Abstract

This study addressed potential groundwater surface-water interactions along the lower reach of Lolo Creek in Lolo, Montana as part of a larger ongoing study conducted by the Montana Bureau of Mines and Geology (MBMG) Groundwater Investigation Program (GWIP). The GWIP focus is to address the causes of late summer dewatering along the lower reaches of Lolo Creek. This study's work attempts to: (1) identify gaining/losing reaches along a 6.5 km stretch and (2) test several methods for investigating groundwater and surface-water interactions. The methods included measuring incremental streamflow, hydraulic gradients, one-dimensional temperature profiles, and collection and evaluation of radon-222. Four sites were chosen along a 6.5 km stretch of Lolo Creek for monitoring streamflow and stage in conjunction with a paired shallow piezometer. The piezometers were instrumented with a transducer and two thermistors at different depths. Stream discharges were measured monthly at each site between June and November 2016 and show a gain of 0.028 to 0.11 m³/s (1 to 4 ft³/s) for the uppermost reach, loss of 0.23 m³/s for the second reach, and loss of 0.14 to 0.28 (5 to 10 ft³/s) for the third reach. Hydraulic gradients are negative at each site with the highest values at the downgradient site and the smallest values at the site that is closest to bedrock. Temperature profiles at the two lowest sites show downward conduction of surface water into groundwater with downward fluxes ranging from 0.33 m/day to 0.53 m/day at the second lowest site and 0.55 m/day to 0.85 m/day at the lowest site. The thermographs from the uppermost site show very little downward conduction of surface water with fluxes ranging from 0.05 to 0.09 m/day. Radon-222 sampling show very low concentrations (~10 pCi/L) at the lowest site with elevated concentrations (40-90 pCi/L) between the uppermost site and the second lowest site. A radon box model developed by Cook et al (2003) was used to estimate gas transfer velocity and an average velocity was determined to be 24 cm/hr. All data are available through MBMG's Ground Water Information Center at www.mbgggwic.mtech.edu (Appendix I).

Introduction

The population in the town of Lolo is approximately 3,900 according to the 2010 US Census and has increased 23% between 1990-2000 and 15% from 2000-2010. Several areas along Highway 12 and US 93 have recently undergone residential development as the population in Lolo continues to rise. Some houses within the neighborhoods receive water from a public water supply well but most homes including the homes in more rural areas, use domestic wells. With the continued growth of Lolo and the land-use changes associated with conversion of agriculture fields to subdivisions, as well as retirement of irrigation ditches, it is important to understand how the surface water interacts with groundwater. Another important factor in regard to water availability and timing relates to climate change. Over the past few decades, there has been a warming trend observed in western North America, which leads to earlier snowmelt and generally a decrease in snowpack (Cayan et al. 2006). Earlier runoff combined with lower snowpack produces a flashy flow system with extremely low flows for an extended period of time in late summer.

Lolo Creek is located 17 kilometers southwest of Missoula, Montana, and it is the northernmost tributary of the Bitterroot River (Figure 1).

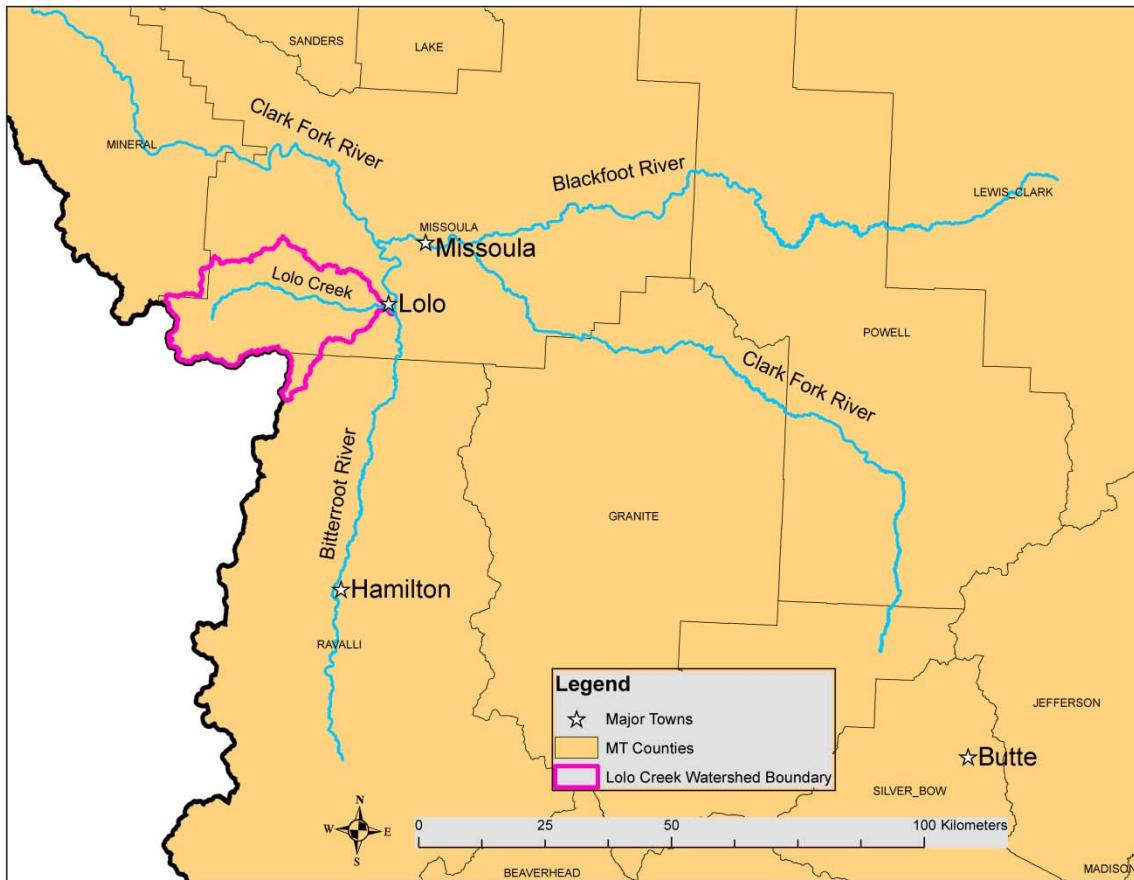

Figure 1: Location map of Lolo Creek in relation to the major rivers and cities in southwest Montana. Lolo Creek flows from West to East.

The Lolo Creek watershed encompasses an area of 700 km^2 in the northern section of the Bitterroot Mountain range in southwestern Montana. Lolo Creek flows for 35 km from its headwaters near the Idaho-Montana border to its confluence with the Bitterroot River. The upper and middle reaches flow through a relatively narrow, high-gradient canyon cut by a series of narrow valleys. The lower reach exits the canyon at a point three miles west of Highway 93 and flows across the low-angle Lolo Creek alluvial fan. Elevations in the watershed range from 970 m AMSL (above mean sea level) near the town of Lolo up to 1275 m AMSL at the headwaters of Lolo Creek near Lolo Hot Springs (Figure 2).

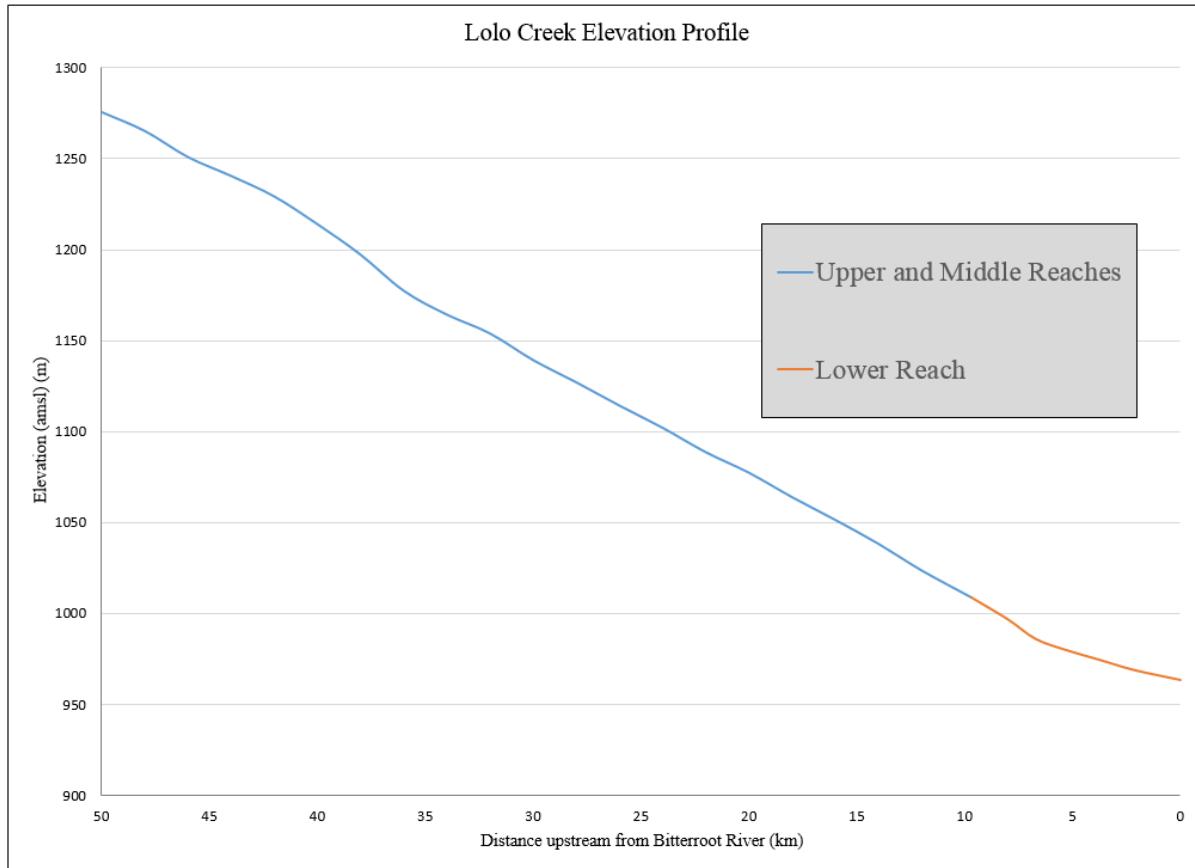

Figure 2: Lolo Creek elevation profile from its confluence with the Bitterroot River up to the headwaters.

The climate in the Missoula Valley area is classified as semi-arid with cold winters and relatively warm summers. Average annual precipitation ranges from 33-38 cm near the town of Lolo, to 61 cm near the headwaters of Lolo Creek, to 123 cm near the Idaho/Montana border. The average annual snowfall near the headwaters (Lolo Hot Springs) is around 250 cm. (Western Regional Climate Center, 2016). Lolo Creek is dominated by the release of snow-melt in the upper parts of the watershed, with some flows generated by early summer rain.

Over the past few decades, there have been several years where Lolo Creek has gone dry along the lower reach during late summer. The goals and objectives of this study were to determine where the creek is losing or gaining, and to use temperature, radon, and incremental streamflow to estimate groundwater/surface-water flux along the lower reach.

Geology

The hills surrounding the lower reach of Lolo Creek to the south and north are composed primarily of the Wallace formation (Yw) of the Belt Supergroup. The Wallace Formation in western Montana is varied and includes carbonate, argillite, and quartzite sequences. In the Lolo area, the Wallace Formation is primarily an argillite. These rocks are faulted and underlie the valley-fill alluvium. The valley floor is composed primarily of unconsolidated alluvium, mostly sand and gravel (Qal). Adjacent to the Lolo Creek floodplain are terrace deposits (Qat) that form a narrow passageway towards the Bitterroot River (Boer 2002). Depth to bedrock varies throughout the valley (30-45 m) but generally shows almost no change in depth to the East (Figures 3-6) (Smith 2006) (Lewis 1998). Cross-sections constructed by the Montana Bureau of Mines and Geology at transects near Dance Hall and Lewis and Clark show a similar sequence of PreCambrian bedrock overlain by Tertiary basin-fill and Quaternary basin-fill. At Lewis and Clark, the interpreted geology shows a slightly thicker Tertiary basin-fill unit than at Dance Hall and also shows the presence of coarser grained material as channel deposits within the younger Quaternary alluvium (Figures 4-6).

Field Methods

There are many different techniques that hydrogeologists use to try to quantify groundwater/surface-water flux. The most common are direct measurements of flux (seepage meters), use of heat as a tracer, Darcy's Law methods, and mass balance approaches (incremental streamflow and environmental tracers E. Kalbus et al 2006). The methods used in this study include incremental streamflow, heat as a tracer, hydraulic gradient, and radon-222. These methods allowed groundwater/surface-water flux to be investigated at two different scales. Incremental streamflow data were able to yield a flux value on a reach scale. Using temperature as a tracer in this study produced a one-dimensional (point-scale) flux value. Using near stream shallow groundwater levels and stream elevations defined directions of flow at four sites.

Incremental Streamflow

The direct measurement of streamflow from one point to another can enable the determination of groundwater/surface-water flux. Streamflow measurements for this study were determined using a Sontek FlowTracker. Manual discharge measurements were taken at each site on a monthly basis from June 2016 to November 2016. Rating curves were developed based on the relationship between stage and discharge. Once the rating curve was established for each site, then the transducer stage data were converted to discharge data. Determination of the point of zero flow on the staff gage was vital for the development of rating curves. The “true” stage was then calculated using the point of zero flow (“e”) as zero stage (Figure 8).

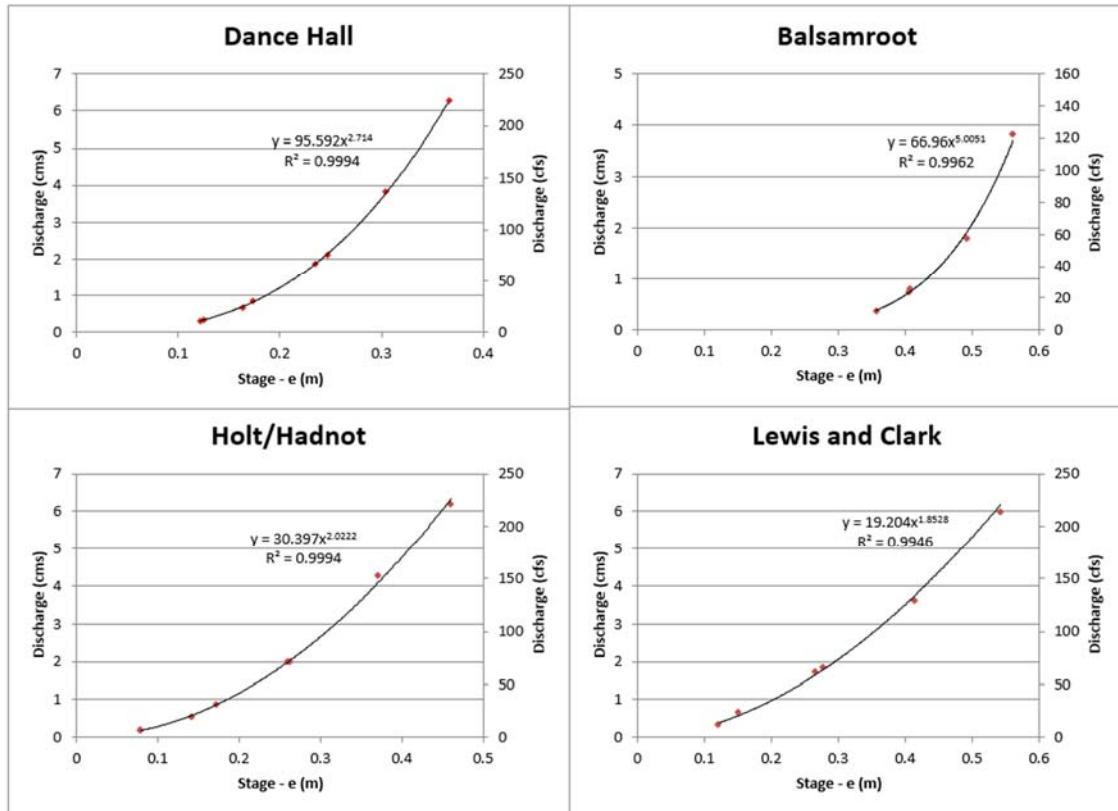

Figure 8: Rating curves developed at each site. The "e" value corresponds to the point on the staff gage for zero flow.

Synoptic flow measurements were performed on 8/22/16, 9/14/16, and 10/4/16 to examine creek gains/losses and account for any inflows and outflows into the system (Table 1). The purpose of the synoptic run was to quantify all of the inflows and outflows of Lolo Creek (not including landowners

drawing from the creek) and measure as many sites as possible within the shortest period of time.

Between the synoptic runs, different sites were chosen based on the amount of time available during the day. Relative elevations between the piezometers and staff gages were determined using a Leica Rugby 100 laser-level.

Table 1: Table of surface water site discharges. Synoptic flow measurements are color-coded by specific date. The GWIC ID is the identification number associated with each site within the GroundWater Information Center. (GWIC 2016)

Hydraulic Gradient

The installation of shallow piezometers provides measurements of hydraulic gradient on a point scale. The gradient can then be used to determine the direction of groundwater flow. If the groundwater elevation is higher than stream stage elevation, then the stream is gaining from groundwater. If the groundwater elevation is lower than the stream surface, then the stream is losing to groundwater. If there is no difference in elevation between the stream and groundwater, the flow of groundwater is horizontal. There can also be the case where a low conductivity layer exists beneath the stream causing the groundwater to be disconnected from the surface water (Constantz 2008). The difference in hydraulic head between the piezometer and the staff gage was also used to calculate flux with a known hydraulic conductivity.

Temperature

The use of heat as a tracer can help quantify the interaction between groundwater and surface water, because of the large difference in stream water temperature and underlying sediment water

temperature. Surface water temperatures change throughout the day with maximum temperatures in the evening and minimum temperatures in the early morning. Groundwater temperatures, when not influenced by surface water, are relatively insulated from the surface and show very minimal diurnal changes. As water moves between the sediment-water interface, heat is also transferred. The transfer of heat through the sediment-water interface is caused by four main mechanisms: conduction, advection, convection, and radiation (Constantz 2008). Conduction occurs as water moves either up or down through the sediment-water interface. Heat convection is due to the difference in water temperature between the stream and sediment as water flows downstream. Advection occurs from the movement of water in the sediments beneath the stream. Radiative transfer is due to adsorption of thermal rays from the sun (Constantz 2008).

Temperature profiles collected with transducers and iButtons were analyzed using 1DTempPro, which solves the one-dimensional flow and heat transport equations. The transducers used in this study are In-Situ LevelTROLL 300, non-vented with a range of 10.9 m. The temperature buttons used in this study are iButton thermal data loggers (Maxim Integrated DS1922L) run with a precision of 0.0625 °C. 1DTempPro allows users to manually calibrate a one-dimensional VS2DH (Variably Saturated 2-Dimensional Heat Transport) (Healy and Ronan 1996) model to a set of temperature time-series data from different depths below a sediment-water interface (Voytek 2014). Vertical groundwater/surface-water flux and hydraulic conductivity were estimated using postprocessor features within VS2DH. The heat-transport equation was solved under the assumption of homogenous hydraulic and thermal properties. The stream and piezometer transducers were used as the upper and lower boundary (respectively) for model calibration.

Four points at each site were used to measure temperatures at different depths below the sediment-water interface. Temperatures were recorded hourly at depths of 0, 0.5, 0.9, and 1.3m below the bottom of the streambed. The upper and lower depths were used as boundary conditions for the model with the two intermediate depths acting as observation points. Figure 9 illustrates how this technique is

used.

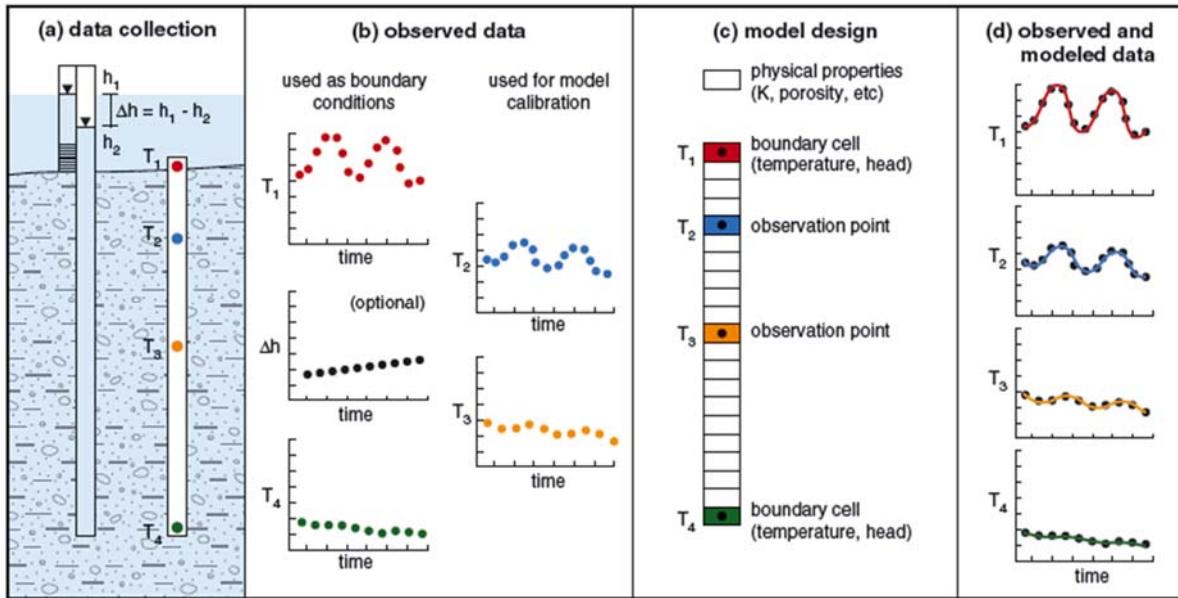

Figure 9: (a) A schematic of data collection including a temperature probe with four sensors and a pair of pressure transducers; (b) measurements of temperature (T) and head difference ($\Delta h=h_1-h_2$) for use as boundary conditions and calibration data; (c) numerical model consisting of a single column of homogeneous, fully saturated finite-difference cells; and (d) comparison of modeled and observed data. (From Voytek 2014)

The main purpose of 1DTempPro is to provide estimates of hydraulic conductivity and specific discharge (flux). After the data are input into the model, parameter estimation and calibration are used to calculate hydraulic conductivity. Before calibration, there is a list of sedimentary materials (e.g. fine sand, silty loam) that are used as the initial condition for the thermal properties of the sediment. The model is run under the assumption that the sediment is fully saturated and homogeneous. To calculate specific discharge, 1DTempPro uses the energy transport equation that accounts for the transport of heat and water through sediments in one-dimensional vertical flow (Stallman 1963).

$$K_T \frac{\partial^2 T}{\partial z^2} - q C_w \frac{\partial T}{\partial z} = C_s \frac{\partial T}{\partial t}$$

Where t is time in seconds, C_w is heat capacity of water in $J/m^3\text{ }^\circ\text{C}$, C_s is heat capacity of the sediment in $J/m^3\text{ }^\circ\text{C}$, T is temperature in $^\circ\text{C}$, K_T is thermal conductivity of the water and solid matrix in $\text{W}/\text{m}^\circ\text{C}$, z is depth in meters, and q is steady liquid water flux through the sediments in m/s . The value of

q is defined as the product of hydraulic conductivity, K , in m/s and the hydraulic gradient between the stream and groundwater (Constantz 2008).

Radon

Radon-222 is a naturally occurring dissolved gas that is useful for locating and quantifying groundwater discharge to surface water (Cecil and Green 2000). Radon-222 is a product of the uranium-thorium decay sequence, and it has a half-life of 3.8 days. As the uranium and thorium in the bedrock and soil decay, they produce Radon-222 from alpha decay of Radium-226. This alpha decay produces an effect called direct recoil, where Radon-222 moves from within the mineral grains and can be incorporated into the pore spaces. Once it enters the pore spaces, it is then able to be transported with the flow of groundwater (Cecil and Green 2000). In areas where groundwater is discharging to surface water, Radon-222 activity may be higher than the stream water, depending on the concentrations in groundwater, but it degasses rapidly as it flows downstream. This rapid degassing combined with the short half life of Radon-222 limit its use to specific points where groundwater discharge may be occurring.

Radon synoptic samples were collected on July 28, 2016 and August 16, 2016. The first sampling date included all surface water sites and two domestic wells, and the second sampling date focused on the reach between Balsamroot and Landquist (Figure 7). This reach was chosen a more refined study because of elevated radon concentrations measured previously at Balsamroot and Landquist. Three groundwater samples were collected in wells screened in 400BELT, 111ALVM, and 112ALVM. Surface water and well samples were collected using a 60-mL high density polyethylene syringe. For surface water sites, the syringe was submerged and rinsed three times and collected from as close to the bottom of the stream as possible. The samples were then injected into a 10 mL glass bottle containing high bi-refrengence mineral oil to prevent interaction with the head space in the bottle or with the atmosphere. At each surface water sampling site, measurements were made of depth, velocity, and width of stream. Radon samples were submitted to the MBMG analytical lab 12-24 hours after collection to allow analysis to occur within 48 hours to decrease loss due to radioactive decay. The samples were

analyzed using a Beckman KS 6000 Series Scintillation counter using Standard EPA Method 913 and were corrected for decay based on time of sampling. Radon concentration was reported in pico curies per liter (pCi/L).

In-stream and groundwater radon-222 concentrations were used with a box model developed by (Cook et al. 2003) to calculate gas transfer velocities on a reach scale. Radon values were converted to becquerels per cubic meter (bq/m^3). The equation used in this box model is:

$$Q \frac{dc}{dx} = I(c_i - c) + wEc + kw(Sc_a - c) + k'w\rho c_a - dw\lambda c,$$

C is the concentration within the stream, I is the concentration in groundwater inflow, c_a is the atmospheric gas concentration, S is the tracer solubility, Q is the stream flow rate (m^3/day), I is the groundwater inflow rate per unit of stream length ($\text{m}^3/\text{m/day}$), k is the gas transfer velocity across the water surface (m/day) (zero for tracers that do not exchange with the gas phase), λ is the radioactive decay constant based on radon's half-life of 3.8 day), E is the evaporation rate (m/day), k' is the air entrapment coefficient ($\text{cm}^3/\text{cm}^2/\text{day}$), w is the width of the river surface (m), d is the mean stream depth (m), and x is the distance in the direction of flow. Sc_a is the concentration of the tracer that would occur in equilibrium with the atmosphere (Cook et al 2003).

Monitoring Network

Four sites were set up along a 4-mile reach from above the town of Lolo to the point where Lolo Creek has historically gone dry during August (Figure 7). Sites were chosen based on map access and previous flow measurements performed by the Montana Department of Natural Resources and

Figure 10: Instrumentation setup with staff gage in the stream and piezometer on the bank.

Conservation (DNRC) and United States Geological Society (USGS). A staff gage with a stilling well was installed in-channel at each stream site with a pressure transducer to record hourly temperature and stream stage (Figure 9).

In addition to the staff gage, a shallow piezometer was also installed on the bank as close as possible to the staff gage. The piezometers were hand driven to a total depth of around 3 m, with a 0.6 m stick-up from ground level. The piezometers were instrumented with a pressure transducer installed 5 cm off of the bottom and two temperature buttons suspended 0.4 m and 0.84

m above the transducer (Figure 11).

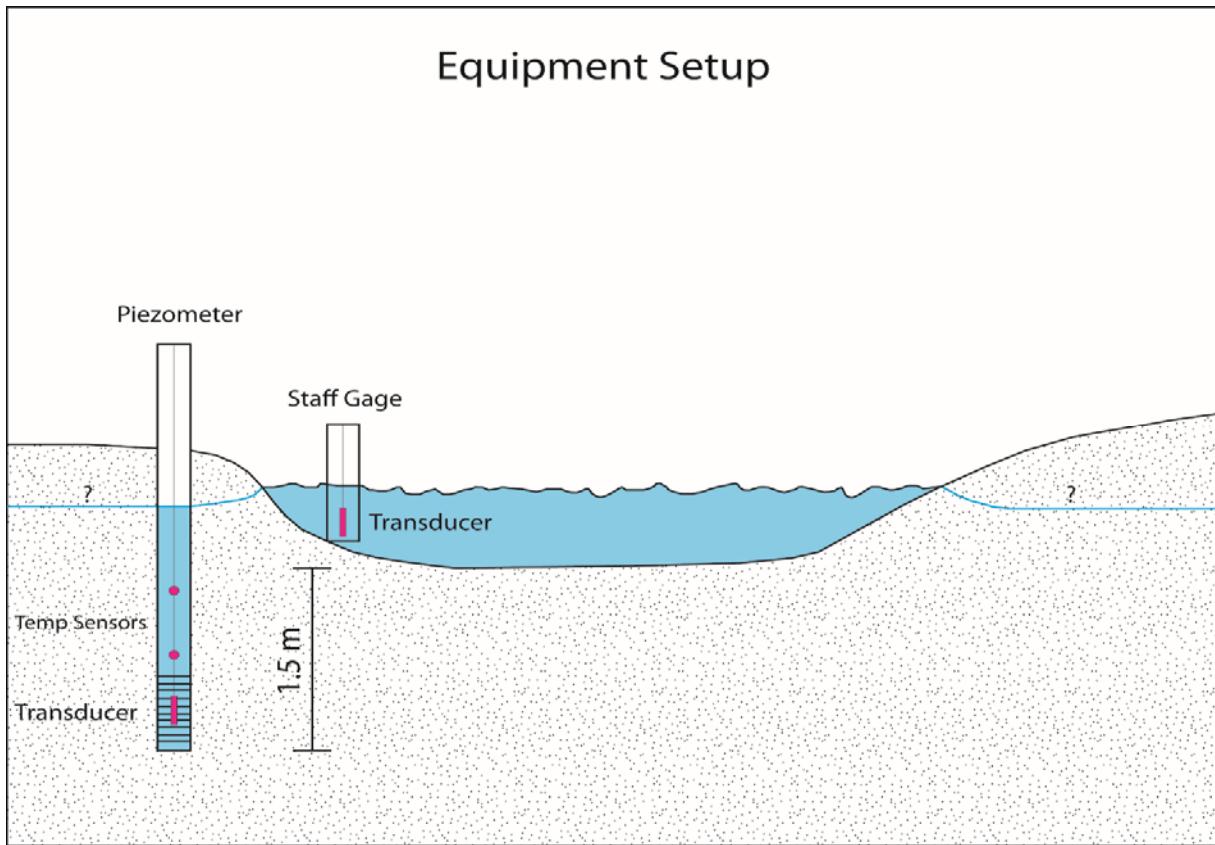

Figure 11: Drawing showing the equipment used in the study. Dance Hall and Holt/Hadnot have equipment on the same side of the creek, while the Balsamroot and Lewis and Clark sites have equipment on opposite banks.

The piezometers at each site are composed of a 91 cm x 3.2 cm well-point attached to galvanized steel risers. The well points were made by Water Source with an 80 mesh screen and a screen length of 61 cm. A barometric pressure logger was installed in a nearby residential well to provide correction from pressure to depth of water.

Results and Discussion

Incremental Streamflow

The flow in Lolo Creek during the study period ranged from baseflow to almost 10 cms. Rating curves were developed at each site (Figure 8) and discharges were calculated from hourly stage measurements. The discharges calculated from the rating curves showed an increase in flow between

Dance Hall and Balsamroot of around 0.028 to 0.11 m³/s (cms) (1 to 4 ft³/s (cfs)). From Balsamroot to Holt/Hadnot, flows decreased by around 0.23 cms (8 cfs). From Holt/Hadnot to Lewis and Clark, flows again decreased by around 0.14 to 0.28 cms (5 to 10 cfs) (Figures 12 and 13). A precipitation event caused a spike in the hydrograph on 7/12/16 and the flows from each limb of the peak were not used to calculate gains and losses.

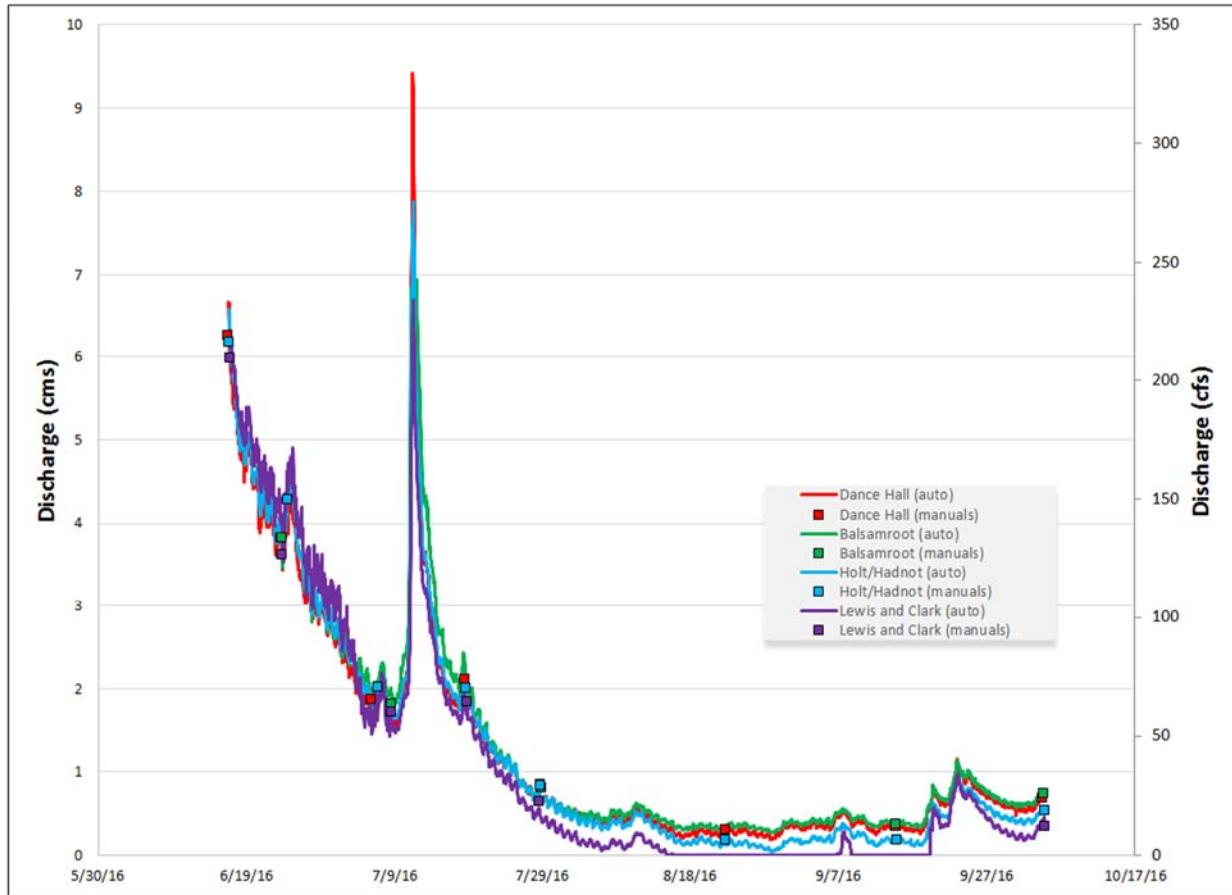

Figure 12: Hydrograph for each site, with discharge calculated from rating curves.

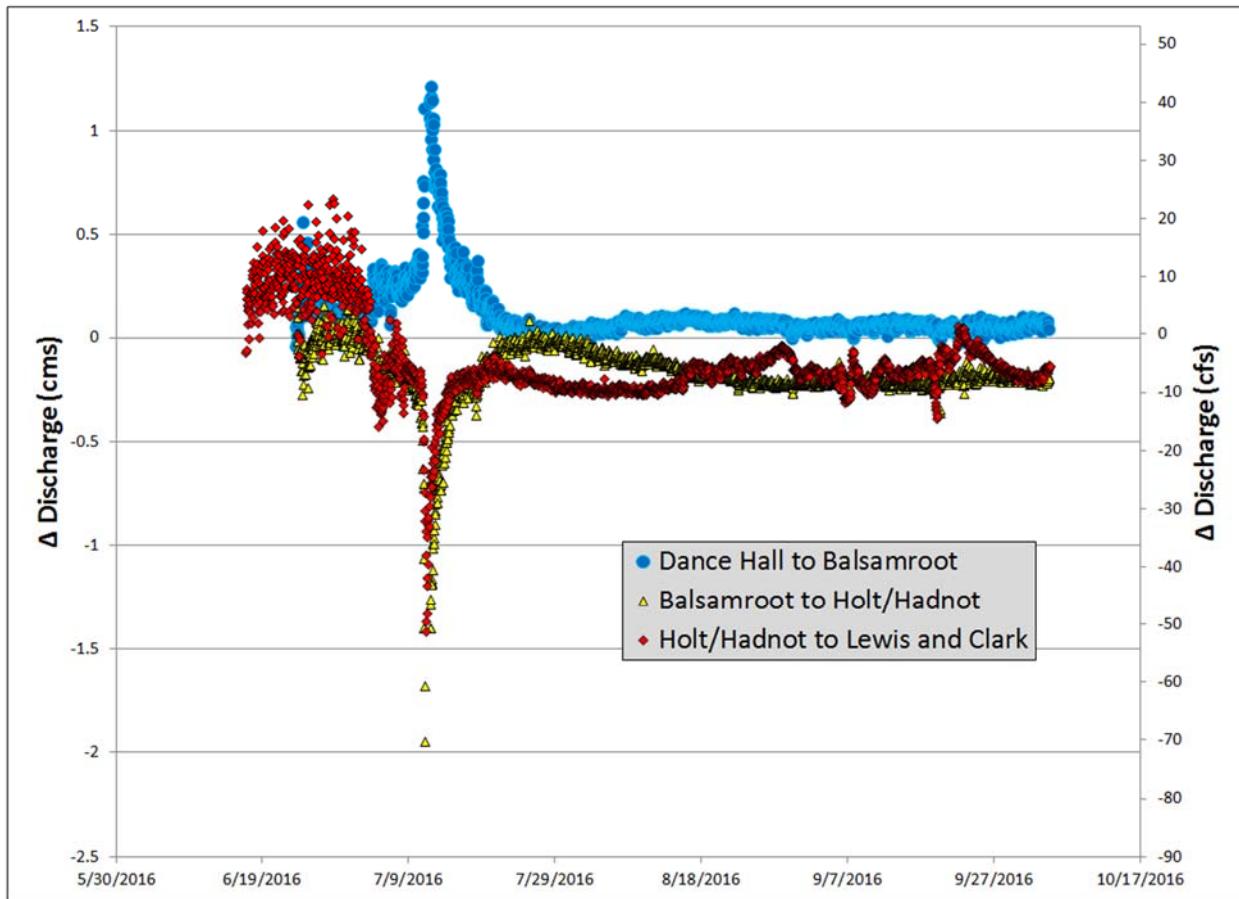

Figure 13: Graph showing the changes in flow between each site in the study area. Positive values indicate a gain in flow, and negative numbers indicate a loss in flow.

The synoptic flow measurements from Dance Hall to Balsamroot showed increases in flow of 0.02 and 0.06 cms for each synoptic run. The reach from Balsamroot to Holt/Hadnot showed a decrease in flow of 0.18 and 0.2 cms for each synoptic run. The next downstream reach (Holt/Hadnot to Lewis and Clark) also showed a decrease in flow of 0.2 cms (Figure 13).

The manual measurements and discharges calculated from transducers show similar magnitude of gains between Dance Hall and Balsamroot, and similar losses from Balsamroot to Holt/Hadnot and Holt/Hadnot to Lewis and Clark. From late August to late September, the Lewis and Clark site was dry, so losses calculated from Holt/Hadnot were based purely on the flows at Holt/Hadnot.

Radon Sampling

Surface water and groundwater radon-222 was sampled on two separate occasions. The first run on 7/28/16 focused on the entire study reach from Dance Hall to Lewis and Clark. The second run on 8/16/16 focused on a shorter reach between Balsamroot and Landquist (Figure 13). The surface-water radon concentrations on 7/28/16 (Figure 14) showed increases between Dance Hall and Landquist (23.6 to 46.6 pCi/L), and decreases from Landquist to Lewis and Clark (46.6 to 13.7 pCi/L). On 8/16/16 the radon concentrations showed similar patterns above Landquist with the highest values between Mormon Creek and Landquist (Figures 14 and 15). Groundwater radon-222 samples were collected in four wells screened in either Quaternary alluvium or bedrock with radon-222 concentrations ranging from 674 to 786 pCi/L.

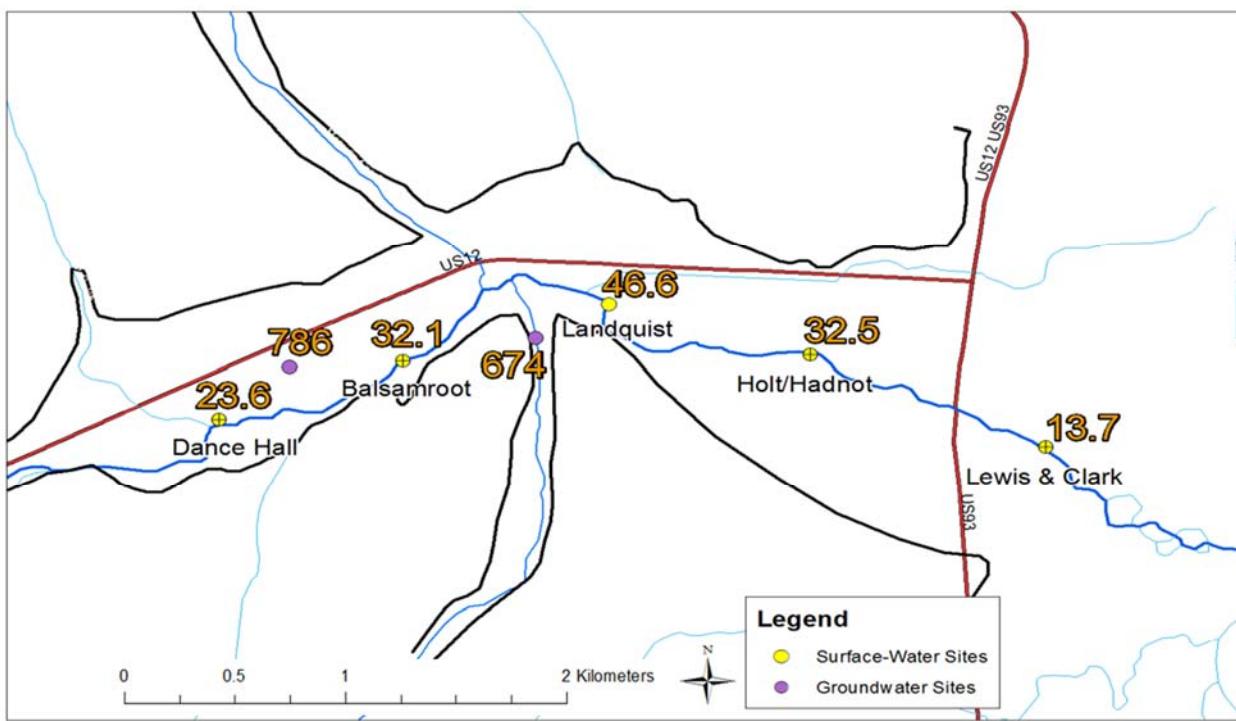

Figure 14: Radon sampling run on 7/28/16. Concentrations are in pCi/L.

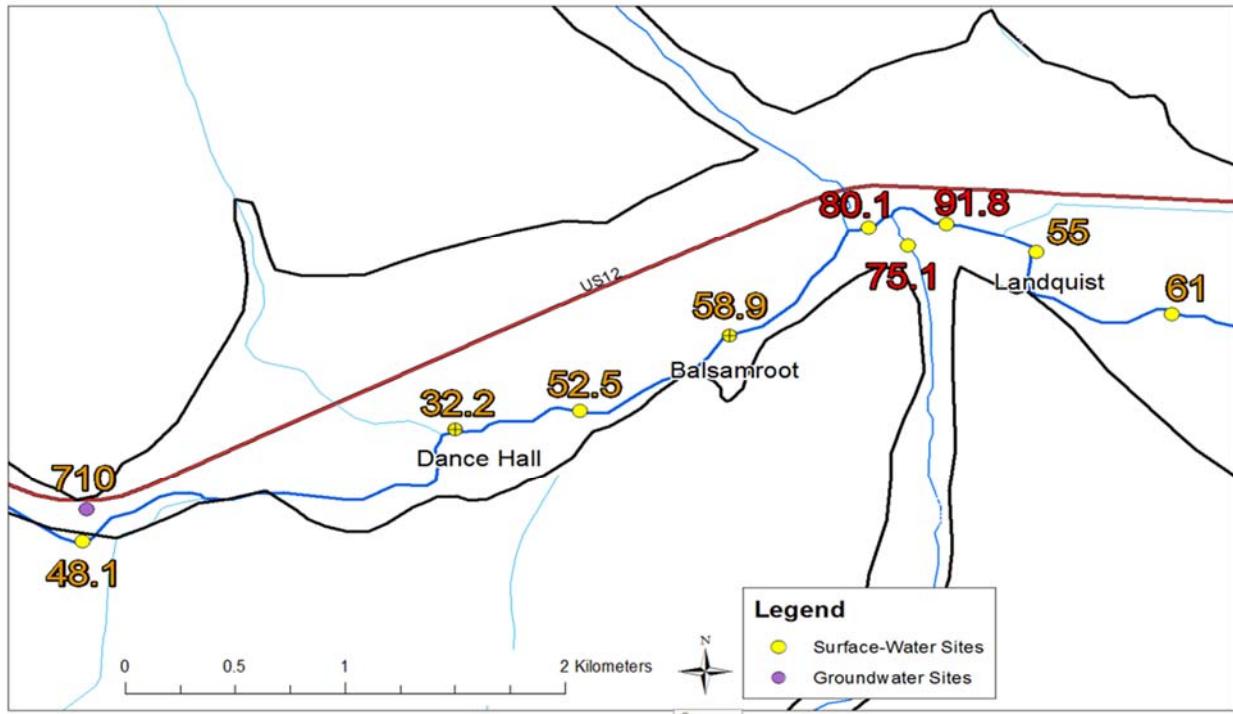

Figure 15: Radon sampling run on 8/16/16. Concentrations are in pCi/L.

Hydraulic Gradient

Vertical hydraulic gradients were calculated from the difference between the water level in the stream and the water level in the piezometer. All of the sites in the study area exhibited a downward gradient (stream elevation higher than the elevation head in the piezometer) with the lowest gradient at Balsamroot and the highest gradient at Lewis and Clark. The vertical gradients were maximum during low-flow periods during late August and early September. Minimum gradients occurred during higher flows in June and early July. The gradient ranges at Dance Hall, Balsamroot, Holt/Hadnot, and Lewis and Clark were (-0.32)-(-0.5)m, (-0.02)-(-0.05)m, (-0.33)-(-0.53)m, and (-0.55)-(-0.85)m respectively.

The hydraulic gradient at each site was negative, which would indicate downward flow of surface water into groundwater. The gradient was the smallest at Balsamroot which might be explained by either groundwater discharging nearby upstream or downstream, or possibly due to a component of horizontal flow of groundwater from the bedrock to the south. Although each piezometer and staff gage exhibit negative gradients at each site, they are only useful for a small area because of the spatial variability of

hydraulic gradient. Placement of the piezometer is extremely important because the location might not provide the most representative data when looking at groundwater and surface-water interactions.

Temperature

Three of the four sites were modeled from 7/14/16 to 7/28/16 using 1DTempPro to determine hydraulic conductivity and flux (Figure 16). The temperatures at the uppermost site, Dance Hall, were modeled with a RMS error of 0.49, and the hydraulic conductivity was estimated to be 0.17 m/day (Figure 17). The flux at Dance Hall ranged from 0.05 to 0.09 m/day. The second lowest site, Holt/Hadnot, was modeled for the same period with a RMS error of 0.19, and a hydraulic conductivity of 1 m/day (Figure 18). The flux at Holt/Hadnot ranged from 0.33 m/day to 0.53 m/day. The lowest site, Lewis and Clark, was modeled for the same period with a RMS error of 0.59, and the hydraulic conductivity was estimated to be 0.86 m/day (Figure 19). The flux at Lewis and Clark ranged from 0.55 m/day to 0.85 m/day. The thermographs at each site are shown in Figure 8. Falling head and rising head slug tests were also performed at each site to look at two-dimensional hydraulic conductivity since 1DTempPro only estimates vertical hydraulic conductivity. The hydraulic conductivities calculated for each site are shown in Figures 20-27 with a comparison between modeled conductivities in Table 2.

The thermographs at each site all show different patterns between the stream and piezometer. At the uppermost site Dance Hall, the temperature profile shows delays and damping with depth but does not show penetration of the daily stream temperature oscillation. The temperatures in the piezometer mirror the stream temperatures but on a scale of a few days. One explanation for a lack of penetration of the daily stream oscillations is a low rate of conduction of the stream water into the sediments and/or the presence of a low conductivity layer beneath the stream. Although the streamflow measurements show gains between Dance Hall and Balsamroot, the temperature profiles and hydraulic gradient show that the creek is losing near the instrumentation at Dance Hall. The next downgradient site Balsamroot was modeled over a shorter period of time than the other sites because it wasn't instrumented until the end of the study period. Temperatures were collected later in the summer while Lolo Creek was cooling off and

there was a smaller range in the daily stream temperatures. The groundwater temperatures show almost no change throughout the study period which could be due to the upward advection of groundwater or horizontal flow of groundwater. 1DTempPro was not able to calculate a hydraulic conductivity at this site which might have resulted from a combination of a slightly negative hydraulic gradient and almost no change in groundwater temperature. Holt/Hadnot exhibits a similar temperature profile to Dance Hall but with greater penetration of the surface water signal and a greater delay in temperature with depth. This pattern is generated from downward advection and conduction of surface water into groundwater. The lowest site in the study area Lewis and Clark, shows the most connectivity of surface water with groundwater. The piezometer temperatures show larger diurnal changes owing to an even greater rate of conduction and advection of surface water into groundwater. It is important to note that the piezometers in this study were installed on the side of the creek. Since the temperature profiles do not represent the conditions directly below the stream, the piezometers might not show the true signal from conduction and advection of surface water.

Radon Box Models

To solve for radon gas transfer velocities, groundwater was assumed to be inflowing between from Enochson to Landquist. From Enochson to Dance Hall, groundwater inflow was modeled as 4 cfs over this reach. From Dance Hall to Balsamroot and Balsamroot to Landquist, groundwater inflows were each modeled as 2.5 cfs over these reaches. The first sampling run on July 28th was inputted into the box model and reach 1 (Dance Hall to Balsamroot) had a gas transfer velocity of 29 cm/hr. The second reach (Balsamroot to Landquist) had a gas transfer velocity of 14.5 cm/hr. The second sampling run on August 16th focused on a finer sampling scale between Balsamroot and Landquist and calculated gas transfer velocities ranged from 3.5-66 cm/hr (Tables 3 and 4).

3	639	4.59	4.0	16.6
4	860	4.15	1.7	7.0
5	335	4.15	0.8	3.5
6	278	4.15	15.9	66.4

Table 4: Table showing the calculated gas transfer velocities (k) for gaining reaches.

Calculated radon-222 gas transfer velocities for each reach are low compared to literature values for smaller streams (Genereux et al 1992) and values calculated at another Montana stream (Machinal 2016). The radon-222 gas transfer velocities calculated by Machinal, 2016 ranged from 20-35 m/day for a total reach length of 0.34 km. Another radon-222 study was completed by Shaw, 2009 over a 17.3 km reach of the Merced River in Yosemite Valley, California. The gas transfer velocities calculated for the Merced River were an average of 0.75 m/day. A main reason why this studies values are comparatively low could be due to long reaches combined with sparse radon measurements. Since radon can degas relatively quickly, it is important to collect samples at the exact location where groundwater may be discharging to surface water.

Conclusions

Incremental streamflow, one-dimensional temperature gradients, hydraulic gradients, and radon-222 were all used in this study and provided different ways of examining groundwater surface-water interactions in Lolo Creek. The incremental streamflow data showed that there were gains from Dance

Hall to Balsamroot and losses from Balsamroot to Lewis and Clark. The estimates based on temperature data agrees well for the lowest two sites, which had the greatest negative flux values and also experienced the most surface water loss to groundwater. The two uppermost sites (Dance Hall and Balsamroot) showed some differences between estimates determined from the temperature data and incremental streamflow. Although streamflow data showed gains between these sites, it could be due to leakage from a ditch that draws water from upstream of the study area. While measurement occurs at the ditch headgate, the ditch is currently unmeasured at any point below the headgate. Modeled hydraulic conductivity increases downstream where hydraulic gradients and fluxes were the greatest. Although the incremental streamflow showed losses between Balsamroot and Holt/Hadnot, the radon sampling showed elevated concentrations between these two sites. While the reach may be under a net loss of surface water to groundwater, there may be locations where groundwater is discharging. Where the creek seems to be losing, radon concentrations were low (<20 pCi/L) or were decreasing downstream. The geology and hydraulic gradient seem to be the controlling factors where Lolo Creek is losing. As the valley widens downstream and coarser grained channel deposits become more prevalent, the hydraulic gradient also increases. Coarser grained material and higher hydraulic gradient are the most important factors in determining flux.
