of 2007–2009 and in summer 2007.

22

23 **Driving transect counts**

24 Rabbits are active during twilight and at night, with two activity peaks that coincide

25 with sunrise and sunset (Díez et al. 2005). However, rabbit counts at night provide more

1   precise estimates than at dusk (Barrio et al. 2010a). We counted rabbits at dusk (starting

2   one hour before sunset) and at night (starting two hours after sunset) in good weather

3   conditions (no strong winds and no rainfall). Surveys were undertaken at each locality

4   and at each of these periods of the day (dusk and night) for three consecutive days,

5   unless climatic or logistic circumstances prevented so. Transects were travelled in an

6   all-terrain pick-up at a speed of 15 km/h along dirt tracks varying in minimum length

7   (mean $\pm$ SE = 14.04 $\pm$ 1.61 km) and traversing different habitats with good visibility.

8   Most of the sightings were observed within 100 m, though some observations were

9   exceptionally obtained up to 200 m approximately. One observer stood at the trunk of

10   an all-terrain pick-up observing the 180º area ahead. At night, a 100-W halogen

11   spotlight was used. The distance (m) of each rabbit from the observer was measured

12   using a telemeter, and the angle between the transect line and the line from the observer

13   to the animal was measured using a compass. We calculated an average kilometric

14   abundance index (rabbits seen km^{-1}, KAI-N and KAI-D) at each locality by pooling the

15   data obtained from the three replicates, and we estimated the rabbit density (rabbits ha^{-1},

16   DEN-N and DEN-D) with the Distance Sampling method (Buckland et al. 1993), using

17   the Fourier series estimator as detection function in TRANSECT software (Burnham et

18   al. 1980).

19

20   **Linear transects on foot**

21   Four-km transects were walked by two observers traversing areas favorable to rabbits,

22   mainly those ecotones between Mediterranean scrubland and pastureland or cropland

23   (Delibes-Mateos et al. 2008b). The variables assessed along the transect were rabbits

24   (rabbits seen km^{-1}, RAB), latrines (latrines km^{-1}, LATR), scrapes (scrapes km^{-1}, SCR)

25   and warrens (warren entrances km^{-1}, WARR) indices. For the latter index, all entrances

1 (either active, inactive or unknown) were considered, since > 90 % of the entrances

2 observed were active, with little difference in indices using only active entrances or total

3 entrances. A pellet index (pellets m^{-2}, PEL) was obtained from 40 circular plots of 0.5

4 m^2 each, regularly distributed along the transect (one plot per 100 m). A relative density

5 index (RDI) was obtained as the first axis score from a Principal Component Analysis

6 (PCA, Zar 1984) of four raw variables that were highly correlated (LATR, WARR,

7 RAB and SCR) following Delibes-Mateos et al. (2008b) and Villafuerte et al. (1998).

8

9 **Local pellet counts in permanent plots**

10 A 30x90 m grid was set in the area with the highest rabbit abundance at each locality,

11 identified from the four-km transect on foot (see above). Every month, we performed

12 cleared-plot pellet counts on the sampling areas, which consisted of 40 plots sited as

13 four parallel lines of 10 plots each (Fernandez-de-Simon et al. *submitted*). The distance

14 between each plot and line was 10 m, resulting in a regular sampling grid. After

15 counting all pellets within the 0.5 m^2 circular plot centered at a wooden stake, we

16 cleared the plot and, approximately one month later, we again counted the pellets in

17 each plot. For each month, we obtained an uncorrected daily pellet accumulation rate

18 (UNC) by calculating the average number of pellets m^{-2} day^{-1} (e.g., Catalán et al. 2008).

19 We also estimated the persistence of rabbit pellets for each month and locality by

20 placing 10 pellets marked with nail polish in each of five plots, (n = 50 marked pellets

21 per locality per month, Fernandez-de-Simon et al. *submitted*). Remaining marked pellets

22 were counted one month later, and daily persistence rates were calculated by assuming a

23 constant daily decay between counts. The daily pellet accumulation rate corrected for

24 persistence (COR) was calculated according to Palomares (2001), using the formula:

25

1    $$COR = UNC \, (DPR-1) \, / \, (DPR^{nd} - DPR)$$

2

3   where DPR = daily persistence rate of pellets, and nd = number of days elapsed since

4   the last count.

5   We used the data from the month closest to the night counts dates, as the density

6   estimates at night (DEN-N) were used as the reference method (see below). We also

7   measured the standing crop counts (pellets m^{-2}, STA) in this high density area by

8   counting dung pellets within 40 0.5 m^2 circular plots interspersed halfway among the

9   cleared-plots within the same line.

10

11   **Stratified pellet counts**

12   We walked seven 400-m transects in each locality that contained 40 standing crop

13   counts in regularly distributed 0.5 m^2 circular plots (one plot every 10 m). Transects

14   were stratified among the habitats according to the proportion of the area occupied by

15   each habitat type in each locality. The rabbit abundance index was determined by

16   calculating the average number of pellets m^{-2} (STR, Table 1) for each locality.

17

18   **Statistical analyses**

19   Density estimates at night (rabbits ha^{-1}, DEN-N) was considered the reference method

20   for estimating rabbit density when comparing the different techniques (Barrio et al.

21   2010a). The Distance Sampling method has been used previously to estimate rabbit

22   density (Barrio et al. 2010a; Martins et al. 2003; Palomares 2001; Palomares et al.

23   2001). Linear regression was used to test the ability of the indices of rabbit abundance

24   (independent variables) to predict DEN-N (dependent variable). First, we calculated

25   linear regression using the data from the summers of 2008 and 2009, when all methods

1   were assessed at each locality. All regressions were forced through zero intercept, as the

2   indices should be zero when the rabbit density is zero. The degree of fitting was

3   assessed using the coefficient of determination (r^2). Relationships were considered

4   significant when $P < 0.05$. Afterwards, we tested whether these relationships were

5   maintained for variables KAI-N, UNC and COR during other seasons, years and

6   localities. Thus, a general linear model (GLM) was used separately for each of these

7   three variables to test the effect of locality (1–8, random effect), season (winter–spring

8   and summer, fixed effect), and year (2007 and 2008, random effect) on the slope of the

9   linear regression between the reference method and each index of abundance

10   (dependent variable). Significant effects by season or year would preclude pooling the

11   data in the linear regressions. All analyses were performed using STATISTICA 6.0

12   (StatSoft 2001).

13

14   **Results**

15   **Density estimates**

16   In summer and in four localities (6, 2, 9 and 8), the low number of sightings precluded

17   reliable estimation of DEN-N. In locality 6, no rabbits were observed during the three

18   nights. Consequently, in these localities, rabbit densities were indirectly estimated from

19   the linear regression between density estimates (dependent variable) and kilometric

20   abundance index (independent variable, Palomares et al. 2001). The mean ± SE rabbit

21   density considering all localities was then 0.85 ± 0.29 rabbits ha^{-1} ($n = 11$, range: 0–2.69

22   rabbits ha^{-1}, Fig. 2). To calculate the density estimates at dusk (DEN-D) in localities

23   with insufficient sightings (2, 6 and 9), we used the linear regression between density

24   estimates at dusk (dependent variable) and kilometric abundance index at dusk

25   (independent variable).

1   **Comparisons between indices**

2   Of the variables tested, the pellet count indices were the most significantly related to the

3   reference method (Table 2, Fig. 3). Among these, the COR showed the best fit to the

4   reference method ($r^2 = 0.79$, $P \leq 0.001$). Nevertheless, we observed a low difference in

5   r^2 among all indices based on pellet counts (see Table 2 and Fig. 3). RAB, based on

6   rabbit counts during linear transects on foot, was also significantly related to the

7   reference method ($r^2 = 0.68$, $P \leq 0.001$). KAI-N was also significantly associated with

8   the reference method ($r^2 = 0.73$, $P < 0.05$), although this was expected because both

9   KAI-N and DEN-N were derived from the same datasets. KAI-D was also significantly

10   related to the reference method, although with lower r^2 than the same index at night

11   (KAI-N). The variables RDI ($r^2 = 0.5$, $P < 0.05$) and WARR ($r^2 = 0.45$, $P < 0.05$), both

12   based on linear transects on foot, were also significantly related to the reference method.

13   In contrast, SCR, LATR and DEN-D were not significantly associated with the

14   reference method ($P > 0.05$).

15   With respect to the model during other seasons, all independent factors except

16   year ($P = 0.46$) significantly affected the slope between KAI-N and the reference

17   method (locality, $F_{7, 17} = 3.30$, $P = 0.02$, season, $F_{1, 17} = 5.78$, $P = 0.03$). Pooling data

18   from different years (2007-2009), we found that KAI-N was significantly related to the

19   reference method both in winter–spring ($r^2 = 0.63$, $P \leq 0.001$, Table 3, Fig. 4) and in

20   summer ($r^2 = 0.78$, $P \leq 0.001$, Table 3, Fig. 4). DEN-N estimates were obtained from

21   these relationships and for each season separately in cases where there were insufficient

22   observations (see above for details). Because no factor was significant for the UNC and

23   COR models ($P > 0.05$), we pooled the data among seasons, years and localities for

24   each variable. Both UNC ($r^2 = 0.45$, $P \leq 0.001$) and COR ($r^2 = 0.4$, $P \leq 0.001$) were

25   significantly related to DEN-N (Table 3, Fig. 4).

1

Discussion

Using DEN-N as a reference standard, we evaluated the applicability of most rabbits abundance indices used previously, as described in the literature. We found that most pellet-count indices may reliably estimate abundances, whereas other indices, such as scrape and latrine indices and density estimates at dusk were not related to abundance on a regional scale. Among the pellet-count indices, cleared-plot pellet counts corrected and uncorrected by persistence were similarly related to the reference method, as previously demonstrated (Palomares 2001; Wood 1988). Estimating these indices in the zone of highest relative abundance within a locality may minimize the number of zero counts in areas of low rabbit density. In yearly monitoring of Mediterranean habitats it is advisable to obtain pellet-count indices during early summer, at the start of the dry season, thereby reducing the biases associated with differences in rabbit pellet persistence due to the effects of rainfall (Fernandez-de-Simon et al. *submitted;* Iborra and Lumaret 1997). Standing crop counts in summer were also related to density, resulting in only a slightly lower fit than COR. Therefore, if two visits are not possible owing to logistical constraints, standing crop counts may be a valid option for estimating rabbit abundance. Long-term monitoring of rabbit populations may be accomplished by repeated cleared-plot pellet counts over time, because they were found to be related to density during both summer and winter–spring periods. Pellet counts, however, are affected by other factors, such as the non-random distribution of pellets over the area due to heterogeneity in the environment (that may be corrected undertaking stratified transects) or the variation in defecation rates between populations or even between individuals (Putman 1984).

1   Of the driving transect indices, KAIs were related to the reference method for

2   the seasons tested, although the relationships with DEN-N differed between seasons.

3   Caution must be taken with KAIs because they do not control for habitat variation in

4   rabbit detectability (Marchandeau et al. 2006). Furthermore, sight counts may

5   underestimate rabbit abundance (Poole et al. 2003; Twigg et al. 1998), since the

6   proportion of rabbits seen in a population are inversely related to rabbit density due to

7   social interactions (Twigg et al. 1998). In the Iberian Peninsula, however, the densities

8   reached are much lower than those of Australia (Barrio 2010), and at such densities the

9   activity levels are relatively high during the spotlight counts (Twigg et al. 1998).These

10   factors probably affects the slope of the regressions and make relationships obtained for

11   each locality and season more reliable. KAI-D was related to the reference method,

12   albeit with a lower fit than KAI-N, as found by Barrio et al. (2010a). DEN-D was not

13   related to the reference method, although the transects were identical and performed on

14   the same days. This may be related to an avoidance of dusk-time hours to prevent

15   higher predation risk (hunting and diurnal raptors, Fernández de Simón et al. 2009) or to

16   an avoidance of dirt tracks during the day to prevent human disturbance (similarly as the

17   roe deer *Capreolus capreolus*; Ward et al. 2004). Driving transect counts may be

18   affected by environmental factors such as visibility, wind speed and rainfall, which may

19   affect to rabbit activity (Martins et al. 2003; Twigg et al. 1998; Villafuerte et al. 1993).

20   Similarly, numbers of predators and hunting pressure should be considered when

21   conducting the se surveys as rabbits may shift their activity to reduce the predation risk

22   (Fernández de Simón et al. 2009). All these factors make advisable to conduct replicates

23   and to complement these estimates with alternative indices to increase the results

24   reliability.

1   The lack of significant relationships of LATR and SCR with the reference

2   method may be due to the strong behavioral component of latrine (Monclús and de

3   Miguel 2003) and scrape (Burggraaf-van Nierop and van der Meijden 1984) abundance,

4   which may not be linked to rabbit abundance. Biases concerning latrine counts may also

5   derive from subjective criteria for latrines (Delibes-Mateos et al. 2008b). Although

6   these indices may locally result in reproducible variations in densities, we do not

7   recommend their use in regional monitoring programs if they are not complemented by

8   additional rabbit data (e.g., RDI). Despite LATR being recently adopted as a

9   standardized methodology for monitoring rabbits in Portugal (Ferreira and Delibes-

10   Mateos *in press*), our findings indicate this method is not reliable for monitoring

11   abundance on large spatial and temporal scales, being preferable other pellet-count

12   indices.

13

14   **Recommendations**

15   Overall, DEN-N may be used to provide reliable estimate of rabbit abundance when

16   sufficient resources are available and when terrain, habitat and weather conditions

17   permit. In other circumstances (wide-scale monitoring programs, many localities

18   surveyed, long-term monitoring), pellet-count indices (except LATR) may be the most

19   reliable for obtaining estimates of abundance when rabbit numbers are low to moderate.

20   In summer and depending on the scale, the best indices for estimating rabbit abundance

21   on small-, intermediate- and large-scales are the cleared-plot pellet counts corrected by

22   persistence, the standing crop pellet index collected along a transect and the standing

23   crop index at stratified transects, respectively. However, other indices obtained from

24   linear transects on foot (rabbit, relative density and warren indices) may also be

25   appropriate. Using an abundance index without knowing its relationship to estimated

1 densities throughout the range of abundances likely to be encountered may compromise

2 the reliability of the results. It would also make it difficult to compare these results with

3 those of other studies. Therefore, standardization of abundance indices allows the most

4 appropriate method to be selected, depending on the characteristics and objectives of the

5 study. This can be performed using the methods described in this study, though the

6 standardization with techniques such as density estimates from night counts may not

7 always be possible. In this situation, equations provided here may be useful for

8 monitoring studies and projects carried out in the same study area. Further research is

9 also encouraged to standardize the abundance and density indices in other study areas or

10 with other reference methods (e.g., live-trapping). Here, we concluded that COR may be

11 optimal for monitoring rabbits on a large-scale and may be implemented as standardized

12 methods for rabbit conservation programs, as well as for management issues (e.g.,

13 hunting, agriculture, etc.). Administrators, researchers and other personnel monitoring

14 rabbits should promote the use of these methods for uniform monitoring and should

15 abandon less reliable methods such as LATR. Effective monitoring to manage and

16 conserve rabbit populations and their endangered predators is only possible when

17 standardized and comparable monitoring methods are used.

1 **Table 1** Variables obtained with the different methods. The reference method (DEN-N)

2 is highlighted in italics

	Driving transect counts
DEN-N	*Density estimates at night (rabbits ha^{-1})*
KAI-N	Kilometric abundance index at night (rabbits km^{-1})
DEN-D	Density estimates at dusk (rabbits ha^{-1})
KAI-D	Kilometric abundance index at dusk (rabbits km^{-1})

	Linear transects on foot
LATR	Latrine index (latrines km^{-1})
WARR	Warren index (warren entrances km^{-1})
RAB	Rabbits seen index (rabbits km^{-1})
SCR	Scrapes index (scrapes km^{-1})
PEL	Standing crop pellet index (pellets m^{-2}) collected along the transect
RDI	Relative density index (PCA from LATR, WARR, RAB and SCR)

	Local pellet counts in permanent plots
COR	Cleared-plot pellet counts corrected by persistence (pellets m^{-2} day^{-1})
UNC	Uncorrected cleared-plot pellet counts (pellets m^{-2} day^{-1})
STA	Standing crop counts (pellets m^{-2}) in the high-density area

	Stratified pellet counts
STR	Standing crop counts (pellets m^{-2}) at stratified transects

3

4

1 **Table 2** Significant linear regressions ($P < 0.05$) between the reference method of rabbit

2 density estimated at night from driving transect spotlight counts (DEN-N, dependent

3 variable), and several rabbit abundance indices in decreasing order of coefficient of

4 determination (r^2). Data were collected during summer surveys of 11 localities in

5 central-southern Spain, and are shown graphically in Fig. 3. Codes of variables are

6 shown in Table 1

Independent variable	r^2	Degrees of freedom	F	P	Equation
COR	0.79	1,10	38.27	≤ 0.001	*y=0.708x*
PEL	0.77	1,9	30.87	≤ 0.001	*y=0.018x*
UNC	0.73	1,10	27.5	≤ 0.001	*y=0.759x*
KAI-N	0.73	1,7	18.64	0.003	*y=0.154x*
STR	0.71	1,9	22.28	≤ 0.001	*y=0.026x*
STA	0.7	1,10	23.29	≤ 0.001	*y=0.004x*
RAB	0.68	1,10	21.55	≤ 0.001	*y=0.153x*
KAI-D	0.5	1,9	9.04	0.02	*y=0.115x*
RDI	0.5	1,10	9.82	0.01	*y=0.798x*
WARR	0.45	1,10	8.11	0.02	*y=0.025x*

7

8

1 **Table 3** Significant linear regressions ($P < 0.05$) between the reference method of rabbit

2 density estimated at night from driving transect spotlight counts (DEN-N, dependent

3 variable), and several rabbit abundance indices in decreasing order of coefficient of

4 determination (r^2). Data were collected during surveys in different seasons (winter–

5 spring and summer) at 11 localities in central-southern Spain, and are shown graphically

6 in Fig. 4. Significant regressions pooling the data from different seasons (pooled) are

7 also exhibited. See Table 1 for codes of variables

| Season	Independent variable	r^2	Degrees of freedom	F	P	Equation
Winter-spring	KAI-N	0.63	1,17	28.5	≤ 0.001	*y=0.103x*
Summer	KAI-N	0.78	1,14	49.11	≤ 0.001	*y=0.161x*
Pooled	UNC	0.45	1,41	33.85	≤ 0.001	*y=0.625x*
	COR	0.4	1,40	26.67	≤ 0.001	*y=0.515x*
