An Interference-Aware Virtual Clustering Paradigm for Resource Management in Cognitive Femtocell Networks

Faisal Tariq, Laurence S Dooley, Adrian S Poulton

Department of Communication and Systems, The Open University, Milton Keynes, UK.

Abstract

Femtocells represent a promising alternative solution for high quality wireless access in indoor scenarios where conventional cellular system coverage can be poor. They are randomly deployed by the end user, so only post deployment network planning is possible. Furthermore, this uncoordinated deployment creates severe interference to co-located femtocells, especially in dense deployments. This paper presents a new architecture using a *generalised virtual cluster femtocell* (GVCF) paradigm, which groups together FAP into logical clusters. It guarantees severely interfering and overlapping femtocells are assigned to different clusters. Since each cluster operates on different band of frequencies, the corresponding virtual cluster controller only has to manage its own FAPs, so the overall system complexity is low. The performance of the GVCF algorithm is analysed from both a resource availability and cluster number perspective. Simulation results conclusively corroborate the superior performance of the GVCF model in interference mitigation, particularly in high density FAP scenarios.

Keywords: Femtocell, Interference Management, Resource Allocation, Heterogeneous Networks, Virtual Clustering

1. Introduction

The impetus for the rapidly increasing demand for high data-rate mobile support in indoor environments has been the inexorable shift in users' focus to more data intensive applications like network video gaming, video conferencing and video-on-demand. Recent studies have revealed that mobile data demand is now increasingly generating from indoor scenarios [1][2]. The provision of high indoor data rates is difficult for conventional cellular services since high wall penetration losses lead to attenuated received signal strengths. The problem is particularly severe in the cell-edge areas furthest from the serving macrocell *base stations* (BS). Increasing the BS transmit power is not a viable solution to this problem as it concomitantly increases the co-channel interference to users located at the edge of neighbouring cells. Similarly, deploying more BS is not feasible due to the probative costs involved.

Femtocell access points (FAP) are an emerging technology specifically designed to address these challenges. They are inexpensive, plug and play devices which provide high data rates in indoor scenarios. The typical radio range for a home femtocell is $< 10m$, which means the transmit power requirement is significantly lower than a conventional

BS. When located indoors, *mobile stations* (MS) connect to the FAP instead of the macrocell BS, with all network traffic being backhauled via either a wired xDSL (digital subscriber line) or fibre optic network.

While FAP is an attractive solution, there are many technical, regulatory and economic obstacles to be overcome to achieve successful deployment. Due to the anticipated high operational densities, managing interference is the most significant challenge for successful femtocell deployment [2]. There are a plethora of interference management techniques including collaborative resource allocation, opportunistic spectrum sharing between tiers and transmit power control [3]. In large-scale deployments, a distributed model [4] is more expedient compared to a centralised solution, with game theoretic approaches affording both cooperative and non-cooperative methods to determine the optimal Nash equilibrium power value for a given set of objectives and constraints [5]. *Reinforced learning* (RL) is a promising alternative technique for interference mitigation, where the FAP combines the current transmission experience with previous experiences to decide the most appropriate channel and power level for the next transmission [6]. In rapidly varying radio environments however, RL can hinder the rate of convergence to a quiescent state and the FAP training period can become too long, resulting in system inefficiencies.

In a cognitive radio based approach [7], SINR measurements are made for all femtocell and macrocell users and fed back to the BS, which then decides the most appropriate operating channel, the transmission power and SINR distribution at any location to ensure either minimal or no interference occurs. Improvements to these techniques are restricted however, by the power required for sensing, the accuracy of channel state information and redundant data incurred for real-time information sharing.

From a femtocell resource management perspective, with the likelihood of progressively larger scale deployments, a centralised model is going to become intractable because it is not scalable and incurs high redundant control data overheads [8]. Conversely, a fully distributed management model may lead to undesirable situations where a unilaterally poor choice for one FAP, particularly in dense deployments, can have serious implications for several other FAPs. Moreover, as deployment densities and radio environments vary dynamically, the resource management architecture must be adaptive to different scenarios. This means hybrid management paradigms [9] are a more propitious option for femtocell networks, with some functionality controlled centrally and some devolved to either the FAP or a local *femtocell gateway* (FGW), which is an intermediary between the FAPs and the *radio network controller* (RNC) in undertaking certain control and management functions.

Since femtocells are arbitrarily positioned by the end users, existing radio resource management paradigms [10], which have been designed for pre-deployment resource planning in either macro-cellular or ad-hoc wireless networks, are simply not applicable in a femtocell context. The absence of any coordination between femtocells means the coverage of one femtocell can overlap with another, resulting in harmful interference [11]. This problem is compounded in high density deployments, so effective interference management strategies are essential in facilitating successful femtocell network operation.

The corollary is that the underlying resource management architecture needs to be redesigned to incorporate the distinctive features of femtocell technology. The resource manager for example, must be flexible and adaptive to accommodate sudden changes in the radio environment, network topology and resource availability. This provided

the motivation for the new generalised resource management paradigm presented in this paper, which does not require any change in its physical architecture. Introducing the concept of FAP clustering, femtocells are classified into virtual clusters, with this terminology reflecting that cluster members are logically linked together, as opposed to the traditional *ad hoc* clustering sense, where members are located within some defined distance of a clusterhead. Members of a virtual cluster may not necessarily be physically co-located, but instead are grouped together to exploit the same set of channels according to a minimum interference generation criterion.

The initial idea of logical clustering was introduced in [12], with a *virtual cluster formation* (VCF) algorithm being applied to a rigid clustering framework, and FAP location information used to create the respective virtual (logical) FAP clusters. The VCF algorithm maximises the minimum distance between the FAPs of any cluster, thereby minimising the overall interference. Since the location of the FAPs remains relatively constant, the corresponding computational complexity of this minimax clustering solution is low compared to other available interference minimisation methods.

The innovative contribution in this paper is the formulation and analysis of a *generalised virtual clustering femtocell* (GVCF) framework which is adaptive to radio environment changes. GVCF actively negotiates with the central network controller whenever more resources are required to ensure the requisite QoS (Quality of Service) is upheld. The fixed cluster structure in [12] is relaxed in the GVCF model by regular monitoring and performance evaluation. It also has the capability to adapt the number of clusters and their respective FAP members in accordance with fluctuations in both the available resources and a prescribed set of network design constraints, such as the minimum throughput requirement or the maximum transmit power. The corresponding results analysis corroborates the enhanced interference management performance and adaptive capability of the new GVCF model in various network scenarios, especially high density deployments.

The remainder of the paper is organised as follows: Section 2 describes the two-tier system model including the various interference options, a cross-tier interference minimisation technique, and both the path-loss and channel allocation models. Section 3 represents the new generalised virtual clustering framework, while Section 4 rigorously analyses the performance of the GVCF paradigm in terms of throughput, received SINR, and the average reuse distance for varying FAP deployment densities and channel availabilities. Finally, Section 5 presents some concluding comments.

2. System Model

A dual-tier (macro-femto) system model is considered in this paper, where the femtocell is overlaid upon the macrocell system. The macrocell is hexagonally shaped, with a BS located at the centre of the cell, and comprising three sectors with MSs being uniformly distributed in each sector. In contrast, femtocells are circular in shape and uniformly distributed inside every macrocell. The FAP is assumed to be located at the centre of a femtocell with an omnidirectional antenna, and the MSs which are connected to it are uniformly distributed across the femtocell. FAP transmission power is fixed, though different power levels are used for the inner and outer cell MSs. A closed access mechanism is adopted for all femtocells so only authorised MSs can connect to a particular FAP. Macro and femtocell coexistence is assumed, with both operating in the

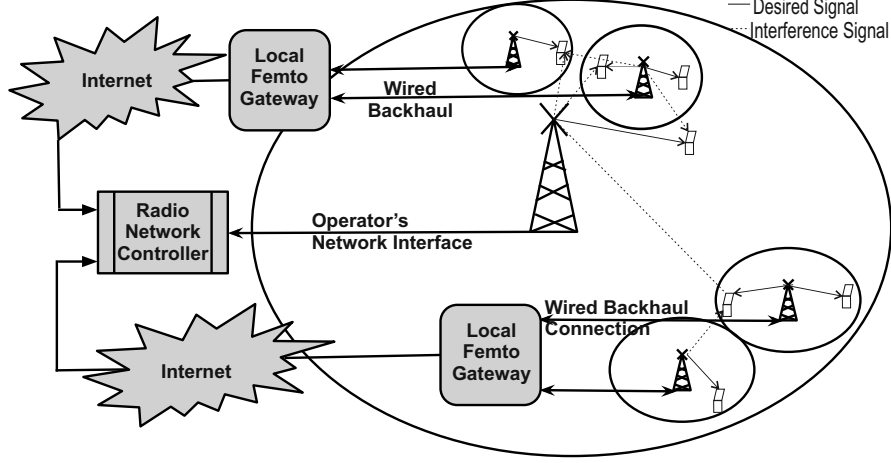

Figure 1: Example joint macro-femto deployment arrangement with backhaul network

same 10MHz spectrum, which is divided into 180KHz wide equi-spaced channels in an analogous way to the 3GPP LTE standard [13].

The interconnection network for joint macro-femto deployment, including the down-link (DL) interference scenarios is shown in Figure 1. The FAPs are connected to a local FGW which retains some FAP control functionality relating to the registering of FAP and its user, assisting in the initial cluster configuration, allocating available femto-tier resources, managing local disputes, routing traffic in both directions and most importantly as a link between the RNC and FAPs. The FGW maintains macro-layer communications via the RNC, the internet and the operator's interface (also known as the X2 interface), which routes traffic in harmony with the RNC. Since the FGW plays a crucial role in cross-tier information sharing acting as an intermediary between the macro and femto tiers, the virtual clusters are formed in the FGW.

Importantly at any location, the macro and femtocells use mutually exclusive sub-channels to avoid macro-to-femto and femto-to-macro interference. This is achieved by employing *fractional frequency reuse* (FFR), in which sub-channels used by a MS connected to a specific BS in one sector are allocated to a MS connected to a FAP in a different sector [14]. The new GVCF paradigm addresses the problem of both cross and co-tier interference management in the DL, with special emphasis on femto-to-femto interference minimisation. A variant of FFR called dynamic FFR is adopted in the GVCF framework for resource sharing. This will be delineated in the next section along with the path loss model used to determine the FAP distance between FAPs able to reuse the same channels, and the MS channel allocation scheme.

Dynamic FFR: Figure 2 illustrates the FFR resource sharing scheme for a macro and femtocell network with 3 macrocells. It divides each macrocell into an inner and outer area, with the latter being further sub-divided into multiple sectors. In dynamic FFR [9], the number of channels available in each sector varies dynamically in proportion to the number of users in the area, with the femto layer being subsequently updated about any changes at regular intervals. Each colour in Figure 2 represents an available spectrum

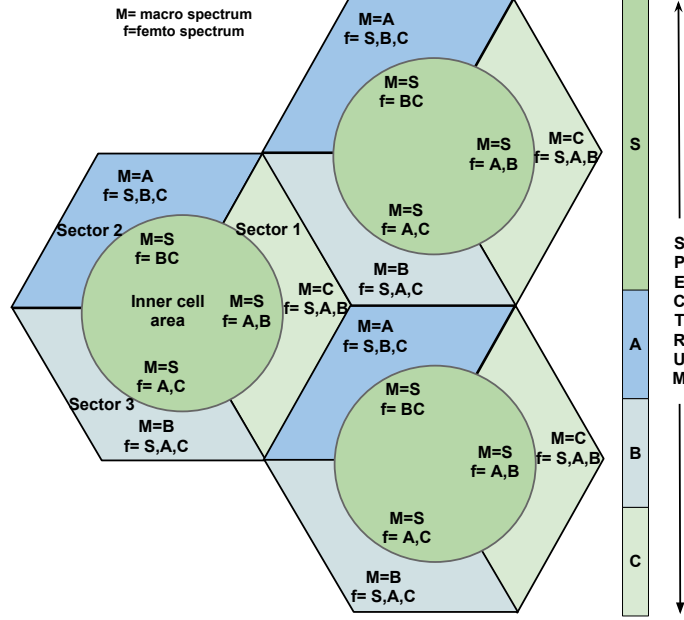

Figure 2: FFR-based resource sharing in joint macro-femto deployments.

band for the macrocell users in that area, with femtocells being prohibited from using these frequencies.

Path Loss Model: The WINNER II path loss model for indoor scenario A1 [15] is utilised, with (1) and (2) giving the indoor *path losses* (PL) for the *line-of-sight* (LOS) and *non-line-of-sight* (NLOS) cases respectively. In the NLOS situation, when there are walls between the transmitter and receiver, an additional wall penetration loss (L_{WP}) component is included:

$$PL_{LOS}^f = 18.7 \log(d) + 46.8 + 20 \log \frac{f_c}{5} \quad (1)$$

$$PL_{NLOS}^f = 20 \log(d) + 46.4 + 20 \log \frac{f_c}{5} + L_{WP} \quad (2)$$

where d is the distance of the user from the FAP in metres, f_c is the carrier frequency, L_{WP} is the wall penetration loss (dB), and PL_{LOS}^f and PL_{NLOS}^f are the femtocell path losses (dB) for the LOS and NLOS signals respectively.

Wall penetration losses vary according to such factors as: transmission frequency, angle of arrival of the signal, wall thickness and the material used, so to simplify the calculations, $L_{WP} = 5dB$ and $L_{WP} = 10dB$ are respectively considered as the internal and external wall penetration losses.

Channel Allocation: The GVCF model assumes every FAP is responsible for allocating channels to its member MSs, based upon feedback from the MSs on the respective received SINR. To assign the best available channel, each FAP calculates the carrier-to-interference ratio for all MSs attached to it, which is formally defined as:

$$\frac{C}{I} = \frac{P_{t0}h_0}{\sum_j P_{nj} + N_0} \quad (3)$$

where C is the carrier power, I the interference-plus-noise power, P_{t0} the transmit signal power, h_0 the channel power gain, P_{nj} the received interference power on channel n from user j and N_0 is the noise power.

3. GVCF Paradigm

3.1. Logical Clustering Architecture

Clustering has been widely investigated in both the wireless sensor and *ad hoc* network domains [16], with the normal approach being to select a clusterhead from a group of nodes according to some criterion. Neighbouring nodes are then assigned membership of a cluster based upon for instance, being physically co-located. In contrast, the GVCF model uses virtual (logical) clusters which are based on an interference-based Euclidean distance measure.

The principal motivation behind the development of the GVCF paradigm is the key challenge in femtocell networks of interference management. Virtual clusters are formed using a minimax criterion by combining FAPs under a virtual cluster controller (VCC) in which all the FAPs operate on the same set of channels, while concomitantly maximising the closest co-channel FAP distance. The rationale for the GVCF model is that as power exponentially decays with distance, the FAP furthest away from a particular FAP will correspondingly generate the lowest interference. The corollary being that by maximising the distance of the closest FAP operating on the same channels, the interference is correspondingly minimised.

Figure 3 shows the block diagram of the logical architecture of the GVCF virtual clustering femtocell network. Based on the FFR distribution and the latest usage information acquired from the macro layer, the RNC firstly informs the FGW about the channel set available for allocation in a given area. When FAPs are switched on, they automatically register with the RNC via the FGW and then depending on the highest number of users connected to a FAP, the FGW determines the number of VCC in accordance with the following relationship:

$$N_{vc} = \lfloor \frac{N_{Ch}(K)}{\max(N^f)} \rfloor \quad (4)$$

where N_{vc} is the number of virtual clusters, $N_{Ch}(K)$ is the number of channels available in the K^{th} area and N^f is the number of femtocell users.

The system continually monitors the performance and identifies network variations such as, changes in resource availability or in the radio environment like when a user leaves the network. In these circumstances, (4) is recalculated and the VCCs are reconstructed as will be elucidated fully in Section 3.2.

Each VCC has specific resource allocation functionality including assigning the channel set to cluster member FAPs and managing disputes on behalf of its FAP membership. Unlike distributed resource allocation approaches, where each FAP independently chooses a channel, the new virtual clustering architecture devolves this task to the VCC which maintains an updated list of available channels. Furthermore, distinct from centralised

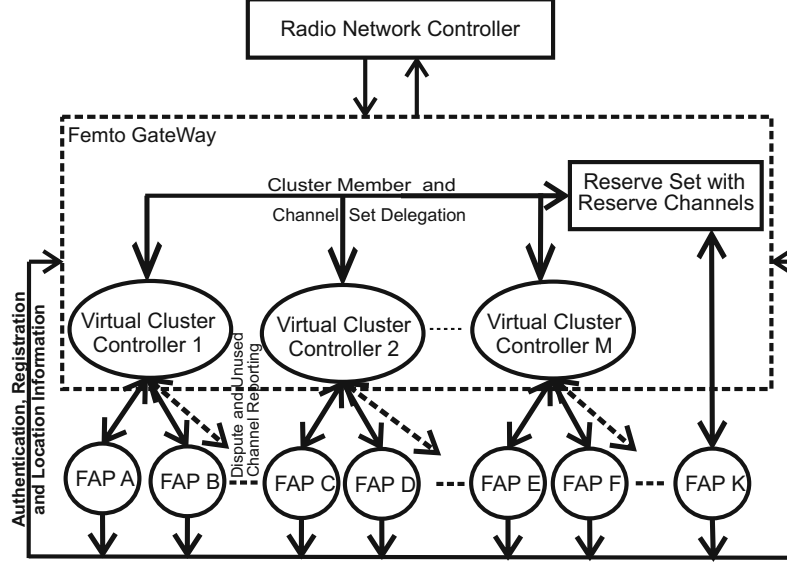

Figure 3: Logical diagram of the generalised virtual clustering femtocell (GVCF) network system.

resource management where every decision, including channel assignment, is performed by the RNC, each VCC takes responsibility for channel set allocation and dispute management on behalf its cluster members. This means the GCVF model inherently provides hybrid resource management, combining the best features of the centralised and distributed resource allocation models. It also saves a significant number of redundant data transfers between each FAP and the FGW and/or RNC.

Since the FAP is connected by a wired network, its approximate location is known by the FGW. In addition, femtocell positions can be detected and the network topology constructed to a certain level of accuracy using RF and time difference of arrival [17][18] measurements, so position information coupled with RF measurements from the respective MSs can be exploited to obtain an accurate FAP location. The GVCF algorithm then assigns each FAP to a designated VCC, which provides access to a set of channels.

GVCF creates and maintains a reserve channel list Ch_R derived from the reporting of unused channels by the FAPs. This list is periodically updated via the FGW, and also includes unused macrocell BS channels informed by the RNC. These reserve channels are allocated to FAPs either in the case of disputes or to members of the reserve set S_R , which includes those FAPs that failed to uphold the safety distance D_{th} . This is the distance all FAPs must sustain from their co-channel FAP to ensure effective femtocell operation, and is determined by setting the maximum level of admissible interference and then calculating the corresponding minimum distance requirement to preserve the SINR level. An estimate of D_{th} can be calculated from the PL model defined in (1).

3.2. Generalised Virtual Cluster Femtocell (GVCF)

The flowchart of the complete GVCF algorithm is shown in Figure 4. All the key system parameters are firstly initialised including: the number of FAPs and MSs; the

safety distance D_{th} and the number of available channels for the area under consideration. It also creates the reserve set S_R , and determines the number of virtual clusters (N_{vc}) and the inter-FAP distance matrix for N FAPs, which is given by:

$$\mathbf{D} = \begin{pmatrix} d_{11} & d_{12} & \dots & d_{1N} \\ d_{21} & d_{22} & \dots & d_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ d_{N1} & d_{N2} & \dots & d_{NN} \end{pmatrix} \quad (5)$$

where, d_{ij} is the Euclidian distance between FAP i and FAP j .

Following initialisation, GVCF identifies the FAP pair from D with the minimum Euclidean distance. The distance matrix D_{temp} , contains all the unallocated FAPs, so when no FAP is allocated $D = D_{temp}$. For each candidate FAP, GVCF firstly checks whether the FAP has already been allocated. If it has not, the algorithm ascertains whether there are any empty VCC and if so, the FAP is duly allocated to a vacant VCC. If both FAPs have already been assigned, then the distance pair is excluded from D_{temp} and both are expunged from the unallocated FAP list.

The next closest pair of FAPs from D is then sought and the above process repeated. When every VCC has at least one member, then for any further FAP allocation, the VCF algorithm chooses the distance from D of the candidate FAP to all members of the VCCs. From these inter-FAP distances, the minimum value to each VCC is selected and the FAP is assigned to the VCC which has the highest minimum distance d_{mm} , to all the other FAPs belonging to that VCC, subject to the safety distance being maintained. If the FAP cannot uphold D_{th} , it is assigned to the reserve set S_R instead, whose members are allocated reserved channels. D_{temp} is then updated, with the FAP pair assigned during this iteration being excluded, and the procedure repeated until all FAPs have been allocated.

After all the FAPs are allocated, the GVCF algorithm begins the adaption phase by continually monitoring and evaluating the performance of the current clustering arrangement as highlighted in the box in Figure 5. For a given constraint such as, an application specific data-rate requirement, if the existing cluster arrangement cannot uphold the requisite performance, then the RNC is requested to allocate more channels in order to increase the number of clusters. Upon receiving these, the iterative virtual clustering process is repeated.

This adaption mechanism importantly identifies radio environment changes such as a MS or FAP either joining or leaving the femtocell network, with the clustering algorithm adjusting accordingly the cluster number and reassigns FAPs to other VCCs to either improve or sustain performance. This uniquely affords the GVCF paradigm flexibility in its ability to automatically respond to changing radio environment conditions and unforeseen network situations.

From a computational complexity perspective, the new virtual clustering framework is very efficient as it principally involves processing FAP coordinates, so the time complexity increases linearly with the number of femtocells deployed. This means compared with alternative FAP deployment techniques such as graph colouring, GVCF has significantly lower overheads since in graph colouring any changes in the network or in assignment causes the graph for each FAP to be reconstructed. In contrast, the main virtual clustering task is maintaining the inter-FAP distance matrix D in (5). The re-

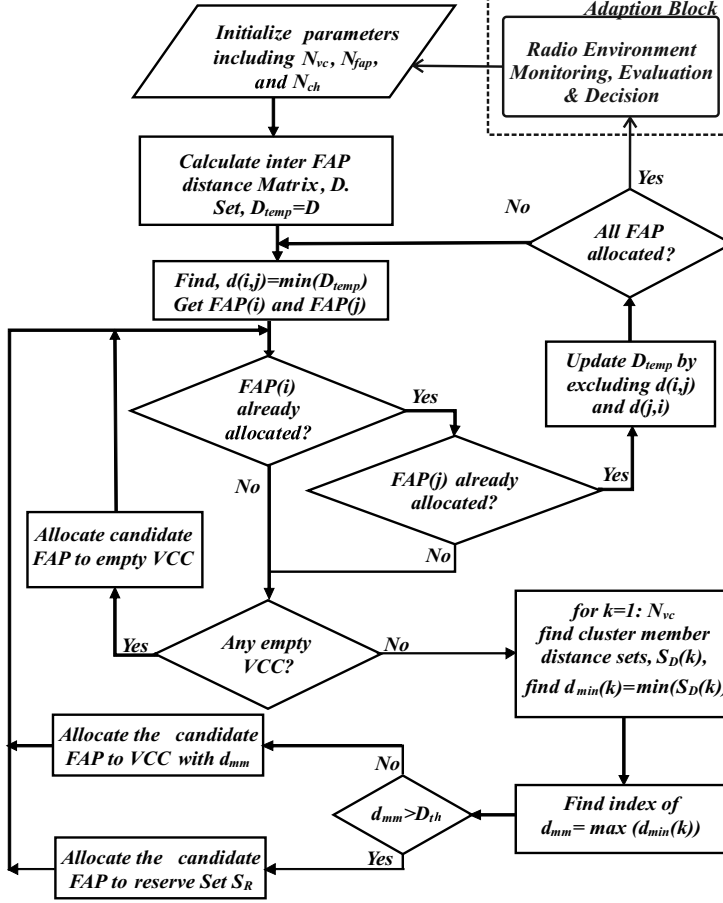

Figure 4: Flowchart for the generalised virtual clustering femtocell (GVCF) algorithm

source reallocation only takes place when there is a need to change the number of virtual clusters. So when a FAP either joins or leaves the system, a corresponding matrix entry change occurs, i.e., a row and column is either added or removed from D . Thus, for N FAP, GVCF incurs $O(N)$ complexity.

4. Results Analysis

To evaluate the performance of the GVCF paradigm, a 200m squared area of one sector in a hexagonal macrocell was considered, for four specific FAP node deployments of 50, 100, 150 and 200. The number of available channels in the area varied between 4 and 20. As a performance comparator for GVCF, a distributed memory-less resource allocation framework was implemented where each FAP independently and randomly chooses its operating spectrum. This scheme is referred to as the *non-clustering system* (NCS) in the ensuing discussion. For the purposes of an equitable comparison, it is

assumed the same number of channels is allocated to each FAP by both the GVCF model and NCS. To clarify the nomenclature adopted in this section, the parenthesis values for both GVCF and NCS are the number of virtual clusters or its equivalent, so GVCF (1) represents the worst-case scenario for the new model, with all FAPs operating on a single set of channels so the clustering and non-clustering systems are the same. The simulation test platform was designed and implemented in MATLABTM, with all the various network environment parameters being chosen from the 3GPP LTE standard [13] as shown in Table 1.

Table 1: Network environment parameters used in all simulations.

System Parameter	Value	System Parameter	Value
Femtocell Radius	10 m	Macrocell Radius	500 m
Experimental Area	200 m \times 200 m	Total Bandwidth	10 MHz
Number of Femtocells	Up to 200	MS Noise Figure	8 dB
Channel width	180 KHz, 10^{-3} S	Shadowing	6 dB
L_{WP}	5 dB, 10 dB	Number of Simulations	10000
$\max(N^f)$	4	$N_{Ch}(K)$	≤ 20
Macrocell Transmission Power	46 dBm (max)	FAP Transmission Power	10 dBm

Following parameter initialisation, the GVCF algorithm was analysed under a variety of different deployment scenarios and resource constraints. The first series of experiments sought to evaluate the performance and flexibility of the GVCF model. The results in Figure 5 and Figure 6 respectively show the the *cumulative distribution function* (CDF) of the received SINR and the corresponding *spectral efficiency* (SE) for various cluster numbers at a FAP deployment density of 50. Although the number of femtocells is relatively low, the graphs reveal a significant SINR performance gain and corresponding throughput improvement for the GVCF model compared to the NCS. Since the number of virtual clusters increases with the number of channels (see (4)), the availability of additional channels means the distance between co-channel FAPs is higher and the corresponding average interference experienced by any femtocell is commensurately lower.

In all cases of channel availability, GVCF outperformed the NCS by a margin of at least 6 to 7dB for the average received SINR. This improvement is manifest as an average SE gain of approximately 0.5 bps/Hz, and up to 0.8 bps/Hz when the 90th percentile value is considered.

Similar performance results are evident at other FAP deployment densities, though as anticipated, both the SINR and SE are lower at higher FAP numbers. The principal observation however, is that the GVCF algorithm consistently outperformed the NCS by a margin of at least 5dB, even at the highest FAP density.

The next set of results displayed in Figure 7 compare the ratio of the number of FAPs which failed to maintain the safety distance threshold D_{th} in the GVCF and NCS models at various FAP deployment densities. When the density is high, i.e. 200, almost all FAPs failed to maintain D_{th} for NCS despite the channel availability being correspondingly high. With increasing numbers of either VCC or an equivalent number of channels, more FAPs are able to sustain the safety distance threshold, though the level of improvement is significantly better for the GVCF model. For example, when 150 FAP

Figure 5: CDF of received SINR with 50 FAP deployed

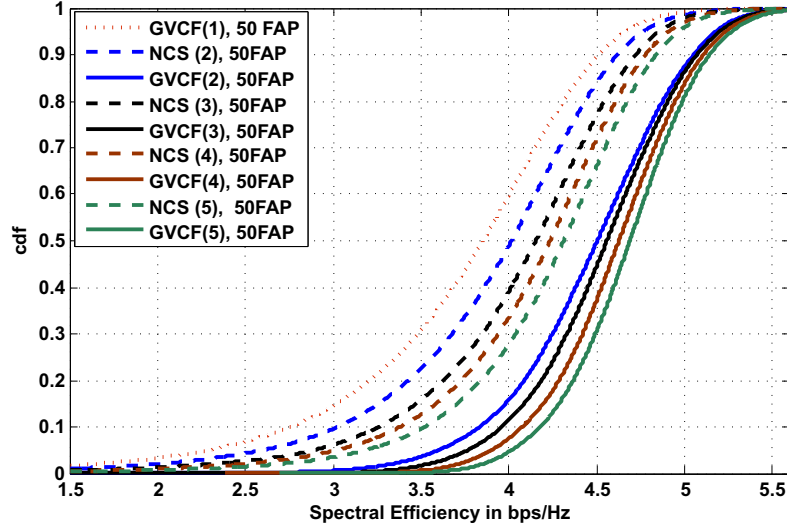

Figure 6: CDF of received SE with 50 FAP deployed

FAP are deployed, if it is assumed at least half are required to maintain D_{th} in order to achieve a particular QoS, then GVCf achieves this with only two clusters whereas NCS requires four channel sets to provide comparable performance. A similar trend is evident at other FAP densities. enhances system performance, though the primary conclusion from this analysis is that adopting a coordinated clustering strategy (GVCf) provides substantial improvement compared to an uncoordinated approach (NCS). For example, for a 200 FAP deployment, if 5 clusters are configured, only 10% of the FAPs failed to maintain D_{th} for GVCf compared with nearly 70% for NCS. This is a significant

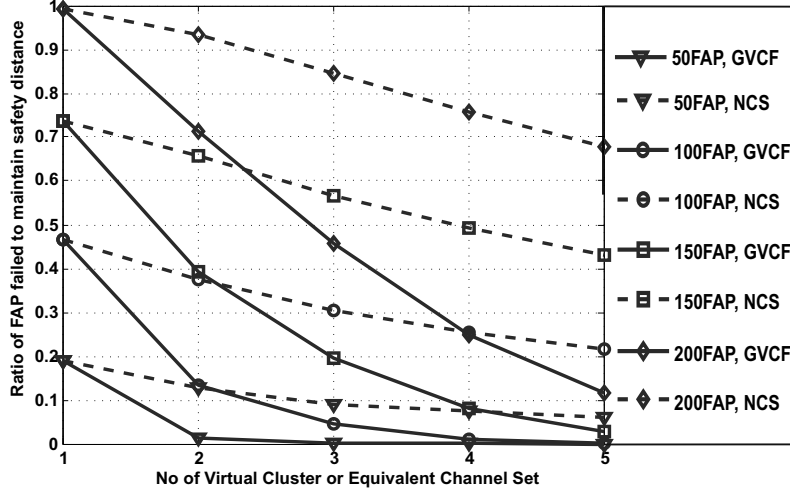

Figure 7: Ratio of FAPs failing to maintain the safety distance threshold D_{th} for different number of clusters in both the GVCF and NCS models, with an equivalent channel set

advance in terms of upholding the minimum safety distance especially in dense femtocell placements.

Interestingly at lower deployments i.e., 50 FAPs, only a small improvement is achieved for either two or more clusters, although GVCF is still palpably superior to the NCS solution. This corroborates a key feature of the virtual clustering framework, namely an awareness of either when to demand more channels from the RNC or to release channels for reuse when they are surplus to requirement. The GVCF paradigm can also crucially determine whether increasing the number of VCC improves the performance, thereby ensuring more efficient usage of the limited available resources.

An insightful indicator of system performance is displayed in Figure 8, which shows the minimum safety distance requirement for different cluster numbers and FAP densities. These results were obtained by averaging the distance for either each FAP from the nearest FAP operating on the same channel in case of NCS, or belonging to the same cluster in the case of GVCF for the same scenarios detailed above. The results confirm that with more clusters, the average minimum distance increases and in all cases, GVCF outperformed NCS. While this is an advantageous performance comparison, from a QoS perspective, SINR and achieved throughput (SE) are the key parameters which reflect system performance and these will now be analysed.

Figures 9 and 10 respectively show the 90th percentile SINR and corresponding SE performances at various FAP deployment densities, and cluster numbers or equivalent channel set. This means in 90% of the times the deployed FAPs were able to provide the SINR performance characteristics displayed in the graphs. The overall performance curves for the GVCF model are consistently superior to the NCS at all FAP deployments, and especially at higher densities, i.e., 200 FAPs, where GVCF exhibits a similar performance to that achieved by NCS with only 50 FAPs.

As FAP density increases, the performance of both the clustering and NCS models inevitably degrade, with a corresponding rise in interference. Crucially however, the

Figure 8: Comparison of the average minimum co-channel distance at various FAP densities for different numbers of GVCF clusters and NCS, for an equivalent channel set.

GVCF is able to uphold an improvement margin of between 6 and 7 dB across all deployment densities. Figure 11 and Figure 12 reveal a similar results trend for the 50th percentile (mean) to that observed above for both systems.

From a network management perspective, the flexibility of GVCF means a series of look-up tables (LUT) can be formed for various SINR and SE values and the corresponding resource estimates stored for different sets of constraints. This ensures GVCF can uphold a range of diverse QoS requirements, so for example, if there are more than 150 FAPs in a macrocell area and the average bit-rate requirement is 3.6 bps/Hz, then from Figure 12, the femto-tier must have at least 8 channels available in order to form 2 clusters to achieve the prescribed QoS. In contrast, the NCS mandates at least 3 sets of channels (12 channels) to achieve analogous performance, so an overall improvement of more than 30% has been achieved by GVCF. If the same QoS provision is necessitated at the 90th percentile, then a minimum of 5 clusters (20 channels) are required for the GVCF model, while NCS is simply unable to realise this QoS performance level because it needs more than 5 sets of channels and the maximum channel availability is 20 (see Table 1).

Conversely, if the maximum number of available channels in the femtocell-tier is 12 and the requisite average SINR is 14dB, then at the 90th percentile, GVCF can service at least 200 FAPs, while for the same QoS requirements, the NCS alternative is unable to serve more than 50 FAP as evidenced in Figure 9. Likewise, if 16 channels are available and there are 150 FAPs, then the maximum achievable SINR at 90th percentile will be 10 dB and in these circumstances, the RNC will need to supply more channels if a better SINR performance is to be accomplished.

By constructing a LUT from these performance characteristics, the FGW is able to more effectively communicate with the RNC to either demand or release the necessary resources for the femto-tier to meet the desired QoS. This highlights the adaptive

Figure 9: Comparison between GVCF and NCS for the received SINR (90th percentile) for various FAP densities with different numbers of clusters and an equivalent channel set.

functionality of the new GVCF paradigm in being malleable to changes in radio environments and network performance by readily adjusting the numbers of clusters and their respective FAP members to always provide a minimised interference solution.

5. Conclusion

This paper has analysed the important dual issues in femtocell networks of cross and co-tier interference management, with a special focus upon the minimisation of intra-femtocell interference in the downlink. A new generalised virtual clustering femtocell (GVCF) architecture for resource management has been presented which logically clusters femto-access-points (FAP) to achieve interference minimisation and corresponding performance enhancements. Simulation results vindicate the rationale for the virtual clustering concept as GVCF consistently outperformed the distributed, random channel allocation system in all test scenarios, providing significant SINR and throughput improvements, especially in high FAP deployments. The inherent flexibility and low complexity of the GVCF paradigm enables the number of clusters and their FAP members to be automatically adapted to either network or radio environment changes, with a look-up table mechanism providing further performance efficiency.
