### ABSTRACT

**Context.** Westerlund 1 is a young, massive Galactic starburst cluster that contains a rich coeval population of Wolf-Rayet stars, hot- and cool-phase transitional supergiants, and a magnetar.

**Aims.** We use spectroscopic and photometric observations of the eclipsing double-lined binary W13 to derive dynamical masses for the two components, in order to determine limits for the progenitor masses of the magnetar CXOU J164710.2-455216 and the population of evolved stars in Wd1.

**Methods.** We use eleven epochs of high-resolution VLT/FLAMES spectroscopy to construct a radial velocity curve for W13. *R*-band photometry is used to constrain the inclination of the system.

**Results.** W13 has an orbital period of  $9.2709 \pm 0.0015$  days and near-contact configuration. The shallow photometric eclipse rules out an inclination greater than  $65^\circ$ , leading to lower limits for the masses of the emission-line optical primary and supergiant optical secondary of  $21.4 \pm 2.6 M_\odot$  and  $32.8 \pm 4.0 M_\odot$  respectively, rising to  $23.2_{-3.0}^{+3.3} M_\odot$  and  $35.4_{-4.6}^{+5.0} M_\odot$  for our best-fit inclination  $62_{-4}^{+3}$  degrees. Comparison with theoretical models of Wolf-Rayet binary evolution suggest the emission-line object had an initial mass in excess of  $\sim 35 M_\odot$ , with the most likely model featuring highly non-conservative late-Case A/Case B mass transfer and an initial mass in excess of  $40 M_\odot$ .

**Conclusions.** This result confirms the high progenitor mass of the magnetar CXOU J164710.2-455216 inferred from its membership in Wd1, and represents the first dynamical constraint on the progenitor mass of any magnetar. The red supergiants in Wd1 must have similar progenitor masses to W13 and are therefore amongst the most massive stars to undergo a red supergiant phase, representing a challenge for population models that suggest stars in this mass range end their redwards evolution as yellow hypergiants.

**Key words.** stars: evolution - supergiants - stars: individual: W13 - stars: magnetars - binaries: general

## 1. Introduction

The Galactic starburst cluster Westerlund 1 (hereafter Wd1; Westerlund 1961; Clark et al. 2005) contains a rich coeval population of OB supergiants, yellow hypergiants (YHG) and red supergiants (RSG) that collectively map out the transitional post-Main Sequence (MS) loop redwards followed by massive stars in the cluster. The relative brevity of the transitional phase and intrinsic rarity of such objects means that this stage of evolution is poorly understood, but recent downward revisions to MS mass loss rates (Fullerton et al. 2006; Mokiem et al. 2007) suggest that it is of critical importance in understanding how massive stars shed their outer layers prior to the Wolf-Rayet (WR) phase.

Due to its unique stellar population, Wd1 has been the subject of intensive observational study in recent years (Ritchie et al. 2009a, hereafter Paper I, and refs. therein; see also Clark et al. 2010a; Negueruela et al. 2010). Studies of the massive stellar population support a single burst of star formation at an age  $\sim 5$  Myr and a distance  $\sim 5$  kpc (Crowther et al. 2006; Negueruela et al. 2010), with the identification of  $\sim O8V$  stars in the cluster (Clark et al., in prep.) and a population of lower-luminosity late-O II-III stars just evolving off the MS both fully consistent with this derived age. Dynamical mass determinations of late-O dwarfs (Gies 2003) and comparison of the population of OB stars in Wd1 with theoretical isochrones (Meynet & Maeder 2000) suggest that stars with  $M_{\text{ini}} \sim 30 M_\odot$  lie at the MS turn-off, with the early-B supergiants having progenitor masses  $M_{\text{ini}} \sim 35\text{--}40 M_\odot$  (Negueruela et al. 2010) and the WR population descended from stars with  $M_{\text{ini}} \geq 40 M_\odot$  (Crowther et al. 2006). However, to date no direct mass determination exists for a member of Wd1; as well as providing confirmation of the current understanding of the cluster derived from spec-

**Fig. 1.** *Left panel:* I-band spectra of W13 at  $\phi = 0.33$  and  $\phi = 0.74$ . *Right Panel:* phase dependent variability of the Pa12 emission line. Five spectra are overplotted, with three from  $\phi = 0.15 - 0.30$  (solid line) and two from  $\phi = 0.30 - 0.35$  (dotted line).

troscopic studies, this is of importance for confirming the high progenitor mass for the magnetar CXOU J164710.2-455216 that has been inferred from its membership of Wd1 (Muno et al. 2006). In addition, the distribution of evolved stars in Wd1 offers the prospect of demanding tests for evolutionary models, with both the distribution of WR subtypes and the large number of cool hypergiants in both YHG and RSG phases at odds with current predictions (Clark et al. 2010a).

In this paper we present spectroscopic radial velocity (RV) measurements of the massive binary W13, identified as a 9.2-day eclipsing system by Bonanos (2007). X-ray observations reveal a hard source with  $L_x \sim 10^{32} \text{ ergs}^{-1}$ , consistent with a colliding-wind system (Clark et al. 2008), while subsequent multi-epoch spectroscopy described in Paper I showed W13 to be a double-lined spectroscopic binary consisting of a B0.5Ia<sup>+</sup>/WNVL emission-line object<sup>1</sup> and an early-B supergiant. We supplement the results of Paper I with an additional six epochs of data, providing a total baseline of approximately 14 months that allows an accurate radial velocity curve to be derived for the W13 system. This is used in conjunction with *R*-band photometry (Bonanos 2007) to determine the masses of the two components.

## 2. Observations & data reduction

Spectra of W13 were obtained on eight epochs in 2008 and three epochs in 2009 using the Fibre Large Array Multi Element Spectrograph (FLAMES; Pasquini et al. 2002), located on VLT UT2 *Kueyen* at Cerro Paranal, Chile. The GIRAFFE spectrograph was used in MEDUSA mode with setup HR21 to cover the 8484-9001Å range with resolution  $R \sim 16200$ ; full details of data acquisition and reduction are given in Paper I, and representative spectra showing the

<sup>1</sup> The WNVL classification is used here to indicate strong spectroscopic similarities with other WNL stars in Wd1; we note the He II  $\lambda 4686$  line necessary for formal classification (Crowther & Smith 1996) lies outside our spectral coverage.

Pa11  $\lambda 8862$  and Pa12  $\lambda 8750$  lines at two extremes of the RV curve are shown in Figure 1. The signal-to-noise ( $S/N$ ) ratio of our spectra is  $\sim 95$  at 8700Å. Photometry of W13 was taken from the published data of Bonanos (2007), obtained on 17 nights between 15/6/2006 and 25/7/2006 using the 1m Swope telescope at Las Campanas Observatory, Chile.

RV measurements were carried out using the IRAF<sup>2</sup> *onedspec* tasks to fit Gaussian profiles to the cores of the Paschen series absorption and emission features in the spectrum of W13: the derived RV at each epoch is an error-weighted average of the RV of individual lines. Strong interstellar C<sub>2</sub> lines from the (2,0) Phillips band overlap the Pa12 line, leading to a systematic phase-dependent bias of up to  $\sim 10 \text{ km s}^{-1}$  in the line centre, and this line was therefore excluded from the analysis. In addition, a broad DIB centred at  $\sim 8648\text{Å}$  (Negueruela et al. 2010) overlaps the Pa13  $\lambda 8665$  line, attenuating the blue flank of the emission component at  $\phi \sim 0.25$  and leading to an offset redwards relative to the other Paschen series lines, although measurement of the absorption component is not affected. Finally, at  $\phi \sim 0.15 - 0.3$  a systematic decrease in strength is seen in all Paschen-series emission lines, with the lines recovering in strength rapidly after  $\phi \sim 0.3$ ; this can be seen in the right panel of Figure 1, which overplots five spectra taken at  $\phi \sim 0.15 - 0.35$ . The weakening in Paschen-series emission was assumed to be wind variability in Paper I, but the persistence of this behaviour over more than  $\sim 30$  orbits in our extended dataset implies that it is not a transitory effect but rather a region of excess absorption periodically crossing the line of sight.

Absorption line RV measurements were therefore carried using the Pa11 and Pa13–16 lines, noting that the weakening of the higher Paschen-series lines leads to an increased fitting error and consequent decreased weight in the derived RV. Emission line RV measurements were carried out as follows:

- Emission lines cannot be measured with accuracy for one spectrum taken near eclipse ( $\phi = 0.03$ , 24/07/2008, MJD=54671.13).
- At  $\phi = 0.1 - 0.3$  attenuation of the blue flank of Pa13 by the  $\sim 8648\text{Å}$  DIB and the decrease in strength of Pa15 and Pa16 leave only Pa11 and Pa14 emission lines available for measurement, with the two lines in good agreement.
- At other epochs, Pa11 and Pa13-16 emission components were measured.

## 3. Results

### 3.1. Spectroscopic classification

#### 3.1.1. The optical primary

The *R*-band spectrum of W13 is dominated by the emission-line optical primary, with strong, relatively broad H $\alpha$  emission (FWHM  $\sim 500 \text{ km s}^{-1}$ ), complex, time-varying P Cygni profiles extending to at least  $-350 \text{ km s}^{-1}$  in the

<sup>c</sup>Unreliable due to the appearance of a central reversal in the emission line, and excluded from the fit to the RV curve.

**Fig. 2.** Intermediate-resolution spectra of W13 and the blue hypergiants W5 (B0.5Ia<sup>+</sup>/WN10–11, top) and W7 (B5Ia<sup>+</sup>, bottom). Spectra taken from Clark et al. (2010a) and Negueruela et al. (2010).

He I  $\lambda\lambda 6678, 7065$  lines and weak C II  $\lambda\lambda 6578, 6582$  emission. A comparison of previously published intermediate-resolution *R*-band spectra of W13 and the blue hypergiants W5/WR S (B0.5Ia<sup>+</sup>/WN10–11; Negueruela & Clark 2005) and W7 (B5Ia<sup>+</sup>; Negueruela et al. 2010) is shown in Figure 2. The luminous mid-late B hypergiants in Wd1<sup>3</sup> are all believed to be on a pre-RSG loop redwards (Clark et al. 2010b), and display narrow H $\alpha$  profiles with strong P Cygni absorption components, along with He I and C II in absorption (Clark et al. 2010a; Negueruela et al. 2010). In contrast, the spectrum of W13 shows strong similarities to both W5 and the WN9h binary W44/WR L (Crowther et al. 2006; Clark et al. 2010a), with the three objects forming a morphologically-distinct group when compared to the mid-late B hypergiants, suggesting that the emission-line object in W13 is also an immediate evolutionary precursor to the WR phase.

<sup>3</sup> W7, W33, and W42a; B5–B9Ia<sup>+</sup> (Negueruela et al. 2010).

The spectrum plotted in Figure 2 shows He I lines that are redshifted by  $\sim 50$  km s<sup>-1</sup> and C II emission lines somewhat blueshifted relative to He I (RV  $\sim 0$  km s<sup>-1</sup>), although accurate measurement of the C II line centres is difficult due to their low strength and the relatively low *S/N* of the *R*-band spectrum. Nevertheless, if the C II lines originated in the companion then we would expect the lines to be significantly blueshifted at this epoch (RV  $\sim -150$  km s<sup>-1</sup>; see Section 3.2), suggesting that the emission lines have a common origin<sup>4</sup>. However, N II  $\lambda 6611$  emission, present in both W5 and W44, appears absent in W13, while the H $\alpha$ , He I and C II emission lines are also considerably weaker, suggesting W13 is the least evolved member of the WNVL population of Wd1.

### 3.1.2. The optical secondary

The Paschen-series lines display complex emission/absorption profiles with the two components moving in anti-phase (see Figure 1). The absorption components have similar strengths to the lower-luminosity O9.5Iab/b objects in our FLAMES dataset, but infilling from the emission-line object is likely to affect these features and an alternative diagnostic is provided by weak He I  $\lambda 8584, 8777$  absorption lines that are apparent in many spectra, moving in phase with the Paschen-series absorption lines. These He I lines are first seen at O8–9I and strengthen rapidly at  $\sim$ B1.5I (Negueruela et al. 2010), with their weakness therefore suggesting a spectral type no later than  $\sim$ B1I, although overlapping interstellar features (including a broad, weak DIB at  $\sim 8779$  Å) preclude precise measurement. A late-O spectral type appears to be excluded by the apparent absence of C III  $\lambda 8500$  absorption, with this line leading to a blueshifted offset and discrepant strength for the C III  $\lambda 8500$ /Pa16  $\lambda 8502$  blend in the O9.5–B0.5 supergiants in Wd1 (Negueruela et al. 2010; see Paper I). Neither classifier should be significantly affected by wind emission<sup>5</sup>, and the weak He I lines and absence of C III absorption therefore suggests a  $\sim$ B0.5–1I

<sup>4</sup> We note that W5 also appears to show C II blueshifted relative to He I.

<sup>5</sup> The He I  $\lambda 8584, 8777$  lines arise from transitions from the  $3p^3P^o$  level, which is well-populated in  $\sim$ B1–4 supergiants, to

Fig. 3. Radial velocity curve for W13.

classification with an uncertainty of roughly half a spectral subtype and lack of strong constraints on the luminosity class. However, we caution that if C III is weak due to abundance anomalies or near-critical rotation then this limit may not apply, and the weakness of the He I lines permit a classification of O9.5–B0I that is broadly consistent with the Paschen-series line strengths.

### 3.2. Radial velocity curve

Figure 3 shows RV curves for the two components of the W13 system. Taking the 9.20-day period reported by Bonanos (2007) as a starting point, an error-weighted  $\chi^2$  fit to the radial velocities of the absorption-line component yielded best-fit values for the orbital period of  $P = 9.2709 \pm 0.0015$  days, consistent with an independent determination using a Lomb-Scargle periodogram (Press & Rybicki 1989), a systemic velocity of  $-65.9 \pm 2.4 \text{ km s}^{-1}$  and semi-amplitude  $K_{\text{abs}} = 137.3 \pm 6.7 \text{ km s}^{-1}$ . The corresponding fit to the emission line RV curve<sup>6</sup> has a systemic velocity of  $-48.2 \pm 3.1 \text{ km s}^{-1}$  and semi-amplitude  $K_{\text{abs}} = 210.2 \pm 8.7 \text{ km s}^{-1}$ . Errors are derived from the fitting residuals using the bootstrap method (Efrom & Tibshirani 1994). We note that systemic velocity derived from the emission line fit is somewhat lower than that derived from the companion, and is in closer agreement with the mean radial velocities of other Wd1 supergiants (see Paper I). Discrepancies in this parameter are commonly observed in early-type spectroscopic binaries (e.g. the 9.8-day O7III(f)+O8.5I binary HD 149404; Rauw et al. 2001) although the effect is small in comparison with some other evolved systems (e.g. HDE 228766; Massey & Conti 1977; Rauw et al. 2002) in which wind contamination strongly affects derived systemic velocities.

upper levels near the ionisation limit of He I (van Helden 1972), but the corresponding downwards transitions are very weak.

<sup>6</sup> In fitting the emission-line RV curve, the discrepant point at  $\phi=0.55$  was excluded.

Fig. 4. Fit to the R-band lightcurve of W13

Taking these values yields a mass ratio  $q = M_{\text{ABS}}/M_{\text{EM}} = 1.53 \pm 0.10$  and masses for the two components of:

$$M_{\text{EM}} \sin^3 i = \frac{(1+q)^2 P K_{\text{ABS}}^3}{2\pi G} = 15.9 \pm 1.9 M_{\odot} \quad (1)$$

and

$$M_{\text{ABS}} \sin^3 i = 24.4 \pm 3.0 M_{\odot} \quad (2)$$

Finally, measurements of blended hydrogen lines with Gaussian fits tend to yield systematically lower values of  $K_1$  and  $K_2$  than methods such as spectral disentangling (Simon & Sturm 1994) that are less affected by blending (Andersen 1975; Southworth & Clausen 2007). The paucity of strong lines free from significant interstellar, telluric and wind contamination in the  $R$ - and  $I$ -band spectra of  $\sim$ B0 supergiants makes the extent of this effect on our determination of  $K_{\text{em}}$  and  $K_{\text{abs}}$  hard to quantify, and we therefore note that our method may underestimate the masses of the two components of W13.

### 3.3. Light curve

To constrain  $\sin^3 i$ , we folded the  $R$ -band photometric data reported by Bonanos (2007) on to the 9.271 day period determined from the RV data. The data were binned to reduce the considerable scatter present in the light curve, which is most probably a consequence of intrinsic aperiodic variability in one or both components: low-level photometric and spectroscopic variability is a feature of all transitional supergiants in Wd1, with the blue hypergiants displaying rapid photometric variability at the  $\sim 0.1$  magnitude level and the early-B supergiants also variable (Bonanos 2007; Clark et al. 2010a). Therefore, given the limited dataset and shallow  $\sim 0.15$  magnitude eclipse, we do not expect to be able to fit the light curve of W13 with high accuracy. Nevertheless, in the absence of longer-term photometric monitoring, the data of Bonanos (2007) allow reasonable constraints to be placed on the orbital inclination.

The *nightfall* code<sup>7</sup> was used to model the light curve of W13. The effective temperature of the emission line object was fixed at 25kK, appropriate for its spectral type,

<sup>7</sup> <http://www.hs.uni-hamburg.de/DE/Ins/Per/Wichmann/Nightfall>

and a linear limb-darkening law and circular orbits were assumed. The mass ratio was derived from the RV curve, and the inclination, Roche lobe filling factors for both objects and temperature of the optical secondary were allowed to vary. The code rapidly converges to a near-contact configuration in which the emission-line object has almost filled its Roche lobe (filling factor  $\sim 0.93 \pm 0.05$ ) and the other star has a somewhat lower filling factor ( $\sim 0.74 \pm 0.1$ ). The best-fit model has an inclination  $i = 62^\circ$  and provides a close match to the light curve from  $\phi \sim 0.5$  to  $\phi \sim 1$ , although the region around  $\phi = 0.2$ – $0.4$  is less well reproduced. Although the *nightfall* code supports additional features such as ‘hot spots’ that may provide a better fit to this portion of the light curve (see, for example, the model of Cyg OB2#5 presented by Linder et al. 2009), we consider further refinement of the model inappropriate given the limitations of the photometric dataset used. Parameters derived from the light curve model are listed in Table 2, although we stress that our primary goal is to constrain the inclination of the system and other parameters should be regarded as provisional pending acquisition of longer-term photometry.

To examine errors in the derived inclination we investigated models in which  $i$  is fixed at values from  $55^\circ$  to  $68^\circ$  while filling factors and temperatures are allowed to vary as before; the best fit  $i = 62^\circ$  curve and models with  $i = 59^\circ$ ,  $i = 65^\circ$  and  $i = 68^\circ$  are plotted in Figure 4. Inclinations greater than our best-fit model lead to slightly lower filling factors and higher temperatures, while the converse is true for lower inclinations. The depth of the eclipse provides the strongest constraint on the model, with inclinations greater than  $\sim 65^\circ$  strongly disfavoured. *I*-band photometry is also presented by Bonanos (2007), but considerably greater scatter is present in the data at mid-eclipse, making it less suitable for modelling. Nevertheless, these data also support  $i \leq 65^\circ$ , favouring a value  $\sim 60$ – $62^\circ$ , although the degree of scatter renders this uncertain. Therefore, taking  $i \leq 65^\circ$  places robust lower limits of  $M_{\text{em}} \geq 21.4 \pm 2.6 M_\odot$  and  $M_{\text{abs}} \geq 32.8 \pm 4.0 M_\odot$  for the emission-line object and its companion, rising to  $23.2^{+3.3}_{-3.0} M_\odot$  and  $35.4^{+5.0}_{-4.6} M_\odot$  for our preferred inclination  $i = 62^{+3^\circ}_{-4^\circ}$ . For the purposes of discussion we take the lower masses derived from the  $i \leq 65^\circ$  limit.

## 4. Discussion and Conclusions

### 4.1. The evolution of the W13 system

The short orbital period, near-contact configuration and evolved, mass-depleted nature of the emission-line object all imply that the two components of the W13 system must have undergone strong interaction during their evolution. The 9.3-day orbital period suggests a late-Case A or Case B scenario, with mass transfer beginning near the onset of shell hydrogen burning (Petrovic et al. 2005, hereafter P05). The presence of unevolved late-O stars ( $M_{\text{ini}} \sim 30 M_\odot$ ) in Wd1 suggests a minimum initial mass  $\sim 35 M_\odot$  for shell burning to have commenced, with in excess of  $\sim 10 M_\odot$  lost once mass transfer begins. However, transfer of angular momentum is expected to lead to the accretor rapidly reaching critical rotation (Packet 1981; Langer et al. 2008), while rapid rotation will also greatly increase wind mass loss rates (Langer 1998), and a fully-conservative transfer scenario appears unlikely. Indeed, models of short-period WR+O binaries by P05 suggests

<sup>a</sup> Note that  $T_0$  corresponds to the eclipse of the B0.5Ia<sup>+</sup> emission-line star.

that mass-transfer is highly *non-conservative* in such scenarios, with only  $\sim 10\%$  of transferred mass being retained by companion star. The current  $21 M_\odot + 33 M_\odot$  (minimum) mass ratio in W13 is consistent with the P05 model of late-Case A/Case B evolution at low accretion efficiency, with higher accretion efficiencies leading to a more unequal mass ratio than we observe.

P05 estimate a relationship between initial MS mass and final WR mass for Case B systems of  $M_{\text{ini}} = (M_{\text{WR}} + 4.2)/0.53$  that suggests that the emission-line object had an initial mass  $\sim 48 M_\odot$ . While this is consistent with estimates of WR progenitor masses (Crowther et al. 2006), it is somewhat higher than expected for a star just entering the WR phase in Wd1. However, W13 will likely shed further mass before becoming a *bona fide* WN9, suggesting that  $M_{\text{WR}} \sim 20 M_\odot$  and consequent initial MS mass around  $\sim 45 M_\odot$  are more appropriate. Assuming an accretion efficiency of  $\sim 10\%$  from P05, this would imply that  $\sim 2$ – $3 M_\odot$  was transferred to the secondary, with the remainder lost from the system. While extended radio emission from W13 is not detected (Dougherty et al. 2010), emission from both the O9Ib star W15 and the extreme RSG W26 overlaps the region around W13 and might obscure direct signs of recent mass loss.

W13 therefore appears to be a less-evolved analogue to WR21 (HD 90657), a 8.3-day  $19 + 37 M_\odot$  WN5 binary considered by P05. One notable discrepancy is the presence of an evolved companion in W13, whereas WR21 contains an unevolved mid-O star. Although abundance anomalies might suppress the C III  $\lambda 8500$  line in a late-O supergiant, leading to an erroneously late spectral type, the presence of He I lines moving in phase with the Paschen-series absorption lines excludes a spectral type earlier than  $\sim \text{O9}$  (Negueruela et al. 2010). It is possible that the supergiant is still in extreme, near-critical rotation from recent mass transfer, and is thus expanded with a complex, latitude-dependent spectrum that features both hot (polar) and cooler (equatorial) components. However, confirmation of this hypothesis is observationally challenging, as infilling of the Paschen-series absorption lines prevents direct deter-

**Fig. 5.** Location of luminous hypergiants in Wd1 for a distance of 5kpc compared to  $z=0.020$  (i.e. solar abundance) evolutionary tracks with and without rotation (Meynet & Maeder 2003). Lower limits for the luminosities of the YHGs W4, W16a and W265 are plotted. W4 is offset vertically by 0.02 dex and error bars are omitted for W265 to highlight the change in spectral type over the pulsational cycle.

mination of  $v \sin i$  while the high reddening towards Wd1 precludes the use of fiducial O-type spectral classifiers in the blue region of the spectrum.

## 4.2. Evolutionary implications for Wd1

### 4.2.1. The cool hypergiant population of Wd1

The likely  $\geq 40M_{\odot}$  MS mass for the emission-line object in W13 provides direct constraints on the masses of the eleven cool hypergiants in Wd1. Of these, only two have been studied in detail<sup>8</sup>, but the long-term dataset compiled by Clark et al. (2010a) reveal a remarkable *lack* of secular evolution amongst these objects, with only the LBV W243 (Ritchie et al. 2009b) apparently undergoing a major outburst in the half-century since the discovery of the cluster by Westerlund (1961). Although early observations are sparse, the available data are sensitive to the long-term evolutionary trends seen in objects such as the YHG IRC +10 420 (Humphreys et al. 2002), the LBV R127 (Walborn et al. 2008) or M33’s Var A (Humphreys et al. 2006). Current observations therefore suggest the supergiants in Wd1 undergo a slow redwards evolution at approximately constant luminosity until they encounter an extended cool-phase state accompanied by growing pulsational instability (Clark et al. 2010a,b).

Evolutionary models of massive stars predict a relatively long YHG lifetime at  $T \sim 6000K$  for stars with  $M_{\text{ini}} \sim 40M_{\odot}$ , consistent with the lack of secular evolution and mid-A to late-F spectral types for the YHGs in Wd1, but do not predict further evolution to the RSG phase (Meynet & Maeder 2003; Drout et al. 2009). However, while the B- and A/F-hypergiant populations plotted in Figure 5 appear in good agreement with the evo-

lutionary tracks<sup>9</sup>, the presence of RSGs in Wd1 suggests that stars in this mass range *do* evolve further redwards (Clark et al. 2010a), with the extended radio nebulae apparent around these objects (Dougherty et al. 2010) revealing extensive mass loss that may account for a significant fraction of the mass lost prior to the WR phase. Lower-mass stars will not reach the RSG phase until  $\geq 6\text{Myr}$ , and the absence of any other indicators of significant non-coevality in Wd1 (Negueruela et al. 2010) and the location of two RSGs near the core of the cluster argue against the RSGs being descended from a separate population of older, lower-mass stars. Short-term spectroscopic variability and lack of contemporaneous photometry render the luminosities of individual RSGs uncertain, and further observations are required to place them firmly on the HR diagram. Nevertheless, the M1–5Ia spectral types derived from TiO band strengths appear robust (Clark et al. 2010a), and are clearly discrepant with respect to current theoretical predictions.

### 4.2.2. The Wd1 magnetar.

The magnetar CXOU J164710.2-455216 (Muno et al. 2006, 2007) lies  $1'.7$  from the centre of Wd1, corresponding to  $2.3(d/5\text{kpc})$  pc in projection. The negligible likelihood of the magnetar being a chance association and the presence of  $\sim 08V$  stars in Wd1 provide strong evidence for a massive progenitor (Muno et al. 2006), a result confirmed by our direct measurement of the mass of W13 which rules out a magnetar progenitor below  $\sim 35M_{\odot}$  and strongly supports a progenitor mass in excess of  $\sim 45M_{\odot}$  unless mass transfer within W13 is unexpectedly conservative. This is consistent with the expected initial masses of the most evolved WR stars in Wd1, and also progenitor masses derived for other magnetars: a  $48_{-8}^{+20}M_{\odot}$  progenitor mass is found for the magnetar SGR1806-20 based on its assumed membership of a massive cluster at G10.0-0.3 (Bibby et al. 2008), while an expanding HI shell around the magnetar 1E 1048.1-5937 is inferred to be a wind-blown bubble from a  $\sim 30\text{--}40M_{\odot}$  progenitor (Gaensler et al. 2005). The progenitor of SGR1900+14 has a significantly lower mass (Clark et al. 2008; Davies et al. 2009), implying a number of formation pathways exist. However, the derived mass of SGR1806-20 is strongly influenced by the distance to the host cluster obtained from spectroscopic observations, and our results place the first *dynamical* constraints on a massive magnetar progenitor. Indeed, our results suggest that CXOU J164710.2-455216 may have the highest dynamically-constrained progenitor mass of *any* confirmed neutron star. The high-mass X-ray binary 4U1700-37 contains a O6.5Iaf<sup>+</sup> mass donor with mass  $58 \pm 11M_{\odot}$  but the nature of the  $2.44 \pm 0.27M_{\odot}$  compact object remains uncertain (Clark et al. 2002), while the  $\sim 43 \pm 10M_{\odot}$ , highly-luminous B1Ia<sup>+</sup> hypergiant in the X-ray binary Wray 977/GX 302-2 may have evolved via quasi-conservative Case A transfer in a 3.5 day binary with

<sup>8</sup> The A3Ia<sup>+</sup> LBV W243 (Ritchie et al. 2009b) and the YHG W265, which varies from F1–5Ia<sup>+</sup> with a  $\sim 100$  day quasi-period (Paper I; also Clark et al. 2010a)

<sup>9</sup> Luminosities for the BHGs W7 and W33 are taken from Negueruela et al. (2010), while the luminosity of the LBV W243 is taken from non-LTE modelling assuming a distance of 5kpc (Ritchie et al. 2009b). YHG luminosities of  $\log(L/L_{\odot}) = 5.7$  are lower limits from the  $M_v\text{--}W(\text{O I } \lambda 7774)$  relationship (Arellano Ferro et al. 2003; Clark et al. 2005).

initial masses  $26M_{\odot}+25M_{\odot}$  (Wellstein & Langer 1999; Kaper et al. 2006).

NTT/Soff  $K_s$ -band imaging rules out a current  $\geq 1M_{\odot}$  companion to the magnetar (Muno et al. 2006), a result we confirm using deep VLT/NACO  $J$ -,  $H$ - and  $K_s$ -band imaging (Clark et al., in prep.). Nevertheless, given the high binary fraction amongst the WR population (Crowther et al. 2006) and the need for a low pre-supernova core mass to avoid direct (or fallback) black hole formation (e.g. Fryer et al. 2002) it would appear likely that the magnetar progenitor *was* part of a (now-disrupted) close binary system (Clark et al. 2008). Support for this hypothesis comes from population synthesis models, which can only form a neutron star from an isolated  $\sim 60M_{\odot}$  progenitor within the  $\sim 5$ Myr age of Wd1 if mass loss rates from stellar winds are greatly enhanced (Belczynski & Taam 2008). In a close binary scenario, however, removal of the hydrogen-rich outer mantle via Case A mass transfer results in a reduced post-MS helium core, and ongoing Case B transfer during shell burning will leave a low mass ( $< 10M_{\odot}$ ) helium-burning WR (P05), permitting isolated neutron star formation within 5Myr via a type Ib/c supernova if the kick velocity is sufficient to disrupt the system<sup>10</sup>. Neutron star formation may also occur for massive binaries with initial periods greater than a few weeks; such systems will not undergo Roche lobe overflow until core hydrogen burning is complete and therefore form higher-mass helium cores than Case A systems, but if Case B or early-Case C mass transfer can suppress hydrogen shell burning before core helium burning is complete then the consequent reduction in the mass of the iron core may limit black hole formation (Brown et al. 2001). Further results on the distribution of binaries on Wd1 from our VLT/FLAMES survey and follow-up observations will therefore allow strong constraints to be placed on the formation channels for such systems.

## 5. Conclusions and future work

We find lower mass limits for the components of the eclipsing binary W13 of  $21.4 \pm 2.6M_{\odot}$  and  $32.8 \pm 4.0M_{\odot}$ , rising to  $23.2^{+3.3}_{-3.0}M_{\odot}$  and  $35.4^{+5.0}_{-4.6}M_{\odot}$  for our best-fit inclination  $62^{+3}_{-4}$  degrees, with spectroscopy suggesting that the evolved emission-line object is likely an immediate evolutionary precursor to the WR phase. As conservative mass transfer would require the exchange of (at least) 5–10 $M_{\odot}$  without the accretor exceeding critical rotation, it appears likely that W13 evolved through non-conservative late-Case A/Case B mass transfer as the (initially) more massive star left the MS. Estimates of the initial WR mass from P05 and the presence of a  $\geq 33M_{\odot}$  supergiant companion, which cannot have greatly increased in mass during highly non-conservative transfer, therefore suggest a MS mass for the emission-line object in excess of  $\sim 40M_{\odot}$ . This is consistent with previous estimates of the transitional supergiant masses in Wd1 obtained from the MS turnoff and spectroscopy of the WR and OB supergiant populations (Crowther et al. 2006; Clark et al. 2010a; Negueruela et al. 2010). Most importantly, this result

places the first dynamical constraint on the mass of a magnetar progenitor, and highlights a discrepancy between the presence of RSGs in Wd1 and the predictions of evolutionary models, which suggest that the most luminous RSGs should evolve from significantly lower masses.

A first study of the binary fraction amongst lower-luminosity late-O II-III stars in Wd1 will be presented in a subsequent paper in this series, but many binary systems are already available for follow-up study. These include short-period spectroscopic binaries (W43a, W3003; Paper I), eclipsing binaries within the WR, OB supergiant and main sequence populations (Bonanos 2007), and X-ray and radio-selected colliding-wind binaries (Clark et al. 2008; Dougherty et al. 2010). Consideration of these data will allow further dynamical constraints to be placed on the progenitor masses of the evolved stars within Wd1 as well as the general mass luminosity relation for stars in the upper reaches of the HR diagram and the post-MS pathways they follow. Moreover, they will yield the first characterisation of the binary properties of a homogeneous population of massive stars, of critical importance for studies of both star and cluster formation and numerous high-energy phenomena such as supernovae, Gamma-ray bursters and the formation of high mass X-ray binaries.
