Abstract

New lines of evidence suggest that less than 10% of neurologic diseases have a strict genetic aetiology while their majority has an unknown origin. Environmental exposures to potentially toxic elements appear to be a risk factor for Parkinson's, Alzheimer's and sclerosis' diseases. This study proposes a multi-disciplinary approach combining neurosciences, psychology, and environmental sciences while integrating socio-economic, neuropsychological, environmental and health data. We present the preliminary results of a neuropsychological assessment carried out in elderly residents of the industrial city of Estarreja. A battery of cognitive tests and a personal questionnaire were administered to the participants. Multivariate analysis and multiple linear regression analysis were used to identify potential relationships between the cognitive status of the participants and environmental exposure to potentially toxic elements. The results suggest a relationship between urinary PTEs levels and the incidence of cognitive disorders. They also point towards water consumption habits and profession as relevant factors of exposure. Linear regression models show that aluminum (R^2=38%), cadmium (R^2=11%) and zinc (R^2=6%) are good predictors of the scores of the Mini Mental State Examination cognitive test.Median contents (µg/l) in groundwater are above admissible levels for drinking water for aluminum (371), iron (860), manganese (250), and zinc (305). Whilst the World Health Organization does not provide health-based reference values for aluminum, results obtained from this study suggest that it may have an important role in the cognitive status of the elderly. Urine proved to be a suitable biomarker of exposure both to elements with low and high excretion rates.

Keywords: neurodegenerative diseases, environmental exposure, potentially toxic elements, urine, groundwater

1. Introduction

Soils and waters are the vehicles which link the inorganic environment to life by supplying the essential macro and micronutrients to living organisms, and particularly to humans. Variations in the chemical composition of soils and waters cause metabolic changes, favouring the occurrence of endemic diseases, related either to deficient or excessive intake, such as gout, fluorosis and Keshan's disease or arsenicosis (Komatina 2004). Until the last decade, little attention was given from the neuroscience community to the neurometabolism of potentially toxic elements (Zatta et al. 2003). However, the neurobiology of the potentially toxic elements (PTEs) is now receiving growing interest, since it has been linked to major neurodegenerative diseases (Zatta et al. 2003; Forte et al. 2004; Gupta et al. 2005; Bocca et al. 2006; Gomes & Wittung-Stafshede 2010; Hozumi et al. 2011; Exley & House 2012; Zhang et al. 2013; Ashok et al. 2015; Ahlskog 2016). Recent studies have been suggesting that no more than 10% of neurologic diseases have a strict genetic etiology, while the majority of cases have unknown origin (Monnet-Tschudi et al. 2006; Kozlowski et al. 2009; Johnson & Atchison 2009). A gene-environmental interaction provides a plausible explanation for the other ~ 90% of cases (Johnson & Atchison 2009). Occupational and environmental (chronic) exposure to specific

PTEs (manganese [Mn], copper [Cu], lead [Pb], iron [Fe], mercury [Hg], zinc [Zn], aluminium [Al], cadmium[Cd]) has been suggested as a possible cause of neurodegenerative disorders, such as manganism, Parkinson's disease (PD), Alzheimer's disease (AD) and sclerosis' (Gorell et al. 1999; Cerpa et al. 2005; Gupta et al. 2005; Maynard et al. 2005; Moreira et al. 2005; Bocca et al. 2006; Moreira et al. 2006; Yokel 2006; Bressler et al. 2007; Fabrizio et al. 2007; Kozlowski et al. 2009; Johnson & Atchison 2009; Exley 2012; Exley & House 2012; Ferrer 2012; Cabral Pinto et al. 2013; Forte et al. 2014; Ashok et al. 2015; Cabral Pinto et al. 2015; Ahlskog 2016). Alzheimer's disease is the most common condition of dementia among the elderly. However, it is important noting that dementia is not an inevitable consequence of ageing but often has a concealed cause (Ferrer 2012). The development of other neurodegenerative diseases, such as PD or Amyotrophic Lateral Sclerosis (ALS), is also accompanied by cognitive disorders, like Mild Cognitive Impairment (MCI) and several dementia levels (Lemos et al. 2014), at the level of global cognitive status and cognitive domains. Currently, epidemiological studies often use urine, hair, and toenail as biological material of exposure because they are less invasive and the samples are easy to obtain in large populations (Reis et al. 2015). The information provided by each biological matrix is rather different. Urine generally reflects recent exposures (days/few weeks), and hair and nails reflect exposures occurring in the last weeks/months (Coelho et al. 2012). However, this distinction is not straightforward for some elements. The half-life, which characterizes the elimination of metals from the body, varies widely between PTEs. It can be larger than 10–12 years for Cd and Pb, with inter-individual variability of about 30%, 4 days for arsenic (As), 60 days for Hg and 0.5 to 1 year for uranium (Dorne et al. 2011). Most PTEs are excreted via the kidney in the urine, and to a much lesser extent by the gastrointestinal tract (Dorne et al. 2011).

Since increasing lines of evidence suggest that environmental exposures may be prevalent in the development of neurodegenerative disorders, studying the impact of exposure to environmental PTEs such as Mn, Cu, Pb, Fe, Hg, Zn, Al, Cd, As on the cognitive functioning of elderly people requires further attention. Hence, we propose a multi-disciplinary approach combining neurosciences, psychology, and environmental sciences, while integrating socio-economic, neuropsychological, environmental and health data.

The Estarreja Chemical Complex (ECC), located in Estarreja, central Portugal, have an intense industrial activity with negative impacts on air, soils, sediments, surface water and groundwater since the early 1950's, while having a population that historically relies on groundwater as a source of water supply for human, cattle and agricultural uses. Ground and surface water, soils and sediment contamination, has been extensively reported for the Estarreja region (Leitão 1996; Pereira et al. 2009; Van der Weijden & Pacheco 2006; Ordens 2007; Inácio et al. 2014). Such contamination has been linked to the industrial activities, enhanced by a natural

vulnerability to contamination due to a combination of factors such as high permeability of the sandy soils, shallow aquifers, flat topography and high rates of groundwater recharge (Ordens 2007). Thereupon, the surrounding area of the ECC was classified by the Portuguese Environmental Agency as a priority site for land remediation (APA 2016). During the 1990's, several remediation actions resulted in an important reduction of the negative environmental legacy, but soil and waters still contain high levels of some PTEs, such As, Mn, Hg, Cu (Ordens et al. 2007; Cachada et al. 2012; Inácio et al. 2014). Consequently, Estarreja provides an ideal study area for multidisciplinary studies such as the one hereby described.

The main aims of the study are: (i) determining urinary levels of PTEs in a group of Estarreja inhabitants with more than 55 years of age; (ii) presenting preliminary results of the neuropsychological assessment of the participants that was carried out at the global cognitive status and cognitive domains (i.e. memory, executive functions, visuospatial skills, language, orientation and attention); (iii) investigating relationships between PTEs urine levels and the neuropsychological diagnosis; (iv) determining concentrations of PTEs in groundwater around the ECC and compare with maximum permissible levels established in the Portuguese guidelines; (v) ascertaining the efficacy of the selected biomarker to provide complementary information on environmental exposure to PTEs.

2. Study area

Estarreja is a municipality within the Aveiro district (central Portugal) with 26,997 inhabitants (INE 2012). The city of Estarreja is located in a low altitude (10 - 70 m), gentle slope (< 2 %) area that comprises several wetlands and shows intense agriculture, fisheries and industrial activities (Figure 1a&b).

The geology is characterized by the predominance of Quaternary unconsolidated sands and clays deposited in dune, beach and lagoon environments (Figure 1a). These sedimentary units dip gently to the west and cover Proterozoic metamorphic rocks and Mesozoic siliciclastic formations (Teixeira and Assunção 1963). The principal watercourse crossing the city of Estarreja is the Antuã river, a tributary of the Vouga river (Figure 1).

The ECC is located close to the city and has been working since the thirties of the XX century, although its development was mainly triggered by the II world war. This complex produces aniline and derivatives (nitric acid, sulfnilic acid, cyclohexilamine, cyclohexanol and nitrobenzene), chlorine-alkalis (hydrochloric acid, chlorine, sodium hypochlorite, caustic soda), aluminium sulfate and polychloride), sodium and chlorate compounds from salt through electrolysis using Hg (mercury) cathodes (Costa & Jesus 2001), polyvinyl chloride resins and polymeric methyl diphenyl isocyanate (PMDI), among others. In the past, ammonium

140 sulphate and ammonium nitrate were also produced (Costa & Jesus 2001), as well as the
141 production of sulphuric acid from arsenopyrite roasting, which has led to a large volume of
142 toxic solid wastes and liquid effluents, piled-up or discharged in areas not prepared for such
143 purpose. The aniline, benzene and its compounds, As, Hg, Zn and Pb-containing liquid effluents
144 were discharged without any previous treatment into manmade, permeable, water channels
145 (Costa & Jesus 2001), contaminating agricultural fields, rivers and groundwater. The solid
146 wastes comprised sludges containing pyrite, calcium hydroxide, mercury and arsenic (Costa &
147 Jesus 2001).

148

149 3. Study design

150 The aim of this study was to identify potential links between exposure to environmental PTEs
151 and data from the neuropsychological assessment of a group of elderly, in order to assess
152 potential factors influencing the predisposition to cognitive impairment. The study involved
153 103 permanent residents from the city of Estarreja (> 55 years old), who were recruited to
154 participate through Private Institutions of Social Solidarity. All inhabitants (or their families)
155 were clearly informed of the aims of the study and those who agree to participate gave their
156 written consent. Urine samples were collected and analysed to determine the levels of selected
157 PTEs. The health status of the participants was assessed by means of a complete socio-
158 demographic questionnaire and through cognitive screening tests, which aim at the early
159 detection of dementia and allow the identification of individuals in preclinical stages. Ethical
160 approval for this study was obtained from the National Committee for Data Protection (Proc.
161 No. 1241/2013). The questionnaires allowed to obtain individual information regarding clinical
162 health status, daily habits, medical record, education level, and factors directly associated to
163 exposure, such as agriculture practices, the sources of water for consumption and irrigation, and
164 crop consumption. The survey instrument collected information on 29 symptoms typically
165 associated with PTEs body burden and/or deficiency. The Mini-Mental State Examination
166 (MMSE), Montreal Cognitive Assessment (MoCA) and Clinical Dementia Rating scale (CDR)
167 were used to assess the cognitive performance of the study group. The test scores were
168 categorized and used in the statistical analysis (Methods section). The Geriatric Depression
169 Scale (GDS) was used to assess depressive symptoms in older adults.

170 The data made available by the cognitive screening tests and by the biomarkers determination
171 were coupled in order to study the effect of human exposure to environmental PTEs on the
172 predisposition to develop dementia. Additionally, PTE levels in groundwater samples collected
173 from wells and boreholes were used to assess the importance of water ingestion as a potential
174 exposure pathway for the population of Estarreja.

175

4. Methods

4.1 Neuropsychological assessment

The criteria for participation in this study were: (i) to have resided in the study area over at least the 5 previous years and (ii) to have more than 55 years of age. The status of the participants was assessed by means of a complete socio-demographic questionnaire and through cognitive assessment, which targeted the early detection of dementia and allowed the identification of individuals in preclinical stages. The following instruments were administered (in this fix order), by a experimented neuropsychologist, for the overall assessment of each participant, which had the duration of at least 1hour per participant:

1) Socio-demographic questionnaire: a complete questionnaire was administered during a personal interview with each participant. This questionnaire was used to obtain information regarding age, marital status, weight, height, nationality, education level, crop consumption, the period of time working in agriculture, pesticide application methods and duration of use, use of personal protective equipment, home-grown foodstuff consumption, irrigation water source and origin of drinking water. The survey instrument collected information on 29 symptoms typically associated with PTEs poisoning and deficiency;

2) An inventory of current clinical health status, past habits, and medical record, usually known as General Health Questionnaire (GHQ) (Goldberg et al. 1997; Fabrizio et al. 2007). The GHQ is designed to cover four identifiable elements of distress: depression, anxiety/insomnia, social impairment and hypochondriasis/somatic symptoms;

3) Mini-Mental State Examination (MMSE) (Folstein et al. 1975; Freitas et al. 2013; Freitas et al. 2015). The MMSE is the most used brief cognitive screening test for detecting cognitive deficits, allowing assessing the global cognitive status, and is not described in detail here. This measure of cognitive function allows comparisons to be made with international studies. The MMSE score ranges from 0-30 and the following categories were used in the statistical analysis described hereunder (0-25: dementia, 26-29: mild cognitive impairment (MCI), 30: normal).

4) Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005; Simões et al., 2008, Freitas et al., 2011). The MoCA is a very sensitive brief cognitive screening test. It cannot be used in illiterate participants. It is a one-page test with a maximum score of 30 points that assesses six cognitive domains: executive functions; visionspatial abilities; short-term memory; language; attention, concentration and working memory; and temporal and spatial orientation. The following categories were used in the statistical analysis that was carried out (0-16: dementia, 17-21: MCI, 22-30: normal).

5) Clinical Dementia Rating scale (CDR) (Hughes et al 1982; Morris 1993; Garret et al. 2008; Santana et al. 2015). CDR is a global staging tool for dementia that is based on the assessment

211   of cognitive function and functional capacity, and comprises six cognitive-behavioural
212   categories: memory; orientation; sense and problem solving; community activities; home
213   activities and hobbies; and personal care. The scale is administered to the adult/elderly patients
214   and an informant through a semi-structured interview. The CDR score ranges from 0-4, and the
215   following categories were used in the statistical analysis: 0- normal, 0.5- MCI, 1-mild dementia,
216   2- severe dementia.

217   6) Geriatric Depression Scale (GDS) (Yesavage et al. 1983; Pocinho et al. 2009; Simões et al.,
218   2015). The GDS is a brief scale to assess depressive symptoms in older adults, composed of 30
219   dichotomous questions that assess emotional and behavioural symptoms of depression. The test
220   score ranges from 0-30 and the following categories were used in the statistical analysis (0-10:
221   absence of depressive symptoms, 11-20: mild depressive symptoms, 21-30: moderate to severe
222   depressive symptoms).

223   **4.2 Urine samples and analysis**

224   Epidemiological studies using biomonitoring data often rely on urine analysis because involves
225   a less invasive sample collection procedure and it is easy to obtain in large populations
226   (Marchiset-Ferlay et al. 2012). First morning urine samples were collected in polyethylene
227   containers and stored at -20 °C until analysis. All reagents used were of trace analysis grade or
228   equivalent. All aqueous solutions were prepared using ultrapure water (>18.2 MΩ.cm).

229   Urine samples were defrosted 24h hours before the analysis and diluted 10-fold diluted with 1%
230   v/v HNO_3 for elemental analysis of 11 chemical elements using a Thermo X-series inductively
231   coupled plasma-mass spectrometry (ICP-MS) instrument. Samples with concentrations higher
232   than 200 µg/L were reanalysed after further 10-folds dilution. Samples with extremely high
233   concentrations were also analysed by inductively coupled plasma-mass spectrometry-optical
234   emission spectrometry (ICP-OES), using a Horiba JobinYvon Activa M instrument, but the
235   results weren't significantly different.

236   Freeze-dried human urine Seronorm™ Trace Elements was used in experimental studies on the
237   validation of the analytical procedure used for PTEs quantification in urine samples. This
238   material was also analysed during each analytical run as a quality control (QC) sample. Results
239   were well within the acceptable range for all the metals, excepting Fe.

240   Urinary data are usually adjusted to a constant creatinine concentration to correct for factors
241   unrelated to exposure, particularly the variable dilutions among spot samples (ref.ª:
242   http://www.ncbi.nlm.nih.gov/pmc/articles/PMC1277864/). Results of urine samples were
243   therefore adjusted and reported as µg/g creatinine.

244

4.3 Groundwater sampling and analyses

The groundwater sampling was part of a larger project aiming at characterizing the contamination of the shallow aquifer in the surroundings of the ECC, as well as developing a conceptual model of contamination and attenuation processes (Ordens 2007; Ordens et al. 2007; Condesso de Melo & Marques da Silva 2008). A total of 31 samples were collected in the phreatic zone of the shallower aquifer. The sampling procedure included measurements of physicochemical field parameters (temperature; pH; electrical conductivity (EC); redox potential (Eh); dissolved oxygen (DO) concentration; and alkalinity) using HANNA instruments. After the stabilization of these parameters, water samples were collected and filtered through a 0.45 µm membrane. A 100 mL volume was titrated for on-field alkalinity analysis with a HACH Alkalinity kit.

The water samples were analysed for major and trace elements by ICP-MS at the Activation Laboratories (Ontario, Canada). Analytical blanks and potential instrumental drifts were carefully monitored, and instrument standardization and reproducibility were performed with Certified Standard Reference Materials.

4.4 Statistical analysis

Relationships between PTEs concentrations in urine samples and the preclinical stages of dementia, as determined by the different tests, were obtained through a method of factor analysis that uses categorical (or discrete) variables and is known as multiple correspondence analysis (MCA). Other variables such as water consumption, dietary habits or the number of years living in the city, were also included in the study to investigate relationships between environmental factors, PTEs concentrations in the urine and the preclinical stages. MCA was designed to describe a two-way contingency table N (Benzécri 1980; Greenacre 1984). MCA defines a measure of distance (or association) between two points, which are the categories of the discrete variables (χ^2). The analysis was performed using the AnDad (v. 7.12) free software package. Given that MCA uses categorical variables, all quantitative variables in the dataset were previously categorised (Reis et al. 2007, 2015). Variables used to compute the MCA factors are known as active variables. New variables usually referred to as supplementary variables can be displayed as supplementary points in the previously calculated MCA factors. Although these supplementary variables are not accounted to obtain the MCA factors, their geometrical relations with the active variables can be seen in the bi-plots (Reis et al. 2004, 2010).

Multiple linear regression (MLR) analysis is an approach for modelling the relationship between a scalar dependent variable (y) and various explanatory variables (or independent

279   variables - X). In linear regression, the relationships are modelled using linear predictor

280   functions whose unknown model parameters are estimated from the data. Such models are

281   called linear models. In this study, stepwise MLR analysis was performed using the

282   IBM®SPSS (v. 21) software and aimed at modelling the relationship between MMSE scores

283   and quantitative variables such as PTEs contents in urine samples. The criteria for stepwise

284   MLR were: probability of F to enter ≤ 0.05 and probability of F to remove ≥ 0.1. The Durbin-

285   Watson test assures the absence of first-order linear autocorrelation in our multiple linear

286   regression data. Residuals plots were used to assess whether residuals were approximately

287   normally distributed.

288   5. Results and Discussion

289   5.1 PTEs levels in urine samples and neuropsychological assessment data

290   From an overall analysis of the socio-economic data, it was found that most of the subjects are

291   female (78.6%) with an education level of 4 years (mode of the population), and mainly falling

292   under the marital status of widowed (60.2%). Considering the neuropsychological assessment

293   results obtained from MMSE, MoCA and CDR tests, 40.2% of the subjects had a normal

294   performance on these tests, 18.3% showed a mild cognitive impairment compatible with the

295   MCI conditions (considering the cut-offs for MCI established in Portuguese validation studies

296   and CDR = 0.5) and 36.6% had a cognitive performance suggestive of dementia condition

297   (CDR$\geq$1 and MMSE and MoCA scores below the respective thresholds). The scores of the

298   GDS (Mode =3) reflect an absence of depressive symptoms in most subjects of the study group.

299   The average results of the MMSE (Mode= 29, Median=22, Standard-Deviation=8) suggest the

300   absence of cognitive impairment in the overall sample.

301   Urinary contents of PTEs are used as indicators of recent exposure (via ingestion or inhalation)

302   because urine is presumed to be the main route of excretion of most trace metal species. Studies

303   of industrial workers and populations exposed to high levels of environmental contaminants

304   have shown that there is a relationship between urinary levels of a few PTEs and estimates of

305   their exposure via ingestion, inhalation or dermal contact (Marchiset-Ferlay et al. 2012; Kuiper

306   et al. 2014). However, to the best of our knowledge, there are few neurological studies using

307   urine samples as biological matrices of exposure to environmental contaminants.

308   Summary statistics for quantitative variables (MMSE scores and elemental concentrations in

309   urine samples) are shown in Table 1. Given the wide ranges in element concentrations in urine

310   samples reported from studies in different parts of the world (Kazi et al. 2008; Kuiper et al.

311   2014), table 1 shows the ranges of concentration (P5-P95) available from the study of Goullé et

312   al. (2005) for healthy people. It can be observed that, on average, urinary levels of PTE for the

313   participants exceed those reported in the literature for healthy people. However, looking to the

314   median values it is of note that, in most cases, the values fall within the range of values reported

315   by Goullé et al. (2005). The exceptions are Al, Cd, Mn, and Zn which show median values

316   above the values available from the literature (Goullé et al. 2005; Kazi et al. 2008; Kuiper et al.

317   2014).

5.2 Relationships between social-behavioral factors, cognitive tests and PTEs

319   Relationships between PTEs levels in urine samples and neuropsychological assessment data

320   were investigated through MCA where elemental concentrations were used as active variables

321   and the results of the neuropsychological tests were projected as supplementary variables. Since

322   PTEs levels in urine are quantitative variables, these were previously categorized in classes of

323   concentration where category 1 represents low levels and correspond to the interval [minimum

324   value of the dataset - median value obtained from the literature for healthy people[, category 2

325   represents average levels and correspond to the interval [median value obtained from the

326   literature for healthy people – 95th percentile value obtained from the literature for healthy

327   people[and category 3 represents high levels and correspond to the interval [95th percentile

328   value obtained from the literature for healthy people – maximum value of the data set].

329   For the cognitive tests, MMSE and MoCA variables were divided into three categories: 0-

330   dementia, 1-MCI, 2-normal, while CDR variable was divided into five categories: 0- normal, 1-

331   MCI, 2- low dementia state, 3 – moderate dementia and 4- severe dementia state. The variable

332   DIA, which results from the overall diagnostic evaluation, has three categories: 0: Normal, 1:

333   Dementia, 2: MCI.

334   The first two factors produced by the MCA account for ca. 60 % of the total variance and were

335   therefore investigated. The coordinates of the categories in the first two MCA factors are

336   provided in the form of supplementary material (Table S1). In order to enhance clarity of the

337   figures, projections of active and supplementary variables are displayed in different plots,

338   although such projections result from the same MCA and correspond to the same factorial

339   plane.

340   The projections in the first factorial plane (Figure 2) of the categories defined for PTEs contents

341   in urine samples (active variables) shows that factor 2 separates high values (categories 3) from

342   medium and low values (categories 2 and 1, respectively). The exceptions are Al and As, where

343   categories 1 and 3 (extreme values) are both associated to the positive semi-axis of factor 2. The

344   first factor separates high contents of Hg+Ni+Pb+Fe+Cu from high contents of Cr+Mn+Se+Cd,

345   suggesting a different behaviour between these elements. Low Al content (Al1) and average Cr

346   concentrations (Cr2) show important contributions to the first factor (Figure 2 and Table S1).

347 Figure 3 shows projections of the categories defined for the cognitive tests and variable DIA
348 (supplementary variables) in the same factorial plane. Projections displayed in Figures 2 and 3
349 can, therefore, be combined and jointly interpreted to infer relationships between PTEs contents
350 in urine samples and the neuropsychological status of the study group, which was the main aim
351 of the study. In the plots, the quadrant defined by the positive semi-axis of factor 2 and negative
352 semi-axis of factor 1 shows the association of MOC0 (dementia) and CDR4 (severe dementia)
353 to high levels of As, Al, Hg, Fe, Ni, Pb, Cr and Zn, and low levels of Al in the urine samples.
354 The quadrant defined by the positive semi-axes of factor 2 and factor 1 shows the association of
355 CDR2 (mild dementia) and MMS0 (dementia) to high contents of Cr, Mn, Cd, and Se. Category
356 DIA1 (dementia) is projected in the positive semi-axis of factor 2 and further supports the
357 association between the diagnosis of dementia and high PTEs contents in urine samples.

358 Involvement of PTEs in the risk of developing neurological disorders has been suggested in
359 several studies (Zatta et al. 2003; Perl and Moalem 2006; Monnet-Tschudi et al. 2006; Rodella
360 et al. 2008; Johnson & Atchison 2009; Gomes & Wittung-Stafshede 2010; Breydo & Uversky
361 2011; Hozumi et al. 2011; Exley 2012; Ashok et al. 2015; Ahlskog 2016), and although
362 controversial, increasing lines of evidence point towards the existence of an actual link.
363 Neurodegenerative diseases constitute a set of pathological conditions originating from the
364 slow, irreversible, and systematic cell loss within the various regions of the brain and/or the
365 spinal cord. Depending on the affected region, the outcomes of the neurodegeneration are very
366 broad and diverse, ranging from dementia to movements disorders (Breydo & Uversky 2011).
367 The aetiology of these diseases is still unclear. A genetic vulnerability seems likely, but
368 additional factors like endo- and exotoxins are proposed to contribute to the induction and, in
369 some cases, possibly the acceleration of the neurodisorders (Gaenslen et al. 2008). Age and
370 dietary habits, as well as environmental and occupational factors, favour the onset of
371 neuropathologies while less than 1% of Parkinson disease cases seem to have a genetic origin
372 (Forte et al. 2004). High PTE levels in urine samples of the participants suggest exposure to
373 them, and Figures 2 and 3 show an association between the diagnosis of dementia or cognitive
374 impairment and high urinary PTE levels. However, for Al, high and low urine levels appear to
375 be associated with neurodegenerative disorders. Bocca et al. (2006) and Forte et al. (2014)
376 found lower concentrations of Al in the urine of neurological patients than in control groups,
377 which is in agreement with our study. However, other authors found a link between high
378 contents of Al and neurological disorders (Roberts et al. 1998; Polizzi et al. 2002), which is also
379 in agreement with our study.

380 Main kinetic characteristics of Al are low intestinal absorption, rapid urinary excretion, and
381 slow tissue uptake. Neurons may be the cells most liable to accumulation (Ganrot 1986; Van der

382 Voet 1992). According to the authors, Al may cause or contribute to some specific diseases,
383 most of them related to aging (Ganrot 1986). Whereas high levels of a few PTEs and low levels
384 of Al in the urine of some participants seem associated to cognitive impairment, this can be
385 explained by probable chemical competition/substitution phenomena, in a similar way to
386 competition/substitution that occur in nature and in crystals. Ions such as Si, Fe, Ca and Cr
387 compete with Al (Ganrot 1986) for binding sites and many of the participants in this study
388 used to take Fe, Zn and Ca supplements, which substantiates the hypothesis of such chemical
389 interactions in the human body, particularly in the absorption process at the gastrointestinal
390 tract..

391 Whereas MCA also aimed at identifying relationships between the health data and socio-
392 economic and environmental factors likely to influence a potential association between PTEs
393 levels in urine samples and the neuropsychological assessment of the subjects, other relevant
394 variables were projected in the same factorial plane. The following characteristics of the
395 participants and their life-habits were considered: a) record of neurological health problems in
396 the family (ANT), which is a binary variable (1-yes, 2-no); b) the number of years living in
397 Estarreja (variable AR), which was divided into three categories of equal amplitude; c)
398 professional occupation (variable PRO), which was divided into four categories, Pro0
399 (agriculture), Pro1 (services and trade), Pro2 (industry), Pro3 (housewife); d) the education
400 level, which was divided into the categories "ana"(illiterate), "4º", "9º" and "12º"; e) type/origin
401 of water used in irrigation (variable REG), which was divided into the categories: "well"
402 (Reg1), "borehole" (Reg2), "stream" (Reg3) and tap water (Reg5); f) the origin of drinking
403 water (variable PRV), which was divided into four categories: Prv1 (tap water), Prv2 (well),
404 Prv3 (bottle), Prv4 (tap water and bottle); g) the variable "Cha", which is binary (1-yes, 2-no)
405 and describes drinking tea habits; h) the consumption of home-grown foodstuffs (Veg), which
406 is also a binary variable (1-yes, 2-no).

407 Figure 4 shows the projections of the categories previously established to assess relationships
408 between environmental factors, cognitive tests (Figure 3) and PTE levels in urine samples
409 (Figure 2). Comparing the three bi-plots, it is of note that Reg5 (tap water is used for irrigation)
410 is associated to average Cr concentration and low As, Fe and Cu levels in urine (Figure 2),
411 while Reg3 (stream water is used for irrigation) is associated to dementia (Dia1, CDR2, MMS0
412 in Fig. 1b) and high Cr, Mn, Cd and Se levels in urine samples. PRV2 (well water is used to
413 drink) is associated to severe dementia (CDR4 in Figure 3) and high levels of As, Al, Ni, Pb and
414 Hg, as well as to low Al contents in urine samples (Figure 2a). Category PRV4 (tap and mineral
415 water) is associated to low PTEs levels in urine samples (Figure 2). The results indicate that,
416 from all the environmental factors under investigation, water used either to drink or for

417   irrigation is probably the most important exposure pathway. From the above, urine appears to be
418   a suitable specimen to assess exposure to environmental PTEs through different pathways.
419   Although acknowledging that factors other than drinking water may influence urine
420   concentrations, Karagas et al. (2001) found a significant correlation between urinary and
421   drinking water As concentrations. Also Lin et al. (2010) found a correlation between As levels
422   in drinking water and urine. Kasper-Sonnenberg et al. (2011) reported a positive association
423   between Ni in ambient air and urinary Ni in a subgroup of 6-yr-old children living near a steel
424   mill. Afridi et al. (2008) state that the association of urinary excretion rates with renal Hg
425   content and functional status suggests that urinary porphyrin profiles may serve as a useful
426   biomarker of mercury accumulation and nephrotoxicity during prolonged Hg exposure
427   through drinking water. The studies of Forte et al. (2004) and Roberts et al. (1998) successfully
428   used urinary PTEs contents as biomarkers for neurological pathologies. Hence, a wide number
429   of studies have used urine to confirm exposures and assess health effects. Whilst a direct
430   relationship between PTE levels in drinking water and urine cannot be established in the present
431   study, the results obtained so far indicate a relationship between urinary PTE levels and water
432   consumption habits of the participants. Furthermore, both factors seem to be related to the
433   incidence of cognitive disorders.

434   Figure 5 shows the projections, in the same factorial plane of MCA, of socio-economic factors
435   considered to be potentially relevant. In this study group, it is not obvious a relationship
436   between the education level and the neuropsychological assessment of the subjects. However, a
437   high number of years of residence in Estarreja (AR3 in Figure 5) seems associated to a
438   diagnosis of dementia (Figure 3) and to high PTE concentrations in urine samples (Figure 2).
439   Individuals who have worked either in agriculture (Pro0) or in industry (Pro2) tend to have
440   higher PTE levels in urine and the results of their neurological tests indicate a state of dementia.
441   Individuals with a family record of neurodegenerative conditions (ANT1) are mainly associated
442   to a diagnosis of "normal" (MMS1-MCI, MOC2-normal, CDR0-normal, dia 0-normal) and low
443   levels (category 1) of PTEs in urine. Although recent studies investigating relationships between
444   PTEs levels in toenail clippings or human hair and socio-economic factors are available from
445   the literature (Cabral Pinto et al. 2013; Ndilila et al. 2014; Cabral Pinto et al. 2015; Hao et al.
446   2015; Reis et al. 2015), to the best of our knowledge this has not yet been attempted using urine
447   samples as specimen to measure biomarkers of environmental exposure and its impact on the
448   health status of the population.

449   The statistical analysis of this multidisciplinary and complex dataset allowed establishing a
450   relationship between high PTE levels in the urine of the participants and their
451   neuropsychological condition. Whilst several environmental factors can be associated to

452 increased PTE levels and to a diagnosis of dementia, no relationship could be established
453 between the genetic burden of the individuals and a tendency to neurodegenerative disorders
454 (Figure 5). Although water ingestion arises as the most likely exposure pathway to
455 environmental contaminants, other environmental and social factors such as profession or the
456 number of years living in the city seem to be relevant, and further studies are necessary to
457 investigate other potential pathways of exposure.

458 In this study, stepwise multiple linear regression (MLR) analysis was used to identify which
459 PTEs are best predictors of MMSE scores. Since the results of MCA associate the number of
460 years residing in Estarreja to high PTEs levels in urine, this variable was also included in the
461 stepwise MLR analysis. The linear models obtained are shown in Table 2. R^2 indicates the
462 proportion of the variance in MMSE scores accounted for by each regression model. All
463 regression models are statistically significant ($p < 0.005$).

464 Although Al is clearly showed to be the best predictor of MMSE scores ($R^2 = 38\%$), Cd and Zn
465 are also relevant predictors as demonstrated by the significant increase in R^2 (17% increase).
466 Whereas model 4 is also statistically significant, the 2% increase in the R^2 value indicates that
467 the number of years residing in Estarreja is not as relevant to predict MMSE scores as the
468 urinary levels of Al, Cd and Zn.

469 Polizzi et al. (2002) applied neuropsychological tests to dust-exposed workers to Al and to an
470 unexposed population, and their findings lead them to suggest a possible role of the inhalation
471 of Al-dust in pre-clinical mild cognitive disorder which might prelude Alzheimer's disease
472 (AD) or AD-like neurological deterioration. Rogers and Simon (1999), studying the link
473 between dietary Al intake and risk of Alzheimer's disease, shown that the past consumption of
474 foods containing large amounts of Al additives differed between people with Alzheimer's
475 disease and controls, suggesting that dietary intake of Al may affect the risk of developing this
476 disease. Albeit an important number of studies have linked exposure to environmental Al, either
477 through inhalation or through ingestion, to neuropsychological disorders, the underlying
478 mechanisms are still largely unknown and further studies are warranted to corroborate or refute
479 these findings.

480 Unlike Al, Cd has a long biological half-life mainly due to its low rate of excretion from the
481 body. Thus, prolonged exposure to Cd will cause toxic effects due to its accumulation over time
482 in a variety of tissues, including kidneys, liver, central nervous system and peripheral neuronal
483 systems. However, mechanisms underlying Cd neurotoxicity are not yet completely understood
484 (Wang &Du 2013). Viaene et al. (2000) observed slowing of visuomotor functioning on
485 neurobehavioural testing and increase in complaints consistent with peripheral neuropathy,

486 complaints about equilibrium, and complaints about concentration ability that were dose-
487 dependent to urinary Cd. They further found that age, exposure to other neurotoxicants or renal
488 function status could not explain these findings.

489 Different studies on the role of Zn have come to very contrasting conclusions. Excess Zn in
490 senile plaques and vascular amyloid deposits may initiate amyloid deposition affecting
491 polymerized microtubule stability. On the other hand Zn may counter oxidative stress and
492 neurotoxicity, thereby preventing neurodegeneration and cognitive impairment, in a process of
493 potential therapeutic use (Yegambaram et al. 2005). Further confirmatory studies are required to
494 fully understand the role of Zn either in the development or in the prevention of
495 neurodegenerative diseases.

496 ## 5.3 Groundwater PTEs concentrations

497 Given the results obtained in the statistical analysis, which indicated a relationship between
498 urinary PTEs levels and a diagnosis of dementia, and further suggested water ingestion as an
499 important probable pathway of exposure to the environmental contaminants, concentrations of
500 major, minor and trace elements in groundwater samples were investigated.

501 Figure 6 shows the concentrations (µg/L) of the PTEs under study in groundwater samples
502 collected from wells and boreholes in ECC's surroundings. Values form the WHO guidelines
503 (2011) and Maximum Admissible Values (MAV) established in Portuguese legislation
504 (Portuguese Decree-Law 1998, 2007) for drinking water are also shown and used as thresholds
505 of water quality. Obtained PTEs concentrations were well above WHO (2011) and MAV in
506 water for human consumption, except for Cr and Se. Means and maximum values were often
507 several orders of magnitude higher than the admissible values, namely for Al, As, Cd, Fe, Hg,
508 Mn and Zn, which showed very high concentrations (contamination). However, when looking at
509 the median values, it is reassuring to see that, in most cases, the median concentrations fall
510 below the international and Portuguese legislation. The exceptions are Al, Fe, Mn, and Zn. It is
511 worth noting that the large difference between the mean and median concentration found for
512 some PTEs suggests variable patterns of contamination. Further studies are required to identify
513 possible PTEs sources, transport of contaminants within the aquifer and fate of the elements of
514 concern, as all this factors modify human exposure risk.

515 Urinary median concentrations of Al, Cd, Mn and Zn of the participants in this study were
516 elevated relative to the typical ranges that have been reported in studies performed in other parts
517 of the world (Goullé et al. 2005; Kazi et al. 2008; Kuiper et al. 2014). Furthermore, the LRM
518 models show that Al, Cd and Zn urinary levels are good predictors of MMSE scores. In

addition, the MCA suggests an association between the consumption of well and stream water and high urinary contents of Al, Cd, Mn, Zn and other PTEs. Finally, the analysis of groundwater samples collected from wells and boreholes located near the ECC indicates unacceptable levels of Al, Fe, Mn and Zn for drinking purposes (Figure 6). Although current median Cd in groundwater samples was below the MAV, a long-term exposure to Cd-contaminated waters could still be reflected in urine samples, because of Cd long biological half-life (accumulation over time in the human body). Thereupon, we can assume that the elevated urinary concentrations of Al, Cd, Mn and Zn are likely related to the ingestion of contaminated groundwater. Martyn et al. (1989) carried out a large survey across England and Wales and found that the risk of AD was 1.5 times higher in districts where the mean Al concentration exceeded 0.11 mg/l than in districts where the concentrations were lower than 0.01 mg/l, which is in good agreement with the present study. Furthermore, the authors have not found any other probable cause for the incidence of the disease. However, in our study, the results suggest that both low and high levels of Al can be related to cognitive impairment. Considering that Al does not play any metabolic role in the human body, an Al deficiency in the participants cannot cause any deleterious health effect. Instead, the high contents of other PTEs such as Cd (and probably Zn), that in some participants are associated to low urinary Al levels, may be the ones actually causing the health effects. Unlike the findings of Martyn and co-authors, the results of the study hereby described suggest that, besides Al, also environmental Cd is related to the cognitive disorders found in the participants.

6. Conclusions

This study describes a multi-disciplinary approach combining neurosciences, psychology and environmental sciences, while integrating socio-economic, neuropsychological, environmental and health data.

For some PTEs, the urinary levels of the study group, elderly residents in Estarreja (a Portuguese industrial city in the Centre of Portugal), are generally above the ranges reported for healthy populations in other parts of the world.

The multivariate statistical analysis (MCA) of the multidisciplinary dataset indicates a relationship between high PTE levels in the urine of the participants and their neuropsychological impairment. It further suggests an association between high urinary PTEs levels and water consumption habits, the number of years residing in the city and the professional. Workers in agriculture and industry have higher PTE levels and lower scores on neuropsychological tests, suggesting that not only environmental but also occupational exposure

552 has to be considered. No relationship was found between the genetic burden of the individuals
553 and a tendency to neurodegenerative impairment.

554 Multiple linear regression models show that the cognitive evaluation results (MMSE scores)
555 can be predicted by Al, Cd and Zn levels in urine and, to some extent, by the number of years
556 living in the city.

557 The groundwater concentrations in ECC's surroundings are often above the Portuguese
558 maximum allowed levels in water for human consumption, particularly in the case of Al, Fe,
559 Mn and Zn. Whereas the WHO (2011) does not provide health-based reference values for PTEs
560 such as Al, this study suggests that long-term exposure to this PTE may have a deleterious
561 effect in the cognitive abilities of the elderly residents. Although median Cd in groundwater
562 samples was below the permissible values, a long-term exposure to Cd-containing waters could
563 still be reflected in urine samples because Cd has a long biological half-life and accumulates
564 over time in the human body. Considering the contrasting behavior of Al and Cd in the human
565 gut that often requires using different biological matrices to assess exposure to these
566 environmental contaminants, in this study urine proved to be a suitable specimen to evaluate
567 long-term exposure, both for elements with low and high excretion rates.

568 The results of the statistical analysis indicate that the time of residence in Estarreja is positively
569 associated with high urinary levels of PTEs, which suggests a long-term body burden of the
570 participants through the ingestion of drinking water. Although technological upgrades
571 associated with remediation measures implemented in the last decade by the industry have
572 reduced the environmental burden of the city, the Estarreja Chemical Complex is still regarded
573 as the major polluter of the region. Residents of Estarreja were exposed to a highly-
574 contaminated environment for decades, which may explain the positive association between
575 high PTEs levels in urine and low MMSE scores.

576 The possible involvement of environmental factors in the aetiology of aging related diseases
577 such as AD, PD and ALS unveils new perspectives for prevention and treatment. Whereas
578 genetic factors cannot always be controlled, if environmental factors causing human exposure
579 can be identified, such information will provide invaluable support to any protective measures
580 considered to be relevant to assure the well-being of the population.

581 Whereas no direct relationships could be established in this study, the relationship between
582 water ingestion, high urinary Al, Cd and Zn levels largely justifies the need for further studies
583 on the water ingestion pathway and potential long-term effects on the cognitive abilities of the
584 inhabitants. Increased understanding on the underlying causal relationships between

585 environmental exposure and health effects is decisive for effective remediation and science-
586 based decision making.

748 **Figure Captions:**

749 Figure 1: Location, geological and land-use (Corine Land Cover of 2006) maps of the studied area.

750 Figure 2: Projection in the first factorial plane of the categories defined for PTEs contents in urine
751 samples (active variables). Categories with label 1 include low PTEs levels while categories with label 2
752 include average PTEs levels and categories with label 3 represent high PTEs contents in urine samples.

753 Figure 3: Projections in the first factorial plane of the categories defined for the cognitive tests and
754 variable DIA (supplementary variables). Key: MOC: MoCA cognitive test (MOC0: dementia, MOC1:
755 MCI and MOC2: normal; MOC9 refers to illiterate participants that could take part in the MoCA test);
756 MMS: MMSE cognitive test (MMS0: dementia, MMS1: MCI and MMS2: normal); CDR: CDR cognitive
757 test (CDR0: normal, CDR1: MCI, CDR2: mild dementia, CDR3: dementia; CDR4: severe dementia,
758 DIA: diagnosis (Dia0: normal, Dia1: dementia, Dia2: MCI).

759 Figure 4: Projections in the 1st factorial plane of the categories defined for environmentally relevant life-
760 habits of the participants. Key: Reg: origin of water used in irrigation (Reg1: well water, Reg2: borehole
761 water, Reg3: stream water, Reg5: tap water); Prv: origin of drinking water (Prv1: tap water, Prv2: well
762 water, Prv3: bottled water, Prv4: tap water and bottled water); Cha: drinking tea habits (Cha1: yes, Cha 2:
763 no); Veg: consumption of home-grown food (Veg1: yes, Veg2: no)

764 Figure 5 - Projections in the 1st factorial plane of categories established for relevant socio-economic
765 factors. Key: Ant: record of neurological health problems in the family (Ant1: yes, Ant2: no); AR:
766 number of years living in Estarreja (AR1: small, AR2: average, AR3: large); Pro: profession (Pro0:
767 agriculture, Pro1: services and trade, Pro2: industry, Pro3: housewife); education level is identified by
768 labels "ana"(illiterate), "4º" (4th grade), "9º"(9th grade), "12º" (12th grade) and ">12ª" (higher education
769 level).

770 Figure 6: Concentrations found in water samples in ECC's surroundings. The top of the error bars
771 indicate one standard deviation. WHO refers to guideline values for drinking water from WHO (2011).
772 MAV refers to Maximum Admissible Value for human consumption, according Portuguese Legislation
773 (Portuguese Decree 1998, 2007).
