ABSTRACT

We report the first mid-infrared detection of highly disturbed ionized gas in the ultraluminous infrared galaxy (ULIRG) IRAS F00183–7111. The gas, traced by the 12.81 μm [Ne II] and 15.56 μm [Ne III] lines, spans a velocity range of -3500 to $+3000$ km s^{-1} with respect to systemic velocity. Optical and near-infrared spectroscopic studies show no evidence for similarly high velocity gas components in forbidden lines at shorter wavelengths. We interpret this as the result of strong extinction ($A_V = 10\text{--}50$) on the high-velocity gas, which identifies the base of the outflow traced in 5007 \AA [O III] as a plausible origin. Unusual excitation conditions are implied by a comparison of the mid-infrared low-excitation neon line emission and the polycyclic aromatic hydrocarbon (PAH) emission for a sample of 56 ULIRGs. For IRAS F00183–7111, the neon/PAH ratio is 8 times higher than the average ratio. Similar mid-infrared kinematic and excitation characteristics are found for only two other ULIRGs in our sample: IRAS 12127–1412NE and IRAS 13451+1232. Both sources have an elevated neon/PAH ratio and exhibit pronounced blue wings in their 15.56 μm [Ne III] line profiles. IRAS 13451+1232 even shows a strongly blueshifted and broad 14.32 μm [Ne V] line. While for IRAS 13451+1232 the observed [Ne III]/[Ne II] and [Ne V]/[Ne II] line ratios indicate exposure of the blueshifted gas to direct radiation from the AGN, for IRAS F00183–7111 and IRAS 12127–1412NE the neon line ratios are consistent with an origin in fast shocks in a high-density environment, and with an evolutionary scenario in which strongly blueshifted [Ne II] and [Ne III] emission trace the (partial) disruption of the obscuring medium around a buried AGN. The detection of strongly blueshifted [Ne V] emission in IRAS 13451+1232 would then indicate this process to be much further advanced in this ULIRG than in IRAS F00183–7111 and IRAS 12127–1412NE, where this line is undetected.

Key words: infrared: ISM – ISM: jets and outflows – galaxies: active – galaxies: individual (IRAS F00183–7111, IRAS 12127–1412, IRAS 13451+1232) – galaxies: ISM

1. INTRODUCTION

Large-scale galactic outflows of gas (sometimes called “superwinds”) are seen in galaxies both at low and high redshifts (e.g., Veilleux et al. 2005; Pettini et al. 2002). Superwinds are generated when the kinetic energy in the outflows from massive stars and supernovae is thermalized, generating a region of very hot ($T \sim 10^6\text{--}10^7$ K) low-density gas in the ISM of a starburst galaxy (Chevalier & Clegg 1985). As the bubble breaks out of the disk of the galaxy, it will rupture, producing a weakly-collimated bipolar outflow into the galaxy halo. As the bubble expands it sweeps up and shocks ambient material, creating an outflowing wind (Castor et al. 1975; Weaver et al. 1977). Superwinds may also be driven, at least in part, by radiation pressure on dust grains (Murray et al. 2005). They may also be driven directly by the interaction of jets on the dense ISM surrounding an AGN (e.g., Holt et al. 2003).

There is morphological, physical, and kinematic evidence for superwinds in nearby starburst and infrared luminous galaxies (e.g., Heckman et al. 1990). Large-scale optical emission-line and associated X-ray nebulae are ubiquitous in starbursts (Armus et al. 1990; Lehnert et al. 1999; Strickland et al. 2004), and these increase in size and luminosity from dwarf starbursts

all the way to ULIRGs (where they can be tens of kpc in size, (Grimes et al. 2005). In addition, the winds are often seen via blueshifted absorption features (e.g., Na D) against the starburst nuclei (Heckman et al. 2000; Rupke et al. 2005; Martin 2005) indicating that the neutral, cold ISM is being swept-up in the outflow. At high redshifts, superwinds have been seen in Lyman break galaxies at $z = 2\text{--}3$ (Pettini et al. 2001; Shapley et al. 2003).

The ultraluminous infrared galaxy (ULIRG: $L(8\text{--}1000 \mu\text{m}) = 10^{12\text{--}13} L_\odot$) IRAS F00183–7111 is known from optical emission line spectroscopy to harbor such a galactic-scale outflow (Heckman et al. 1990). In this paper, we study the mid-infrared evidence for this outflow based on the *Spitzer*-IRS emission line spectroscopy. The emission line data is analyzed and presented along with new 3.6, 5.8, 70, and 160 μm *Spitzer* photometric observations, obtained to better constrain the infrared spectral energy distribution of this interesting ULIRG.

With an integrated 8–1000 μm luminosity of $8.6 \pm 1.3 \times 10^{12} L_\odot$ (this work) IRAS F00183–7111 is one of the most luminous ULIRGs discovered by IRAS. Near-infrared imaging by Rigopoulou et al. (1999; Figure 1) shows a disturbed morphology and what appears to be a single nucleus. Evidence for the presence of an accreting central supermassive black hole

is provided by the radio luminosity, which is in the range of powerful radio galaxies and a factor ten in excess of what would be expected for starburst galaxies based on the far-infrared luminosity ($q = 1.14$; Roy & Norris 1997; Norris et al. 1988). The presence of an AGN was recently confirmed by Nandra & Iwasawa (2007), who detected a 6.7 keV Fe $K\alpha$ line (Fe xxv) with a large equivalent width, indicative of reflected light from a Compton thick AGN.

The most common star-formation tracers, the PAH emission bands, were not detected in the 5–12 μm ISO-CAM-CVF spectrum (Tran et al. 2001). Instead, the spectrum is dominated by a strong silicate absorption band centered at 9.7 μm , indicative of strong absorption of a background continuum source, most likely a deeply buried AGN (Tran et al. 2001). One of the PAH emission bands, the C–H bending mode at 11.2 μm , was later identified in the *Spitzer*-IRS low-resolution spectrum and was used to constrain the contribution of mid-infrared detectable star formation to the energy budget of IRAS F00183–7111 to be $\leq 30\%$ (Spoon et al. 2004). The same spectrum may also offer indications for ongoing *buried* star formation through the detection of absorption bands of crystalline silicate features at 16, 19, and 23 μm (Spoon et al. 2006). Crystalline silicates are known to be forged by young stars in their circumstellar disks and by evolved stars in their dense stellar winds (Molster & Kemper 2005, and references therein). Their presence in the general ISM of IRAS F00183–7111 may indicate fierce ongoing star formation at mid-infrared optical depths significantly larger than one (Spoon et al. 2006).

Optical long-slit spectroscopy of IRAS F00183–7111 has revealed the presence of kinematically highly disturbed ionized gas extending from 10 kpc west to ~ 25 kpc east of the nucleus. This gas, traced in both the 4959 and 5007 \AA [O III] lines, is clearly blueshifted between 5 and 20 kpc east and shows line widths in excess of 600 km s^{-1} (FWHM) over a range of 25 kpc. The double-peaked profile of both [O III] lines in this range is in agreement with a superwind model in which the line emission originates from the thin outer shell of shock-heated, swept-up ambient gas. Beyond 25 kpc east, the gas is much more quiescent, with line widths of $\sim 200 \text{ km s}^{-1}$ centered close to systemic velocity (Heckman et al. 1990).

Recently, Nandra & Iwasawa (2007) have pointed out that the presence of an outflow may also explain the clear eastward offset by about 22 kpc of the soft (0.3–1.0 keV) X-ray radiation detected from IRAS F00183–7111. It also may identify the secondary peak at 25 kpc east in the *R*-band image⁹ by Drake et al. (2004) to be related to this outflow (Nandra & Iwasawa 2007). A corresponding *K*-band peak is absent in the 2.2 μm image (rest frame 1.65 μm) by Rigopoulou et al. (1999; Figure 1).

In this paper we report the first identification in a ULIRG of broad, asymmetric and somewhat blueshifted emission lines of [Ne II] at 12.81 μm and [Ne III] at 15.56 μm in the high-resolution *Spitzer*-IRS spectrum of IRAS F00183–7111. We compare our detection to available optical and near-infrared spectroscopy to investigate the processes responsible for this broadening. Our paper is organized as follows. In Section 2 we present our observations of IRAS F00183–7111. In Section 3 we present the 1–120 μm SED and an analysis of the mid-infrared emission line spectrum. In Section 4 we analyze line profiles of two other ULIRGs which display strong blue shifts

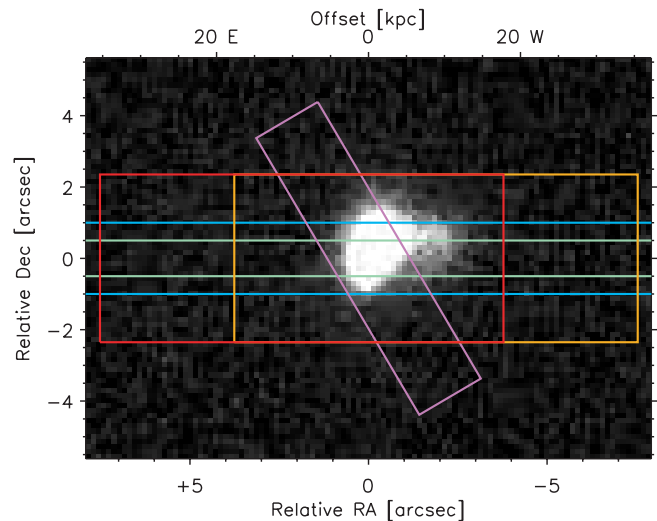

Figure 1. *K*-band image of IRAS F00183–7111 replotted from Rigopoulou et al. (1999). North is up, east is to the left. Overlaid on the image are the various slits used to obtain spectra of the emission line features discussed in the paper. In red and orange is the *Spitzer*-IRS SH slit in the two nodding positions; in blue is the slit used by Heckman et al. (1990), in green the slit used by Dannerbauer et al. (2005), and in purple the slit used by Buchanan et al. (2006). (A color version of this figure is available in the online journal.)

in their fine-structure neon line profiles. Results are discussed in Section 5 and conclusions are provided in Section 6. Additional results for IRAS F00183–7111 are presented in the Appendix. Throughout this paper we assume $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.27$, $\Omega_\Lambda = 0.73$, and $\Omega_K = 0$.

2. OBSERVATIONS AND DATA REDUCTION

2.1. IRAC and MIPS Photometry

Spitzer Space Telescope (Werner et al. 2004) IRAC (Fazio et al. 2004) 3.6 and 5.8 μm photometry was obtained on 2006 August 14 (AOR key 17517824). IRAS F00183–7111 was imaged at five dither positions using 2 s ramp times. The source flux density was measured by integrating over a 12'' radius aperture placed upon the SSC pipeline-produced (S14) post-BCD mosaic. We estimate the uncertainty in the photometry due to the background to be $\sim 2\%$. The absolute calibration uncertainties of the IRAC post-BCD images are 10%. As part of the same program we obtained MIPS (Rieke et al. 2004) 70 and 160 μm photometry on 2006 June 17 (AOR key 17528320). IRAS F00183–7111 was imaged for 1 cycle at 70 μm and for four cycles at 160 μm using 3 s ramps. The source flux densities were measured from the SSC pipeline-produced (S14) unfiltered post-BCD images by integrating the flux within 8'' and 20'' radius apertures at 70 and 160 μm , respectively. Aperture corrections were applied to recover the full point-source flux densities. We estimate the uncertainty on the 70 and 160 μm flux densities due to the background to be around 1% and 2%, respectively. The absolute calibration uncertainties of the MIPS post-BCD images are 10%–20%. We present the results of our photometric observations in Table 1. The calculation of infrared luminosities which utilize this photometry are described in Section 3.1.

2.2. IRS Spectroscopy

High resolution ($\Delta v \sim 500 \text{ km s}^{-1}$; $R \sim 600$) 10–37 μm IRS (Houck et al. 2004) spectra of IRAS F00183–7111 were obtained at two epochs: 2005 June 2 (AOR key 6651904) and

⁹ At the redshift of the source the *R*-band filter includes the 5007 \AA [O III] line (Drake et al. 2004).

Table 1
Photometry of IRAS F00183–7111

Band	λ_{rest} (μm)	Flux density (mJy)
IRAC-1	2.7	2.9 ± 0.3
IRAC-3	4.4	22 ± 2
IRAS-12	9.0	$< 60^a$
IRAS-25	18.8	133 ± 10^a
IRAS-60	45	1200 ± 837^a
MIPS-70	53	1500 ± 225
IRAS-100	75	1190 ± 119^a
MIPS-160	121	540 ± 80

Notes.

^a IRAS Faint Source Catalog version 2.

2008 June 1 (AOR keys 25289472 and 25289984). In both cases the source was acquired using a high-accuracy blue peak-up and observed in staring mode. The 10–19.5 μm portion of the spectrum was obtained in nine cycles of 120 s integrations in IRS Short High (SH; slit size $4''.7 \times 11''$) at PA = 91° . The 19.3–37.0 μm portion of the spectrum was obtained in two sets of 35 cycles of 60 s integrations, alternated with sky background observations (30 cycles of 60 s), in IRS Long High (LH; slit size $11''.1 \times 22''.3$) at P.A. = -15° . Figure 1 shows the SH slit overplotted on the *K*-band image of the source (Rigopoulou et al. 1999). The LH slit is not shown as it is more than twice as wide and long as the SH slit.

Data reduction started from two-dimensional droop level (i.e., pre-flatfield) images provided by the S17.2 pipeline of the *Spitzer* Science Center (SSC). For SH, in a first step we used IRSCLEAN to interpolate over the bad and ‘rogue’ pixels. For LH, this step was preceded by subtraction of the contemporaneous sky background images. We then used the SMART data reduction package (Higdon et al. 2004) to extract the one-dimensional target spectrum in ‘full slit’ mode. The same procedure was followed for a large number of observations of the calibration star ξ Dra. The final spectrum was obtained by multiplying the spectrum of IRAS F00183–7111 by the relative spectral response function created from the ratio of the observed spectrum of ξ Dra to the stellar reference spectrum (Cohen et al. 2003; G.C. Sloan 2005, private communication). Note that given the absence of contemporaneous SH background observations, the SH portion of the spectrum is *not* background subtracted.

The wavelength calibration of our spectrum is accurate to about 1/5 (SSC, private communication) of a resolution element (500 km s^{-1}), which amounts to 100 km s^{-1} .

3. ANALYSIS

3.1. Infrared SED

With the addition of the IRAC 3.6 μm and MIPS 70 and 160 μm photometry it is possible to fit the infrared SED of IRAS F00183–7111 over the entire rest frame wavelength range of 1–120 μm . Especially important is the addition of the MIPS 160 μm point, which extends the sampling of the rest frame SED from 75 μm (pre-*Spitzer*) to 120 μm (see Figure 2), allowing a more reliable extrapolation of the SED into the submillimeter range. For the latter, we have used the multicomponent spectral energy distribution decomposition code of Marshall et al. (2007).

Based on our fit, we have computed the following integrated rest frame infrared luminosities for IRAS F00183–7111: $L(1-$

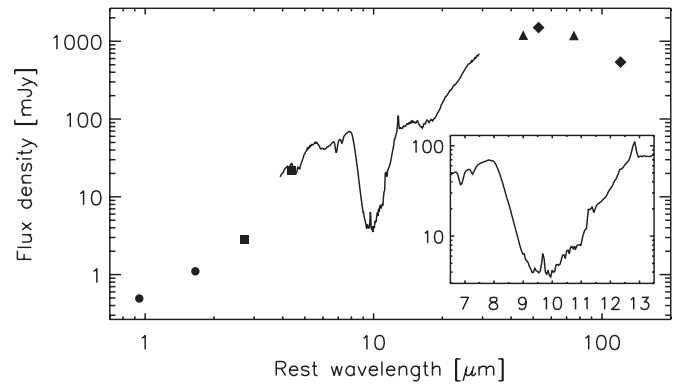

Figure 2. Near-to-far-infrared spectral energy distribution of IRAS F00183–7111. The 4–29 μm *Spitzer*-IRS low-resolution spectrum (Spoon et al. 2004) is shown as a continuous line. Photometric points are labeled with the following symbols: circles: ESO-NTT J & K (Rigopoulou et al. 1999), squares: IRAC 3.6 & 5.8 μm , triangles: IRAS 60 & 100 μm , diamonds: MIPS 70 & 160 μm . Error bars on the photometric points are too small to be visible. Inset: detailed view of the spectral range around the 9.7 μm silicate absorption profile. Note the emission lines of $\text{H}_2 \text{ S}(3)$ at 9.66 μm and $[\text{Ne II}]$ at 12.81 μm .

Table 2
Synthetic Photometry for IRAS F00183–7111

Band	λ_{rest} (μm)	Flux density (mJy)	Uncertainty
IRAC-1	3.6	8.6	1%
IRAC-2	4.5	29.6	1%
IRAC-3	5.8	47.3	1%
IRAC-4	8.0	48.6	1%
MIPS-24	24	370	1%
IRAS-25	25	360	1%
IRAS-60	60	1410	1%
MIPS-70	70	1190	2%
IRAS-100	100	890	3%
MIPS-160	160	490	5%
SCUBA-450	450	20	6%
SCUBA-850	850	2.0	6%

Notes. Rest-frame synthetic fluxes measured from the model spectrum of IRAS F00183–7111 (see Section 3.1). The statistical uncertainty in the synthetic photometry is computed from the uncertainty in the total fitted flux.

$1000 \mu\text{m}) = 9.9 \pm 1.3 \times 10^{12} L_{\odot}$, $L(8-1000 \mu\text{m}) = 8.6 \pm 1.3 \times 10^{12} L_{\odot}$, $L(40-500 \mu\text{m}) = 4.4 \pm 0.8 \times 10^{12} L_{\odot}$ and $L(40-120 \mu\text{m}) = 4.0 \pm 0.6 \times 10^{12} L_{\odot}$. We have further used the results of the fit to derive rest frame filter flux densities for the IRAC, MIPS, IRAS, and SCUBA bands. These values are tabulated in Table 2. Given the 15% absolute calibration uncertainty of the MIPS 70 and 160 μm data, and the fact that the MIPS 160 μm data is the longest wavelength point constraining our fit, there is clearly some uncertainty in our extrapolation of the flux density out to 1000 μm . The spectral shape of the extrapolated flux density beyond 160 μm is a function of the chosen power-law spectral index of the far-IR dust opacity. The above stated uncertainties in the integrated luminosities incorporate both the systematic uncertainty resulting from our choice of this dust opacity spectral index as well as the statistical uncertainty resulting from the MIPS calibration uncertainty.

The ratio of the observed IRAS-25 to IRAS-60 filter fluxes is commonly used to classify ULIRGs as ‘‘warm’’ ($25/60 \mu\text{m} > 0.2$) or ‘‘cold’’ ($25/60 \mu\text{m} < 0.2$), separating ULIRGs believed to be AGN-dominated from those which are thought to be powered predominantly by star formation (de Grijp et al. 1985;

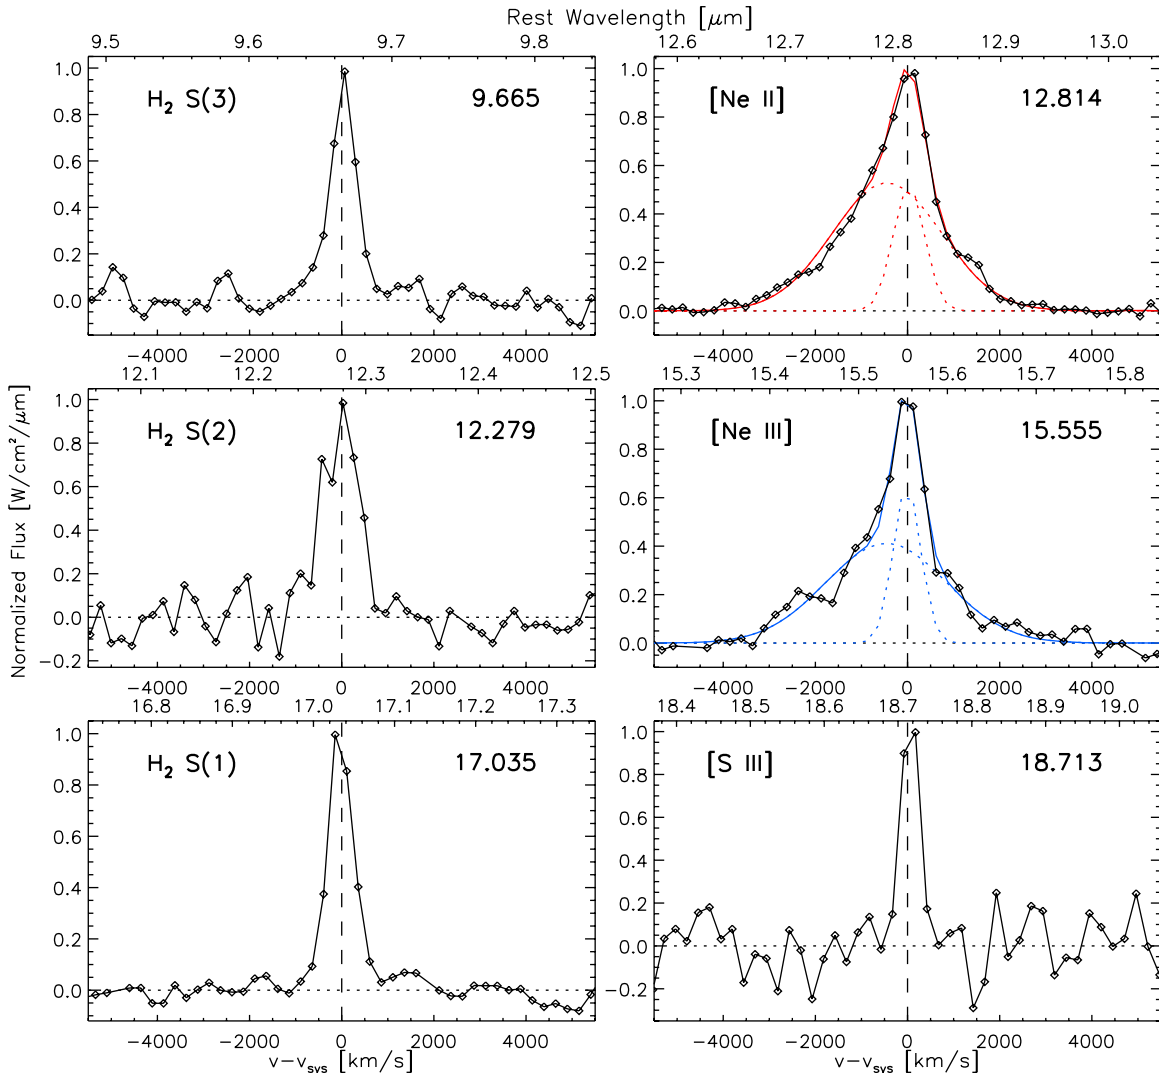

Figure 3. Comparison of the emission line profiles for the six detected emission lines in the spectrum of IRAS F00183–7111. The left column shows the S(1), S(2) and S(3) pure rotational H₂ lines, the right panel the [Ne II], [Ne III] and [S III] lines. All six lines have been observed at the same spectral resolution $R = 600$. The [Ne II] and [Ne III] line profiles are clearly asymmetric and broadened beyond the instrumental spectral profile (FWHM = 500 km s⁻¹). Their profiles are fit by two Gaussian components (red and blue dotted lines, respectively), the sum of which is shown as a red or blue continuous line.

(A color version of this figure is available in the online journal.)

Sanders et al. 1988). For the classification to be meaningful also for higher redshift targets like IRAS F00183–7111, rest frame synthetic *IRAS* fluxes should be used. For IRAS F00183–7111, this results in an *IRAS*-25 to *IRAS*-60 flux ratio of 0.26, which places it among the class of “warm,” AGN-dominated ULIRGs, in agreement with results obtained at other wavelengths (see Section 1).

3.2. Emission Lines

The high-resolution *Spitzer*-IRS spectrum of IRAS F00183–7111 covers the rest frame wavelength range of 7.5–27.8 μm. In Table 3 we list the line fluxes and 3σ upper limits for 17 emission lines, as well as for the 11.2 μm PAH emission feature. For the latter, the feature flux was measured above a spline continuum defined shortward of 11.1 μm and longward of 11.6 μm. The only lines that are detected in our spectrum are the S(1), S(2), and S(3) pure rotational lines of molecular hydrogen, and the 12.81 μm [Ne II], 15.56 μm [Ne III], and 18.71 μm [S III] fine-structure lines. In Figure 3 we present

their continuum-subtracted line profiles as a function of velocity relative to systemic.¹⁰

Of the six detected emission lines, the two neon fine-structure lines appear clearly resolved beyond the instrumental resolution (500 km s⁻¹; $R = 600$), most notably the [Ne II] line, at an observed FWHM of 1500 ± 100 km s⁻¹ (Table 3). The other emission lines have observed FWHM ranging from 490 ± 50 to 950 ± 130 km s⁻¹. In what follows any FWHM values quoted in the text refer to the true FWHM, i.e., the observed FWHM corrected for the instrumental profile.

3.3. Neon line Profile Analysis

Extracting a [Ne II] line profile requires careful removal of the underlying spectral structure. As illustrated in Figure 4 by

¹⁰ In the absence of CO or 21cm redshift determinations, we have used the mid-infrared S(1) and S(3) molecular hydrogen lines to determine the recession velocity of IRAS F00183–7111 to be 98400 ± 200 km s⁻¹ ($z = 0.328 \pm 0.001$). This redshift is 360 km s⁻¹ higher than the value adopted by Heckman et al. (1990) and 180 km s⁻¹ higher than the value used by Roy & Norris (1997).

Table 3
Emission Features in the Spectrum of IRAS F00183–7111

Feature ID	λ_{rest} (μm)	Flux ($10^{-21} \text{ W cm}^{-2}$)	obs. FWHM (km s^{-1})	true FWHM (km s^{-1})
[Ne VI]	7.65	< 0.25

Notes. Line fluxes and 3σ upper limits above the separator line are measured from our *Spitzer*-IRS spectrum, those below have been taken from the literature. The uncertainties in our line fluxes are the larger of either the error in the Gaussian fit or half the difference of the two nodding positions. The FWHM in column four (five) is from a Gaussian fit to the data, before (after) removal of the instrumental profile, in quadrature.

^a Dannerbauer et al. (2005).

^b Buchanan et al. (2006).

^c Heckman et al. (1990).

the starburst galaxy NGC 2146 and the ULIRG NGC 6240, the [Ne II] line is superimposed on the $12.7 \mu\text{m}$ PAH emission feature, which arises over a velocity range of $-13,500$ to $+3500 \text{ km s}^{-1}$ relative to the [Ne II] line. However, unlike NGC 2146 and NGC 6240, the spectrum of IRAS F00183–7111 shows hardly any PAH emission, with the exception of the PAH feature at $11.2 \mu\text{m}$, which is detected at very low equivalent width. We conclude that the remarkable width of the $12.81 \mu\text{m}$ [Ne II] line cannot be ascribed to improper subtraction of the underlying spectral structure. In fact, the resulting profile is consistent with that of the $15.56 \mu\text{m}$ [Ne III] line.

The shape of the [Ne II] line profile is asymmetric, with the peak emission arising very close to systemic velocity. To characterize the asymmetry we have decomposed the line profile into two Gaussian components (Figure 3). The resulting fit is good. We find the dominant component to have an FWHM of $2570 \pm 90 \text{ km s}^{-1}$, centered at a blueshift of $400 \pm 50 \text{ km s}^{-1}$ with respect to systemic. The narrow component has an FWHM of $610 \pm 60 \text{ km s}^{-1}$ and a redshift of $60 \pm 20 \text{ km s}^{-1}$ with respect to systemic. The fit components are shown overplotted in red onto the observed [Ne II] profile in the top-right panel of Figure 3. Further fit details are provided in Table 4.

Unlike the $12.81 \mu\text{m}$ [Ne II] line, the $15.56 \mu\text{m}$ [Ne III] line resides in a relatively uncomplicated part of the spectrum.

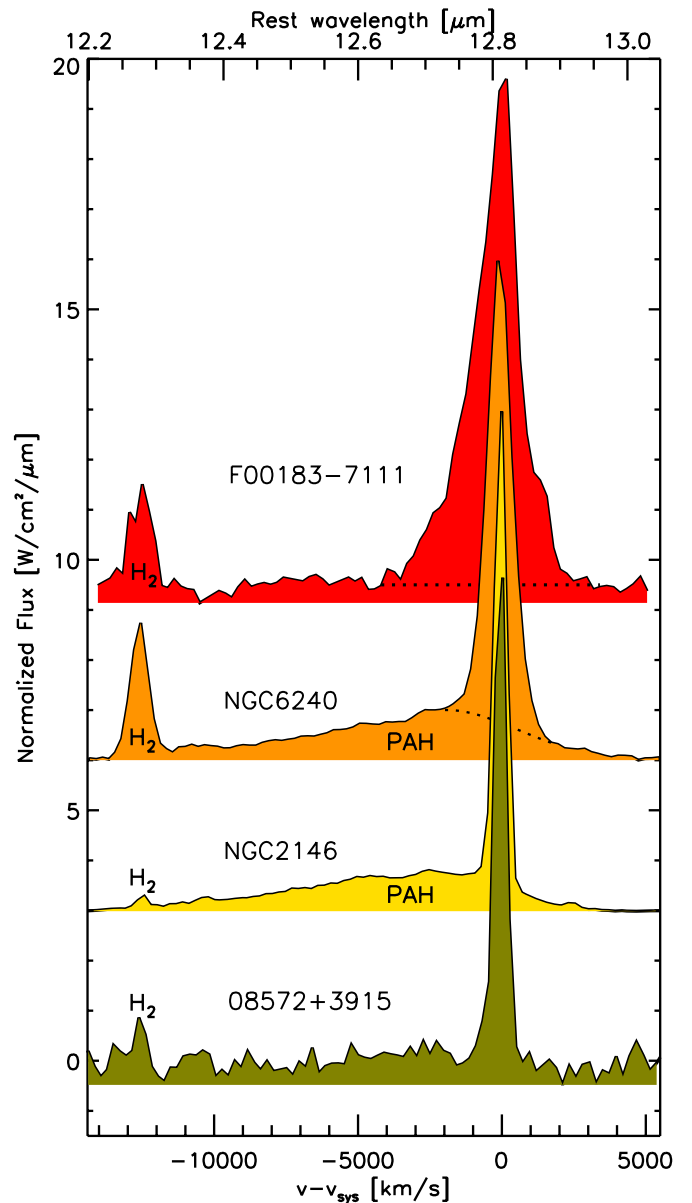

Figure 4. Comparison of the continuum-subtracted spectral structure around the $12.81 \mu\text{m}$ [Ne II] line for four galactic nuclei, at a spectral resolution $R = 600$. The spectral features included are the H₂ S(2) line at $12.28 \mu\text{m}$, the $12.7 \mu\text{m}$ PAH emission feature (extending from $-13,500$ to $+3,500 \text{ km/s}$) and the [Ne II] line. The latter is clearly broadened in the spectra of IRAS F00183–7111 and NGC 6240. Note that the $12.7 \mu\text{m}$ PAH emission feature appears to be absent in the spectra of IRAS F00183–7111 and IRAS 08572+3915NW.

(A color version of this figure is available in the online journal.)

We determined its profile by defining and subtracting a local third-order polynomial continuum. We then performed a two-component decomposition in the same way as for the [Ne II] line. The narrow component has a FWHM of $460 \pm 90 \text{ km s}^{-1}$ and is centered at the systemic velocity, whereas the broad component has a FWHM of $2850 \pm 240 \text{ km s}^{-1}$ and is blueshifted by $450 \pm 100 \text{ km s}^{-1}$. The fraction of the [Ne III] flux emitted in the broad component is $3/4$, slightly lower than the fraction found for the [Ne II] line, $4/5$. As a result, the [Ne III]/[Ne II] ratios are 0.31 ± 0.03 for the broad component and 0.39 ± 0.08 for the narrow component.

Table 4
Fit results for mid-infrared neon emission lines

Feature	Component	λ_c (μm)	v_c (km s^{-1})	obs. FWHM (km s^{-1})	true FWHM (km s^{-1})	Flux ($10^{-21} \text{ W cm}^{-2}$)

Notes. Results from a two-component Gaussian decomposition of the 12.81, 14.32, and 15.56 μm neon emission line profiles into narrow (n) and broad (b) components. λ_c denotes the central wavelength of the component and corresponds to a velocity shift v_c of the component with respect to systemic velocity. The formal error on the velocity shift does not include corrections for the uncertainty in the wavelength calibration, which is 1/5 of a resolution element (100 km s^{-1}). The FWHM in column five (six) is measured before (after) removal of the instrumental profile ($500 \pm 60 \text{ km s}^{-1}$; Dasyra et al. 2008), in quadrature.

3.3.1. Comparison to Other Line Measurements for IRAS F00183–7111

The most detailed spectral line study that we are aware of focuses on the [O III] doublet at 4959 and 5007 \AA and was published by Heckman et al. (1990). They observed IRAS F00183–7111 in a $2'' \times 100''$ slit along P.A. 90° (see Figure 1) at a spectral resolution $R = 1900$. In Figure 5 we compare the 5007 \AA [O III] profile obtained at a position $3''$ (13 kpc) East of the nucleus to that of our galaxy-integrated spectrum, after degrading the spectral resolution of the [O III] line from 1900 to 600. According to Figure 12 of Heckman et al. (1990), at this position the centroid of the [O III] line profile has its highest blueshift (700 km s^{-1} ; using our preferred redshift of 0.328 ± 0.001) at an FWHM $\sim 600 \text{ km s}^{-1}$, typical for the entire region extending from 10 kpc west to 20 kpc east of the nucleus. Clearly, the [Ne II] and [Ne III] emission extends to much higher velocities than the [O III] line emission does.

More recently, Buchanan et al. (2006) published line fluxes and FWHMs for 11 optical lines observed at $R = 1000$ in a $2'' \times 9''$ slit oriented along P.A. $= 329^\circ$ (C. L. Buchanan 2008, private communication). For the $H\alpha$ line, which is strongly blended with the [N II] line on either side, they infer a FWHM of 720 km s^{-1} (compared to 700 km s^{-1} reported by Armus et al. 1989). For the 4959/5007 \AA [O III] doublet, they report FWHMs of 800–900 km s^{-1} (Table 1), which are comparable to those given by Heckman et al. (1990) in their Figure 12, even though the slit orientations in the two studies in question differ by 239° (Figure 1).

We also compared our mid-infrared results to near-infrared H - and K - band spectroscopy by Dannerbauer et al. (2005) obtained using a $1'' \times 290''$ slit oriented at P.A. $= 90^\circ$ (Figure 1). Their data have similar spectral resolution as ours. The two detected [Fe II] lines at 1.257 and 1.644 μm have FWHMs in the range 900–1000 km s^{-1} , while the 1.282 μm Pa β

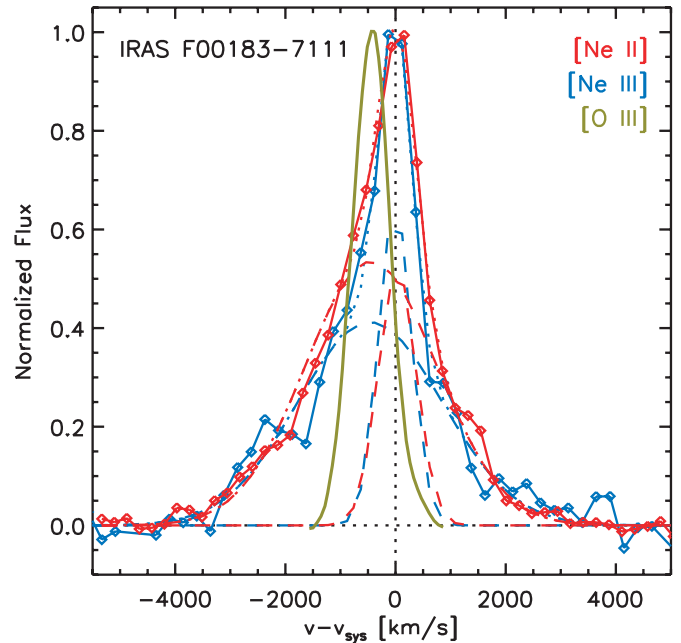

Figure 5. Comparison of the galaxy-integrated line profile of 12.81 μm [Ne II] (red) and 15.56 μm [Ne II] (blue) to 5007 \AA [O III] (green) at a position $3''$ east of the nucleus of IRAS F00183–7111, where the O^{2+} gas reaches its highest blue shift. The spectral resolution of the double-peaked [O III] profile ($R = 1900$) has been degraded to the resolution of the *Spitzer*-IRS-SH measurement ($R = 600$). Overplotted are the two-component Gauss fits to the [Ne II] and [Ne III] line profiles. The individual components are shown as dashed lines, their sums as dotted lines.

(A color version of this figure is available in the online journal.)

line appears to be unresolved. Again, like in the optical range, none of the lines have FWHMs as large as the mid-infrared neon lines (see Table 3).

3.4. AGN Tracing Mid-infrared Lines

The rest wavelength range covered by the *Spitzer* IRS high-resolution modules includes three high-ionization lines commonly used as tracers of AGN activity: $7.65\ \mu\text{m}$ [Ne VI] and $14.32\ \mu\text{m}$ & $24.32\ \mu\text{m}$ [Ne V] (e.g., Sturm et al. 2002). None of them are detected (Table 3). The 3σ limit on the fraction of 8–1000 μm infrared power contained in the $14.32\ \mu\text{m}$ [Ne V] line is $L_{[\text{Ne V}]} / L_{\text{IR}} < 1.3 \times 10^{-5}$, which is 1–2 orders of magnitude smaller than the detections for classical AGNs, but similar to the limits derived for other ULIRGs with deep $9.7\ \mu\text{m}$ silicate features like IRAS 08572+3915, IRAS 15250+3609 and IRAS 20100–4156, and for the type-1 ULIRG/LoBAL-quasar Mrk 231 (Armus et al. 2007). For the limit on $7.65\ \mu\text{m}$ [Ne VI] no ULIRG comparison data exists. However, the 3σ upper limit $L_{[\text{Ne VI}]} / L_{\text{IR}} < 2.6 \times 10^{-5}$ is at least an order of magnitude below what is found for classical AGNs (Sturm et al. 2002).

3.5. PAH Emission

The quality of our *Spitzer* IRS high-resolution spectrum allows us to measure the flux in the $11.2\ \mu\text{m}$ PAH feature more accurately than has been possible from the low-resolution spectrum (Spoon et al. 2004). The latter showed strong disagreements between the spectra obtained in nod positions 1 and 2 at the short wavelength end of IRS Long-Low order 2. The new feature flux, measured from the IRS SH spectrum is tabulated in Table 3 and is 25% smaller than previously reported by Spoon et al. (2004) based on the low-resolution spectrum. We also remeasured the upper limit on the $6.2\ \mu\text{m}$ PAH feature from a re-extracted low-resolution spectrum, using the same continuum pivots at 5.65 , 6.07 , and $6.50\ \mu\text{m}$ to define the local spline continuum as in Spoon et al. (2004). Given the clear reduction in noise and artifacts between IRS pipeline versions 9.1 and 14.2, the new 3σ upper limit on the $6.2\ \mu\text{m}$ PAH flux is $1.9 \times 10^{-21}\ \text{W cm}^{-2}$, which is a factor of 2 lower than previously reported by Spoon et al. (2004). Note that we do not attempt to measure the flux in the $7.7\ \mu\text{m}$ PAH band, as this emission feature—if present—would be strongly blended with the silicate feature.

Based on the new PAH fluxes we compute an *upper* limit on the ratio of 6.2-to- $11.2\ \mu\text{m}$ PAH of 0.70. This is at the *low* end of the range found for starburst nuclei and ULIRGs in our sample (2σ below the average ratio of 1.4), but not untypical for a sample of IR-faint LINERs ($L_{\text{IR}} = 10^{7.83-10.59}$) studied by Sturm et al. (2006), and for the spiral arms of M 51 and the halo of M 82 (Galliano et al. 2008).

The low 6.2-to- $11.2\ \mu\text{m}$ PAH ratio may indicate a high ratio of neutral to ionized PAHs, which would imply a low ratio of the ionizing radiation field to the electron density, and physical conditions similar to those in the Galactic reflection nebula NGC 2023 (Galliano et al. 2008). In IRAS F00183–7111 these conditions could plausibly exist outside the deeply buried nucleus. Alternatively, the low observed 6.2-to- $11.2\ \mu\text{m}$ PAH ratio for IRAS F00183–7111 may indicate destruction of small PAHs exposed to hard radiation from an AGN. This would selectively lower the fluxes emitted in the PAH emission bands at 3.3 , 6.2 , and $7.7\ \mu\text{m}$ relative to those at $11.2\ \mu\text{m}$ and beyond (Smith et al. 2007). Given, however, the absence of detections of high ionization lines, indicative of a hard AGN radiation field, this scenario may not hold for IRAS F00183–7111.

Note that strong extinction on the PAH emitting region can be ruled out as a third explanation for the low observed 6.2-to- $11.2\ \mu\text{m}$ PAH ratio, as this would have the opposite effect on

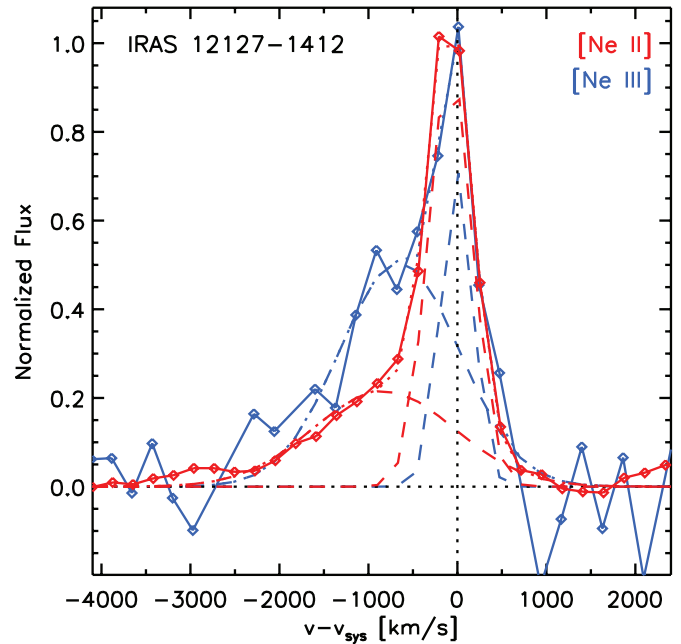

Figure 6. Comparison of the galaxy-integrated line profiles of $12.81\ \mu\text{m}$ [Ne II] (red) and $15.56\ \mu\text{m}$ [Ne III] (blue) for IRAS 12127-1412NE at a spectral resolution of $R = 600$. Overplotted are two-component Gauss fits to the line profiles. The individual components are shown as dashed lines, their sums as dotted lines.

(A color version of this figure is available in the online journal.)

the PAH ratio: the attenuation on the $11.2\ \mu\text{m}$ PAH feature is stronger than the attenuation on the $6.2\ \mu\text{m}$ PAH feature (e.g., Chiar & Tielens 2006).

4. OTHER ULIRGS SHOWING RESOLVED MID-IR NEON LINES

The discovery of high velocity [Ne II] emission in IRAS F00183–7111 raises the question whether there are other luminous infrared galaxies that show evidence for disturbed ($\text{FWHM} \geq 800\ \text{km s}^{-1}$) neon gas in their *Spitzer*-IRS spectra. If so, do these galaxies have properties similar to IRAS F00183–7111? To address this question we have inspected the line profiles of the low-ionization emission lines $12.81\ \mu\text{m}$ [Ne II] and $15.56\ \mu\text{m}$ [Ne III] of the 53 ULIRGs in the sample of Farrah et al. (2007), as well as the archival spectra of the ULIRG IRAS 12127–1412NE and the HyLIRGs IRAS F09104+4109 and IRAS F15307+3252. In our search we distinguish two classes. One consisting of sources with symmetric resolved neon line profiles, and another with sources which show asymmetric resolved line profiles.

The class of asymmetric resolved [Ne II] and [Ne III] line profiles consists of only two sources besides IRAS F00183–7111. In all three cases the line asymmetry takes the form of a blue wing.

4.1. IRAS 12127–1412NE

One source is IRAS 12127–1412NE (Figure 6), the brighter of the two nuclei in this widely separated LINER system (projected nuclear separation $9''$, or $21.9\ \text{kpc}$; Veilleux et al. 1999). In the near-infrared, Imanishi et al. (2006) classified the NE nucleus as a buried AGN based on the absence of $3.3\ \mu\text{m}$ PAH emission and the presence of $3.0\ \mu\text{m}$ water ice and $3.4\ \mu\text{m}$ hydrocarbon absorption bands. The deeply buried nature of the nuclear power

source(s) is confirmed by the presence of a deep $10\ \mu\text{m}$ silicate feature in the *Spitzer*-IRS low-resolution spectrum (Imanishi et al. 2007).

On 2008 July 10, we reobserved the source in staring mode in IRS-SH, using an integration time of 12 cycles of 120 s. Sky-subtraction was performed using a contemporaneous sky background observation of six cycles of 120 s. Data reduction proceeded along the same steps as detailed in Section 2.1.

Like for IRAS F00183–7111, the asymmetry of the neon emission lines of IRAS 12127–1412NE may be characterized using a two-component Gaussian fit. For the [Ne II] line the narrow component is practically unresolved (FWHM = $175 \pm 45\ \text{km s}^{-1}$) and is centered close to systemic velocity¹¹ ($-80 \pm 10\ \text{km s}^{-1}$). The other component has a FWHM of $1670 \pm 100\ \text{km s}^{-1}$ and is centered at a blue shift of $530 \pm 60\ \text{km s}^{-1}$ (Figure 6). The fraction of the [Ne II] line flux emitted in the broad component is slightly smaller than that in the narrow component. This is less than for IRAS F00183–7111, for which about 4/5 of the line flux is associated with the broad component. We also examined the $15.56\ \mu\text{m}$ [Ne III] profile. Its shape is not as well constrained as that of the [Ne II] line due to a five times lower line flux, but the profile clearly shows the presence of a blue wing. A two-component Gauss fit results in an unresolved narrow component centered at systemic velocity ($-7 \pm 40\ \text{km s}^{-1}$) and a broad component with FWHM of $1500 \pm 340\ \text{km s}^{-1}$ blueshifted by $650 \pm 200\ \text{km s}^{-1}$. We find that the contribution of the broad component to the [Ne III] line profile is far stronger than to the [Ne II] profile, 3/4 as compared to 1/2 (Figure 6). This implies a difference in excitation of the narrow and broad components. For the narrow component we find a [Ne III]/[Ne II] ratio of 0.095 ± 0.04 , while for the broad component we compute a ratio of 0.29 ± 0.08 . Unfortunately, a comparison to the line profile of the optical [O III] doublet is not possible as the equivalent widths of these lines in the spectrum of Veilleux et al. (1999) are too low for a meaningful analysis of their profiles.

4.2. IRAS 13451+1232

The third ULIRG with asymmetric neon line profiles is IRAS 13451+1232,¹² also known as PKS 1345+12 (Figure 7). The source, which is optically classified as Seyfert-2 (Veilleux et al. 1997), comprises two nuclei separated by $1''.8$ (4.3 kpc; unresolved at the spatial resolution of *Spitzer*-IRS). Both the low-resolution near-infrared $2.6\text{--}3.65\ \mu\text{m}$ (Imanishi et al. 2006) and the *Spitzer* mid-infrared spectra are virtually featureless, characteristic of AGN heated hot dust. At the higher resolving power of IRS-SH, emission line profiles of $12.81\ \mu\text{m}$ [Ne II], $15.56\ \mu\text{m}$ [Ne III], and $14.32\ \mu\text{m}$ [Ne V] can be discerned on the continuum, the clearest of which is the [Ne III] line. We fit its profile with a broad component of FWHM $2360 \pm 110\ \text{km s}^{-1}$ blueshifted by $950 \pm 85\ \text{km s}^{-1}$ and a narrow component of FWHM $670 \pm 70\ \text{km s}^{-1}$ blueshifted by $200 \pm 25\ \text{km s}^{-1}$. The broad component is responsible for 2/3 of the

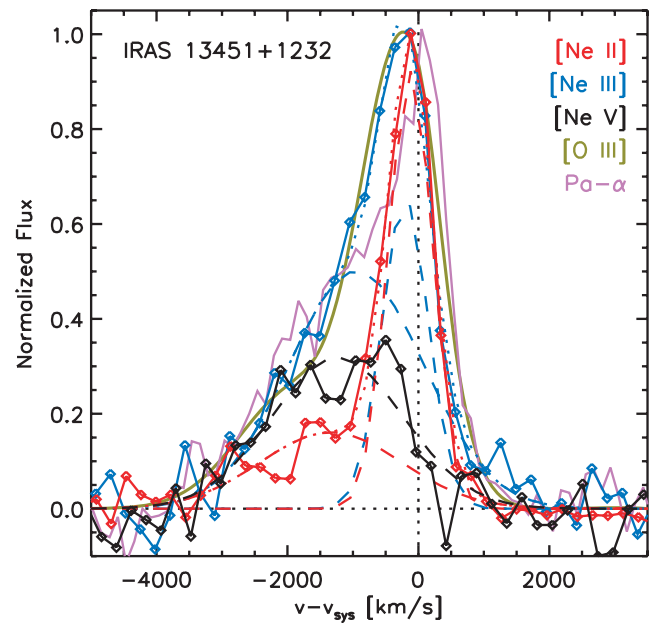

Figure 7. Comparison of the galaxy-integrated line profiles of $12.81\ \mu\text{m}$ [Ne II] (red), $15.56\ \mu\text{m}$ [Ne III] (blue) and $14.32\ \mu\text{m}$ [Ne V] (black) for IRAS 13451+1232 at a spectral resolution of $R = 600$. Overplotted are two-component Gauss fits to the neon line profiles. The individual components are shown as dashed lines, their sums as dotted lines. The [Ne V] line has been scaled to match the blue wing of the [Ne III] line profile. Also shown is the sum of the three-component Gauss fit to the $5007\ \text{\AA}$ [O III] line (green) as presented by Holt et al. (2003), degraded to a resolution of $R = 600$, and the Pa α profile (purple) obtained by Veilleux et al. (1997) at $R = 650$.

(A color version of this figure is available in the online journal.)

[Ne III] emission, significantly more than for IRAS F00183–7111 but somewhat less than for IRAS 12127–1412NE. For the [Ne II] line profile the two-component decomposition results in a narrow component with a FWHM of $610 \pm 50\ \text{km s}^{-1}$ blueshifted by $120 \pm 10\ \text{km s}^{-1}$ and a broad component with FWHM $2470 \pm 340\ \text{km s}^{-1}$ blueshifted by $1290 \pm 220\ \text{km s}^{-1}$. The broad component carries 1/3 of the total [Ne II] line flux, significantly less than for IRAS F00183–7111 and IRAS 12127–1412NE. The third line, the [Ne V] coronal line at $14.32\ \mu\text{m}$, only has a blueshifted component, centered at a $-1240 \pm 80\ \text{km s}^{-1}$, which we fit with a Gaussian profile of FWHM $2300 \pm 190\ \text{km s}^{-1}$. The presence of [Ne V] emission only at blueshifted wavelengths is consistent with the difference in excitation between the narrow and broad components as measured from the [Ne III]/[Ne II] ratio. For the narrow component this ratio is 0.44 ± 0.07 , while for the broad component it is 1.6 ± 0.3 . The [Ne V]/[Ne II] ratio for the broad component is 0.76 ± 0.14 .

In Figure 7 we also show the sum of a three-component fit to the profile of the $5007\ \text{\AA}$ [O III] line, centered on the nucleus (Holt et al. 2003). The spectral resolution was degraded from $R = 1200$ to 600 for a proper comparison to our IRS-SH data. As a result of the degradation, the narrowest (FWHM = $340 \pm 23\ \text{km s}^{-1}$) and weakest of the three kinematic components, centered at systemic velocity, gets blended with the intermediate width component (FWHM = $1255 \pm 12\ \text{km s}^{-1}$) centered at $-402 \pm 9\ \text{km s}^{-1}$. The broadest, most blueshifted component (FWHM = $1944 \pm 65\ \text{km s}^{-1}$), centered at $-1980 \pm 36\ \text{km s}^{-1}$, can however still be recognized as a separate component. We also overplot the line profile of Pa α (Veilleux et al. 1997) with a narrow component of FWHM =

¹¹ We infer the systemic velocity of IRAS 12127–1412NE from the line centers of the H₂ S(1) and S(3) lines and find $39870 \pm 200\ \text{km s}^{-1}$ ($z = 0.1330 \pm 0.0004$), in good agreement with the redshift of 0.133 quoted by Veilleux et al. (2002).

¹² We adopt $z = 0.12174 \pm 0.00001$ as the systemic velocity for IRAS 13451+1232. This velocity corresponds to the velocity center of the narrow component in the three-component fit to the $4959\ \& 5007\ \text{\AA}$ [O III] doublet in the $R = 1200$ spectrum of Holt et al. (2003). Using this redshift, the line centers of the H₂ S(1) and S(3) lines occur at 40 ± 30 and $20 \pm 35\ \text{km s}^{-1}$, respectively. Note that our adopted redshift is $200\ \text{km s}^{-1}$ lower than the value derived from CO observations (Evans et al. 1999).

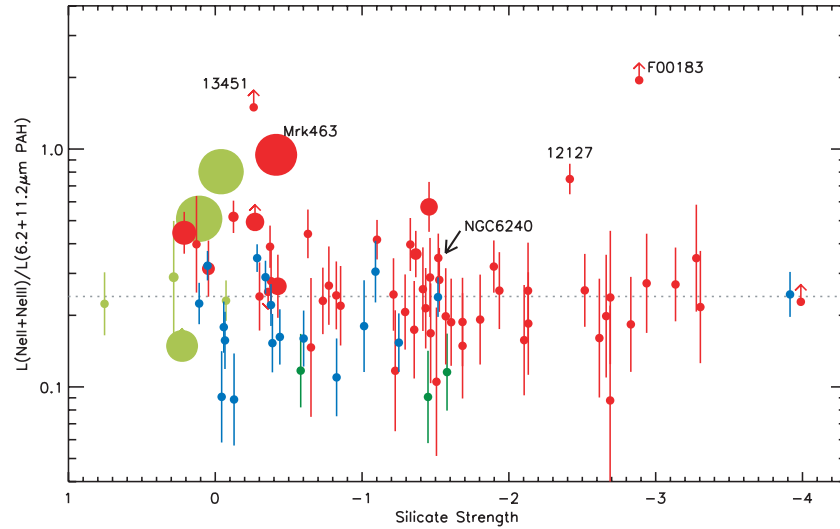

Figure 8. Ratio of the combined [Ne II]+[Ne III] luminosity and the combined PAH(6.2 μm)+PAH(11.2 μm) luminosity as a function of silicate strength (Spoon et al. 2007). The symbol size scales linearly with the [Ne V]/[Ne II] ratio above a threshold ratio of 0.4. The largest symbol corresponds to a [Ne V]/[Ne II] ratio of 2.2. The horizontal dotted line indicates the average neon/PAH ratio for low-excitation ULIRGs. IRAS F00183–7111 is more than a factor 8 above this value, indicating that it is overluminous in its neon lines compared to its PAH emission. The same is true to a lesser extent for the ULIRGs IRAS 12127–1412NE and IRAS 13451+1232. Galaxy types are labeled as follows: ULIRGs: red, starburst galaxies: blue, Seyfert-2 galaxies: dark green, Seyfert-1 galaxies and QSOs: light green.

(A color version of this figure is available in the online journal.)

773 km s⁻¹ and a broad component of FWHM = 2588 km s⁻¹. The overlay suggests that the 15.56 μm [Ne III] line traces more or less the same blueshifted kinematic components as the 5007 Å [O III] and Pa α lines. The comparison further shows that, unlike IRAS F00183–7111, there is no evidence for the 5007 Å [O III] line to cover a more limited velocity range than the 12.81 μm [Ne II] and 15.56 μm [Ne III] lines (Figures 5 & 7). The latter is in agreement with the differences in the distribution of the obscuring medium as probed by the 9.7 μm silicate absorption features (see Section 5.4).

5. DISCUSSION

5.1. AGN Activity in IRAS F00183–7111

Observations at various wavelengths suggest that IRAS F00183–7111 derives a substantial fraction of its bolometric power from accretion onto a central black hole. Especially important in this respect is the detection by Nandra & Iwasawa (2007) of a 6.7 keV Fe K α line (Fe xxv) with a large equivalent width, indicating the presence of a Compton-thick AGN in IRAS F00183–7111. Another clear indication is a higher than expected radio power based on the radio-far-infrared correlation for starburst galaxies (Roy & Norris 1997), as well as unpublished radio interferometric data showing the nucleus to be unresolved on the 200 pc scale (R.P. Norris, 2004, private communication).

The nondetection of several common mid-infrared AGN tracers in our *Spitzer*-IRS high resolution spectrum may hence indicate that the AGN coronal line region (CLR) is small or absent or, alternatively, that our line of sight to the AGN CLR is strongly obscured. The latter would be in agreement with the detection of a deep 9.7 μm silicate absorption feature (Spoon et al. 2004; Figure 2), which is unusual for classical seyfert galaxies and quasars (Spoon et al. 2007; Hao et al. 2007). Even stronger obscuration, along all lines of sight, is suggested by Lutz et al. (2004), who concluded from a study of the 4.7 μm CO gas absorption band that the strong detection of this feature in IRAS F00183–7111 (Spoon et al. 2004) and its non-detection in local AGNs observed with ISO indicates that the central power

source in IRAS F00183–7111 must be fully covered rather than blocked by an edge-on torus.

5.2. Excitation Conditions in the Outflow of IRAS F00183–7111

To gain insight into the processes responsible for the presence of high velocity gas in IRAS F00183–7111 we compare IRAS F00183–7111 to the only other two ULIRGs in our sample that show pronounced blue wings in their 12.81 μm [Ne II] and 15.56 μm [Ne III] line profiles: IRAS 12127-1412NE (Figure 6) and IRAS 13451+1232 (Figure 7).

Clear evidence for unusual excitation conditions in IRAS F00183–7111 emerge if we compare the PAH emission and low-ionization neon line emission for AGNs, ULIRGs and starburst galaxies from the various *Spitzer*-IRS GTO programs, (U)LIRGs from *Spitzer* program 1096 and IRAS 12127–1412NE. The PAH luminosity should track the low-ionization neon line luminosity to within a factor two, if predominantly excited in star forming regions. This was indeed found to be the case for the sample of ULIRGs published by Farrah et al. (2007). In Figure 8 we plot the ratio of these two quantities (the combined [Ne II]+[Ne III] luminosity and the combined luminosity of the 6.2 and 11.2 μm PAH features) as a function of increasing apparent depth of the 9.7 μm silicate feature (i.e., the negative of the silicate strength, S_{sil} ; Spoon et al. 2007). The symbol size scales linearly with the [Ne V]/[Ne II] ratio above a threshold value of 0.4. This distinguishes ULIRGs with a strong AGN contribution to the [Ne II]+[Ne III] luminosity (e.g., Mrk 463; Farrah et al. 2007) from those without. As expected, for the sources lacking a strong AGN signature the average value of neon/PAH has a reasonably low scatter of a factor 1.4,¹³ in agreement with the scaling relation between neon and PAH flux for ULIRGs found by Farrah et al. (2007). The notable exception is IRAS F00183–7111, which appears to be at least 8

¹³ In this computation we excluded the outliers IRAS F00183–7111, IRAS 12127–1412NE and IRAS 13451+1232. Keeping them included would increase the scatter to a factor 1.7.

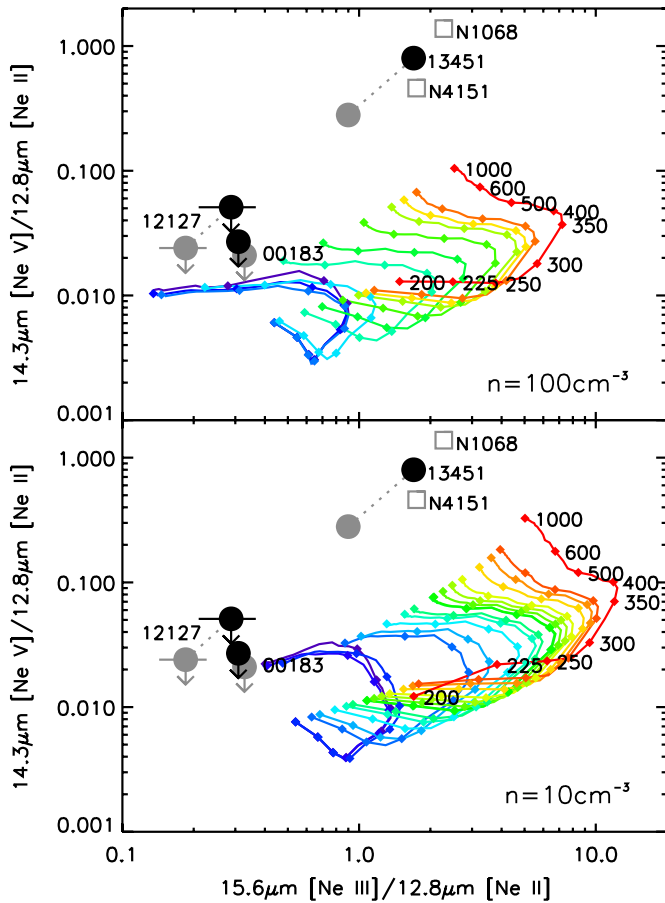

Figure 9. Mid-infrared diagnostic diagram for the line ratio $15.56 \mu\text{m}$ [Ne III] / $12.81 \mu\text{m}$ [Ne II] versus $14.32 \mu\text{m}$ [Ne V] / $12.81 \mu\text{m}$ [Ne II]. Plotted are predicted line ratios as computed by MAPPINGS version IIIq (Allen et al. 2008) for combined precursor+shock models at solar metallicity at a gas density $n = 100 \text{ cm}^{-3}$ (upper panel) and $n = 10 \text{ cm}^{-3}$ (lower panel). Different colors (ranging from purple to red) denote different magnetic field strengths, ranging from 10^{-3} to $100 \mu\text{G}$. Shock velocities range from 200 to 1000 km s^{-1} and are labeled along the red curve. Overlaid are the positions of IRAS F00183–7111, IRAS 12127+1412NE and IRAS 13451+1232 for the integrated fluxes (gray disks) and for just the blueshifted component (black disks). Gray squares mark the positions of the nuclear spectra of the classical AGNs NGC 1068 and NGC 4151 (Sturm et al. 2002).

(A color version of this figure is available in the online journal.)

times overluminous in the neon lines compared to its combined PAH luminosity. Another exception in the $S_{\text{sil}} < -1.5$ regime is IRAS 12127–1412NE, which is overluminous in neon/PAH by a factor of 3. At $S_{\text{sil}} > -1.5$, the situation is less straightforward. In this regime there are several sources with large $[\text{Ne v}]/[\text{Ne II}]$ ratios for which the AGN contributes significantly to the $[\text{Ne II}]+[\text{Ne III}]$ luminosity, thereby raising the neon/PAH ratio (Figure 8). The only ULIRG in this regime which has an elevated neon/PAH ratio despite a low $[\text{Ne v}]/[\text{Ne II}]$ ratio of 0.28 is IRAS 13451+1232, at more than 6 times the average neon/PAH ratio (Figure 8). This brings the number of ULIRGs with unusual excitation conditions to three. Since these same three ULIRGs are also the only ULIRGs in our sample that show pronounced blue wings in their $12.81 \mu\text{m}$ [Ne II] and $15.56 \mu\text{m}$ [Ne III] line profiles, it seems plausible that the high neon/PAH ratios for these sources could be the result of additional neon line emission contributed by these blue wings rather than unusually weak PAH emission in these three sources.

In Figure 9 we show a mid-infrared diagnostic diagram based on the $12.81 \mu\text{m}$ [Ne II], $15.56 \mu\text{m}$ [Ne III], and $14.32 \mu\text{m}$

[Ne v] lines. In the diagram we plot shock excitation models from the MAPPINGS IIIq library (Allen et al. 2008) for solar metallicity gas with densities $n = 100 \text{ cm}^{-3}$ (upper panel) and $n = 10 \text{ cm}^{-3}$ (lower panel). The model tracks plotted include the ionizing effects from UV and soft X-ray photons in the shock cooling zone on the gas ahead of the shock front. Overplotted are the positions of IRAS F00183–7111, IRAS 12127+1412NE, and IRAS 13451+1232 from our Spitzer observations. Black filled circles indicate the results for just the broad blueshifted emission line components, the gray versions denote the results based on the velocity-integrated line fluxes (i.e., the narrow and broad components combined). For IRAS F00183–7111 and IRAS 12127+1412NE the low observed $[\text{Ne III}]/[\text{Ne II}]$ line ratios are consistent with high-velocity shocks ($v > 500 \text{ km s}^{-1}$) in high-density environments ($n > 100 \text{ cm}^{-3}$) with low magnetic field strengths ($< 1 \mu\text{G}$). At lower gas densities ($n = 10 \text{ cm}^{-3}$), only the highest velocity shocks ($v = 1000 \text{ km s}^{-1}$) at the lowest magnetic field strengths ($< 0.1 \mu\text{G}$) are consistent with the observed $[\text{Ne III}]/[\text{Ne II}]$ line ratios. Below this density the observed line ratios cannot have an origin in shock emission. Given the absence of density measurements we cannot rule out either scenario. However, as we will argue later, if the neon line emission originates at the base of the optical outflow, gas densities of $n > 100 \text{ cm}^{-3}$ may not be unreasonable. In IRAS 13451+1232 it is the high observed $[\text{Ne v}]/[\text{Ne II}]$ ratio which appears to rule out shocks of any velocity and density as the source of excitation for the neon lines. For the latter source, exposure of the blueshifted gas to direct radiation from the AGN seems a likely explanation for the presence of [Ne v] emission at the observed ratio to [Ne II]. This explanation is supported by the proximity of the blueshifted component of IRAS 13451+1232 to the positions of the classical AGNs NGC 1068 and NGC 4151 in Figure 9.

5.3. Strong Obscuration on the Outflow in IRAS F00183–7111

In Section 3.3 we analyzed the velocity structure of the $12.81 \mu\text{m}$ [Ne II] and $15.56 \mu\text{m}$ [Ne III] lines in IRAS F00183–7111 and compared the results to those of studies of its optical and near-infrared forbidden lines. This revealed that the mid-infrared neon emission lines have strongly blueshifted components not detected in both the optical 5007 \AA [O III] and near-infrared $1.644 \mu\text{m}$ [Fe II] line profiles. Given the mid-infrared spectral evidence for strong obscuration in the nucleus of IRAS F00183–7111 (Spoon et al. 2004), the simplest explanation for the absence of strongly blueshifted gas components in the optical and near-infrared emission lines is extinction. We estimate the required extinction by assuming line emission at any wavelength λ to be effectively suppressed by a specific extinction $A(\lambda) \geq 2$. The level of screen extinction required to obscure the high-velocity components of the 5007 \AA [O III] line then amounts to $A_{5007 \text{ \AA}} = A_V > 2$. If the same screen is responsible for obscuring the high-velocity components of the $1.644 \mu\text{m}$ [Fe II] line, the required extinction increases to $A_V > 10$ ($A_{1.64 \mu\text{m}} > 2$). Then to still be able to see the strongly blueshifted $12.81 \mu\text{m}$ [Ne II] emission through this screen, the maximum extinction is constrained to $A_V < 50$ ($A_{12.81 \mu\text{m}} < 1$). This implies a column density of the obscuring screen of $N_{\text{H}} = 2\text{--}10 \times 10^{22} \text{ cm}^{-2}$, assuming $N_{\text{H}} = 1.9 \times 10^{21} \times A_V$.

In the absence of spatial information for the mid-infrared neon line emission, the location of the screen blocking the optical and near-infrared line emission cannot be determined with any certainty. However, it is plausible for the screen to be situated

at the base of the outflow traced in 5007 \AA [O III]. The observed strong decrease in blueshift of the 5007 \AA [O III] line from $3''$ to $0''$ east of the nucleus (Figure 12 of Heckman et al. 1990) may hence indicate that the material that obscures the most highly disturbed optical (but not mid-infrared) line emission is located within the inner 10 kpc.

5.4. The Evolutionary State of IRAS F00183–7111

IRAS F00183–7111 is a clear outlier in a mid-infrared diagnostic diagram which combines the equivalent width of the $6.2 \mu\text{m}$ PAH emission feature and the silicate strength in the so-called “fork” diagram (Spoon et al. 2007). In this diagram most ULIRGs are found along one of two branches. One branch connects starburst-dominated mid-infrared spectra (e.g., NGC 7714 and M 82) to spectra of deeply buried central sources, characterized by very deep silicate features and the (virtual) absence of PAH emission (e.g., IRAS 08572+3915). The other branch connects starburst-dominated sources with featureless hot dust-dominated sources, which are mostly AGN dominated.

IRAS F00183–7111 is located in the scarcely populated region in between the tips of the two branches and has IRAS 12127+1412NE as its nearest neighbor. Their location, away from other deeply obscured sources, either implies a more than 10 times lower $6.2 \mu\text{m}$ PAH equivalent width than other ULIRGs with similar silicate strength, or a less pronounced silicate feature than other deeply obscured ULIRGs. Spoon et al. (2007) have proposed that sources in between the two branches may be AGN evolving from a fully covered obscuring geometry to an incomplete or clumpy obscuring geometry, with a decrease in apparent depth of the silicate feature as a result. In this scenario, the detection of strongly blueshifted neon line emission would then trace a unique phase in the (partial) disruption of the obscuring medium around the powerful AGN. Alternatively, the isolated positions of IRAS F00183–7111 and IRAS 12127+1412NE in the fork diagram may be the result of unusual lines of sight into these systems. The unusual mid-infrared excitation conditions and kinematics may then be associated to that.

If sources with mid-infrared kinematic properties and neon/PAH ratios similar to IRAS F00183–7111 and IRAS 12127+1412NE are indeed AGN evolving from full to incomplete or clumpy obscuration, there should be observational characteristics linking them. However, the only ULIRG in our sample with these same mid-infrared properties, IRAS 13451+1232, has a mid-infrared continuum spectrum which is very different from the other two sources, displaying only a weak silicate absorption feature on an otherwise featureless power law spectrum. This places it firmly on the AGN branch in the fork diagram, far off from the other two sources. Evidence supporting an unusual evolutionary stage is presented by Holt et al. (2003). Based on the shape of its radio SED and a kinematic study of its optical emission line spectrum, they conclude that IRAS 13451+1232 must be a young compact radio source whose radio jets are expanding through a dense nuclear dust shell, entraining gas and dust from this shell. They infer the reddening to be highest toward the broadest (most disturbed), most blueshifted kinematic component in their optical line study, reminiscent of our findings for IRAS F00183–7111 using optical, near and mid-infrared line profiles.

6. CONCLUSIONS

We have discovered high-velocity ionized gas with velocities ranging from -3500 to $+3000 \text{ km s}^{-1}$ as part of a nuclear outflow from the ULIRG IRAS F00183–7111. The gas is traced by the mid-infrared $12.81 \mu\text{m}$ [Ne II] and $15.51 \mu\text{m}$ [Ne III] lines, which are dominated by blueshifted components. Optical and near-infrared spectroscopic studies show no evidence for similar high-velocity gas components in forbidden lines at shorter wavelengths. We interpret this as the result of strong extinction ($A_V = 10\text{--}50$; $A_{12.81\mu\text{m}} < 1$) on the blueshifted gas, identifying the base of the optical outflow ($< 3''$ east) as its most likely origin.

Unusual excitation conditions in IRAS F00183–7111 are further implied by a comparison of the combined [Ne II] and [Ne III] luminosity and the combined 6.2 and $11.2 \mu\text{m}$ PAH luminosity for a large sample of AGNs, ULIRGs and starburst galaxies. This reveals the neon line emission in IRAS F00183–7111 to be at least 8 times stronger compared to its PAH emission than the typical ratio for the sample.

Two other ULIRGs in our sample of 56 display mid-infrared excitation and kinematic properties similar to IRAS F00183–7111: IRAS 12127–1412NE and IRAS 13451+1232. Both sources have elevated neon/PAH ratios and exhibit pronounced blue wings in their $15.56 \mu\text{m}$ [Ne III] line profiles. Wings are also present in their $12.81 \mu\text{m}$ [Ne II] profiles, but are less pronounced, indicating blueshifted gas to have a higher [Ne III]/[Ne II] ratio than gas closer to systemic velocity. IRAS 13451+1232 even shows strongly blueshifted $14.32 \mu\text{m}$ [Ne V] emission.

While for IRAS 13451+1232 the observed [Ne III]/[Ne II] and [Ne V]/[Ne II] ratios indicate exposure of the blueshifted gas to direct radiation from the AGN, for IRAS F00183–7111 and IRAS 12127–1412NE the observed ratios are consistent with an origin in fast shocks ($v > 500 \text{ km s}^{-1}$) in an environment with gas densities $n > 10 \text{ cm}^{-3}$.

IRAS F00183–7111 and IRAS 12127–1412NE are clear outliers in the mid-infrared diagnostic diagram of silicate strength and $6.2 \mu\text{m}$ PAH equivalent width, the so-called “fork” diagram (Spoon et al. 2007). The sources are found in between the two branches which separate deeply buried nuclei and sources with incomplete or clumpy obscuring geometries. Spoon et al. (2007) have proposed that ULIRGs in between the tips of these branches may be AGN in the process of disrupting their fully covered geometry before settling on the AGN branch. IRAS 13451+1232 would then already be there, given its nearly featureless mid-infrared power law spectrum.

The results from our mid-infrared kinematic and excitation study are consistent with the above evolutionary scenario in that the strongly blueshifted [Ne II] and [Ne III] emission (from shocks) may trace the (partial) disruption of the obscuring medium around buried AGNs in IRAS F00183–7111 and IRAS 12127–1412NE. The detection of strongly blueshifted [Ne V] emission in IRAS 13451+1232 may then indicate the lifting of the obscuration around the AGN coronal line region to be further advanced in this ULIRG than in IRAS F00183–7111 and IRAS 12127–1412NE, where this line is undetected.

APPENDIX A

MOLECULAR HYDROGEN LINES

Our measurements of the S(1), S(2), S(3), and S(4) pure rotational molecular hydrogen lines allow us to investigate the properties of warm molecular hydrogen in IRAS F00183–7111.

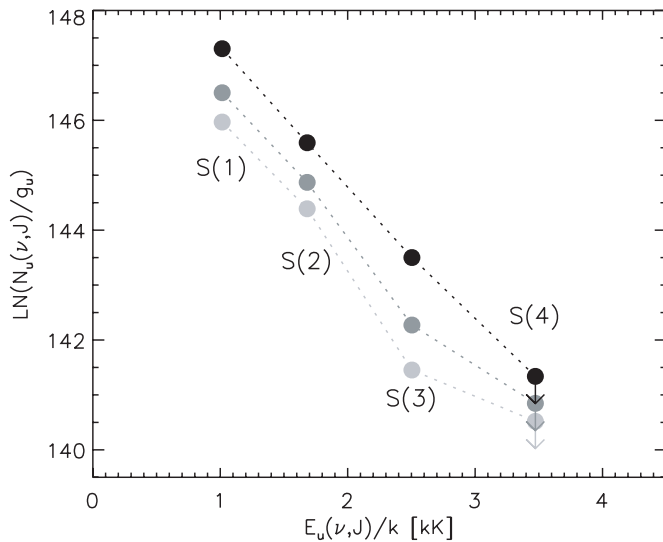

Figure 10. Excitation diagram for warm molecular hydrogen in IRAS F00183–7111 based on the line fluxes for the pure-rotational transitions S(1)–S(4). Different shades of gray are used to distinguish different levels of dereddening: black: $A_V = 25$, dark gray: $A_V = 10$, light gray: $A_V = 0$. Error bars are too small to be visible.

Unfortunately, a measurement of the important S(0) line is lacking as it is outside the IRS–LH bandpass. In Figure 10 we show the excitation diagram for molecular hydrogen for the four measured lines. Given the placement of the H(3) line at the peak of the silicate absorption feature, we can attempt an extinction correction on the four data points under the assumption that (a) the excitation temperature should be constant or increase monotonically with increasing upper level energy $E_u(\nu, J)$, (b) that the ortho-to-para ratio is 3 (i.e., assuming LTE), and (c) that the cooler gas probed by the S(1) and S(2) lines is more or less co-spatial with the warmer gas probed by the S(3) and S(4) lines. Adopting the local ISM extinction law of Chiar & Tielens (2006), we then find that the extinction on the H₂ lines ranges between $A_V = 15$ and 25. This is far lower than the extinction on the continuum source, which is $A_V > 54$ based on the apparent depth of the 9.7 μm silicate feature ($\tau_{9.7} = 3.0$; Spoon et al. 2006) and $A_V/\tau_{9.7} = 18$ (Roche & Aitken 1984). Based on the two detected ortho-H₂ lines, it is possible to infer an excitation temperature for the warm molecular hydrogen. The value ranges from 330 to 390 K for extinction corrections ranging from $A_V = 0$ to 25. Assuming all H₂ levels to be in LTE at 330–390 K, we derive a total warm molecular hydrogen mass of $8\text{--}20 \times 10^8 M_\odot$. This value becomes a lower limit if the excitation temperature based on the upper level populations of the S(0) and S(1) lines is lower than those based on the S(1) and S(3) lines – which is usually the case (e.g., Higdon et al. 2006). Unfortunately, we cannot determine the warm to total molecular hydrogen fraction and compare this to other ULIRGs, as no millimeter CO line measurement exists for IRAS F00183–7111 from which to infer the cold molecular hydrogen mass.

APPENDIX B

NON-DETECTION OF ABSORPTION BANDS OF C₂H₂ AND HCN GAS

Several ULIRGs show absorption bands of C₂H₂ and HCN gas in their 13.7–14.1 μm *Spitzer* IRS–SH spectra (Spoon et al. 2005; Lahuis et al. 2007). Detections are especially strong among ULIRGs with pronounced silicate absorption features,

like IRAS 20100–4156 and IRAS 15250+3609. Far weaker detections are reported for ULIRGs with AGN-like spectra, like IRAS 05189–2524, IRAS 01003–2238 and Mrk 231 (Lahuis et al. 2007). Detections at these levels require spectra to have signal-to-noise ratios (S/Ns) of at least 100 in their continua. The IRS–SH spectrum of IRAS F00183–7111 does not show any indication for the presence of either feature, despite a continuum S/N of 70. This translates into upper limits on the C₂H₂ and HCN gas column densities of $N(\text{C}_2\text{H}_2) < 1.2 \times 10^{16} \text{ cm}^{-2}$ and $N(\text{HCN}) < 3.0 \times 10^{16} \text{ cm}^{-2}$ for an adopted excitation temperature of 300 K (F. Lahuis 2008, private communication).

The authors thank Jan Cami, Helmut Dannerbauer, Brent Groves, Lei Hao, Timothy Heckman, Lisa Kewley, Dieter Lutz, and Xander Tielens for discussions, Catherine Buchanan, Joanna Holt, and Sylvain Veilleux for sharing their published spectra, and Mark G. Allen for providing MAPPINGS shock models ahead of publication. We also thank the slow but diligent referee for comments which helped to strengthen the paper. Support for this work was provided by NASA. This research has made extensive use of the NASA/IPAC Extragalactic Database (NED) which is operated by the Jet Propulsion Laboratory, California Institute of Technology, under contract with NASA.
