### Abstract

Butterflies and moths are subject to different evolutionary pressures that affect several aspects of their behaviour and physiology, particularly sexual communication. Butterflies are day-flying insects (excluding hedyliids) whose partner-finding strategy is mainly based on visual cues and female butterflies having apparently lost the typical sex pheromone glands. Moths, in contrast, are mostly night-flyers and use female-released long-range pheromones for partner-finding. However, some moth families are exclusively day-flyers, and therefore subject to evolutionary pressures similar to those endured by butterflies. Among them, the Castniidae, also called ‘butterfly-moths’ or ‘sun-moths’, behave like butterflies and, thus, castniid females appear to have also lost their pheromone glands, an unparalleled attribute in the world of moths. In this paper, we review the sexual communication strategy in day-flying Lepidoptera, mainly butterflies (superfamily Papilionoidea), Zygaenidae and Castniidae moths, and compare their mating behaviour with that of moth families of nocturnal habits, paying particular attention to the recently discovered butterfly-like partner-finding strategy of castniids and the fascinating facts and debates that led to its discovery.

## Introduction

Lepidoptera is one of the most diverse insect groups with currently about 160,000 described species (Kristensen *et al.*, 2007; van Nieukerken *et al.*, 2011), although the total number of extant species is estimated to be around half a million (Kristensen *et al.*, 2007). Within this vast group of insects and until the late 1980s, only two basic partner-finding strategies pertaining to ‘butterflies’ and ‘moths’ were known. In short, male butterflies used their vision to detect conspecific females at some distance and to pursue them. Female butterflies, in turn, had no sex pheromone glands in their ovipositors and therefore did not release any long-range pheromone to attract males. In contrast, male moths used their olfaction system to detect females at some distance because the latter release long-range pheromones\* from their pheromone glands. Once together and in close courtship interactions, males (butterflies and moths), and in some cases also females, released close range pheromones or ‘scents’ that facilitated or prevented the last courtship steps leading to copulation. The butterflies, all diurnal except the moth-like hedyliids, simply used vision to find mates in their sunlit environment with no need to produce long-range sex pheromones. The mostly nocturnal moths, in turn, kept the so-called “female calling plus male seduction” strategy, which implied the production of long-range sex pheromones. Table 1 summarises the partner-finding strategies of nocturnal and diurnal lepidopteran groups.

It must be mentioned, however, that three other partner-finding strategies have been described in night-flying moths (Hallberg & Poppy, 2003), although their occurrence is rare: (1) mutual calling in the noctuid *Trichoplusia ni* (Hübner) where both sexes “call” (Landolt & Heath, 1989), (2) reverse calling in the Pyralid rice moth *Corcyra cephalonica* (Stainton), where the

---

\*Note: Long-range sex pheromones are generally emitted from epidermal glands in membranous areas of the ovipositor, the ancestral state in ditrysian Lepidoptera (Hallberg & Poppy, 2003).

74 male emits a pheromone at a distance, and the female responds by releasing a pheromone at  
75 close-range and induces the male to copulate (Zagatti *et al.*, 1987; Hall *et al.*, 1987), and (3)  
76 “lekking”, where several males gather together in a group (the lek) to which females are  
77 attracted by the male-produced pheromones, and mating takes place within the lek. Lekking  
78 behaviour has been reported in Hepialidae, Pyralidae and Arctiidae (Hallberg & Poppy,  
79 2003). A good understanding of the above-mentioned strategies is important in natural  
80 resource management, not only for Lepidoptera of economic importance but also for  
81 endangered species and for those living in threatened habitats. The case of the Gondwanan  
82 family Castniidae, also called ‘butterfly-moths’ or ‘sun-moths’, is particularly exemplary in  
83 this respect. In the Neotropics, many of them live in threatened habitats since their boring  
84 larvae depend on tree-dwelling forest plants; however, a few species have adapted to boring  
85 into crop plants introduced by man, such as sugarcane, banana and African oil palm,  
86 subsequently becoming important pests of such crops (Sarto i Monteys & Aguilar, 2005). One  
87 of them, *Paysandisia archon* (Burmeister) was introduced into Europe (Spain) in the mid-  
88 1990s to spread eastwards to Bulgaria, Greece and Cyprus and become a serious pest of many  
89 palm species (Sarto i Monteys & Aguilar, 2005). In Australia, less than 50 castniid species  
90 occur, all included in the genus *Synemon* Doubleday (Edwards *et al.*, 1998). *Synemon* larvae  
91 feed underground on the roots and rhizomes of grasses and sedges, and suffer a drastic  
92 reduction in their populations because of the clearing or modification of vast areas of native  
93 grasslands, woodlands and heathlands across Australia, therefore requiring urgent protection  
94 measures (Douglas, 2004). In this respect, knowing in detail how a species communicates  
95 sexually may give resource managers significant clues to either control or protect any specific  
96 endangered population. This review deals with the sexual communication in day-flying  
97 Lepidoptera, either butterflies or moths with diurnal habits, paying particular attention to  
98 castniids and to their recently suggested butterfly-like partner-finding strategy. We have also

99 included Zygaenidae moths (genus *Zygaena* Fabricius) because they display a dual partner-  
100 finding strategy between the castniids/butterflies and the other day-flying moths.

101

### 102 **The Butterflies (Superfamily Papilionoidea) and their reproductive behaviour**

103 Butterflies comprise 11.9% (*ca.*18,800 species) of all described Lepidoptera. They are  
104 currently grouped within the taxonomic superfamily Papilionoidea, with seven families,  
105 namely Papilionidae, Pieridae, Riodinidae, Lycaenidae, Nymphalidae, HesperIIDae (skippers)  
106 and HedyIidae (van Nieukerken *et al.*, 2011). Two recent molecular studies (Regier *et al.*,  
107 2009; Mutanen *et al.*, 2010) strongly supported this grouping, although formerly skippers and  
108 hedyIids were placed in separate superfamilies and the other five families were grouped into  
109 only one superfamily. Skippers are more closely related to hedyIids than to the other  
110 butterflies (Regier *et al.*, 2009; Mutanen *et al.*, 2010), although hedyIids are mainly nocturnal  
111 and the available data (Scoble, 1986; Scoble & Aiello, 1990) suggest that their reproductive  
112 behaviour resembles that of moths. It has been suggested that the reproductive behaviour of  
113 skippers and other butterflies (but not hedyIids) may have evolved independently as an  
114 adaptation to diurnal habits (Sarto i Monteys *et al.*, 2012).

115 Butterflies had always been thought to be unique in their partner-finding, at first based on  
116 visual cues as mentioned above. After the pursuit flight, when the two sexes get together (*i.e.*  
117 in close-range interactions), males release short-range pheromones and there is mounting  
118 evidence that females may also do the same (Wiklund, 2003). However, females lack  
119 conspicuous scent organs, such as the typical sex pheromone glands, which makes the study  
120 of their chemical signals for male recognition and mating particularly difficult (for reviews  
121 see Boppré (1984), Hallberg & Poppy (2003)).

122 Male butterflies use basically two mating strategies, namely perching and patrolling (Scott,  
123 1974; Wiklund, 2003). Perching males (Fig. 1) sit and wait for flying females, which actively  
124 assume the role of searching for males. Perchers are territorial, typically faithful to their

125 perching sites and readily willing to expel other males from their territories, largely by non-  
126 contact aerial interactions. The two ‘fighting’ males circle or hover near each other for a  
127 period of time before one of them flies away from the site. In contrast, patrolling males do not  
128 sit waiting for females, but actively search for them in places where they can be expected with  
129 a certain probability (Davies, 1978; Wickman & Wiklund, 1983; Wiklund, 2003; Kemp &  
130 Wiklund, 2004). Perching and patrolling may not be mutually exclusive and some species can  
131 perform both. Thus, in the speckled wood butterfly, *Pararge aegeria* (Linnaeus), males fight  
132 over sunspot territories on the forest ground; winners gain sole residency of a sunspot and  
133 behave as perchers, whereas losers patrol the forest in search for females (Bergman *et al.*,  
134 2007). In other cases, a male butterfly which usually patrols might behave as a percher, e.g.  
135 on windy or overcast days. After female detection, perchers and patrollers pursue the female  
136 at close range, assessing her size, shape and wing pattern to be certain she is suitable for  
137 mating (Rutowski, 2003; Warrant *et al.*, 2003; Wiklund, 2003). At this close range male  
138 butterflies release pheromones that convey information to the females, inducing them to  
139 respond (mate or reject). Such male scents are produced and/or disseminated in special  
140 structures, the most common being alar androconia, i.e. specialised male scales located on the  
141 forewings, hindwings or both, and ‘hairpencils’, modified scales present on wings or the  
142 abdomen.

143 Male sex pheromones (MSPs) in butterflies have long-been thought to be vital in courtship,  
144 mate-choice or acceptance by females (sexual selection), species isolation and/or recognition  
145 (Boppré, 1984; Costanzo & Monteiro, 2007). In this respect, it is noteworthy that in the  
146 nymphalid butterfly *Bicyclus anynana* (Butler) the MSP composition changes along the  
147 insect life span, a signal which may be used by the insect for male identity and male age  
148 (females prefer to mate with middle-aged rather than younger males) (Nieberding *et al.*,  
149 2012).

150

## 151 **Burnets and Forester moths (Family Zygaenidae) and their reproductive behaviour**

152 The zygaenids comprise four subfamilies and about 1,000 described species worldwide  
153 (Tarmann, 2004; van Nieuwerkerken *et al.*, 2011). With few exceptions, e.g. the nocturnal  
154 *Zygaena nocturna* Ebert and some related species, they include typically day-flying moths  
155 with a slow, fluttering flight. Their partner-finding strategy corresponds to the typical pattern  
156 for moths, with females calling males by releasing long-range sex pheromones (Subchev,  
157 2014). Their sex glands are located at the tip of the abdomen (between segments 8-9, as usual  
158 in moths) (Fig. 2A-B), or on the anterior parts of tergites 3-5 of the abdomen, as found  
159 widespread in the subfamily Procridinae (Hallberg & Subchev, 1997).

160 Visual cues are also important in the mating behaviour of zygaenids, although only in the  
161 short-range phase of the courtship. Thus, in the six-spot burnet, *Zygaena filipendulae*  
162 (Linnaeus), the long-range attraction of males is mediated by female-released pheromones,  
163 but when the flying male is within ca. 50 cm range, then visual cues determine the rest of the  
164 courtship (Zagatti & Renou, 1984). Also, in the vine bud moth *Theresimima ampelophaga*  
165 (Bayle-Barelle) (Procridinae) males attracted to a synthetic sex pheromone dispenser  
166 displayed more copulation attempts when a female model (visual stimulus) was attached to  
167 the dispenser (chemical stimulus) (Toshova *et al.*, 2007). It is uncertain whether optical cues  
168 play a significant role in the rare nocturnal zygaenids, like *Z. nocturna*, since males were  
169 found to reach calling females in the dark, mostly between 21 and 23 h (A. Hofmann pers.  
170 com.).

171 More surprising is the dual partner-finding strategy shown by the five-spot burnet, *Zygaena*  
172 *trifolii* (Esper) (Naumann, 1988; Prinz & Naumann, 1988). The females have typical sex  
173 pheromone glands that release pheromone to attract males in late afternoon. In the morning,  
174 however, they rest atop grasses close to where their cocoons were spun, do not release  
175 pheromones and can be found by males using optical cues exclusively (female wing pattern,  
176 spot colouration and specimen size). In late afternoon, the females move down into the

177 vegetation, where they would not be easily spotted by flying males, and release the  
178 pheromone.

179 The likely evolutionary advantages of the dual partner-finding strategy have been reported  
180 (Naumann *et al.*, 1999). Although it is likely that the dual strategy may be present in other  
181 species of the subgenus *Zygaena*, it is not well-established how widespread this strategy is  
182 among other European *Zygaeninae*. In this context, Hofmann & Kia-Hofmann (2010) noted  
183 that the optical cues used by males of *Z. trifolii* during the morning and occasionally leading  
184 to ‘morning copulae’, cannot be considered as a general strategy and may vary from species to  
185 species depending on ecological circumstances (e.g. altitude, semi-desert, woodland). In this  
186 respect, behavioural studies carried out on *Z. niphona* Butler (Koshio, 2000) and *Z. fausta*  
187 (Linnaeus) (Friedrich & Friedrich-Polo, 2005) revealed that these species did not show the  
188 dual partner-finding strategy but only the widespread combined chemical and optical  
189 afternoon strategy, as described above for *Z. filipendulae*.

190 Notwithstanding, the discovery of the above-mentioned dual strategy in *Z. trifolii* is very  
191 significant from an evolutionary point of view because it was the first documented case in  
192 which a day-flying moth was not using long-range pheromones for partner-finding, at least in  
193 the morning.

194

### 195 **The Castniids or ‘Butterfly-moths’ (Family Castniidae) and their reproductive** 196 **behaviour**

197 The Castniidae are day-flying, brightly coloured and median/large-sized moths, occurring in  
198 the Neotropics, SE Asia and Australia, with only about 110 species described (Edwards *et al.*,  
199 1998). They are currently grouped within the superfamily Cossoidea, with seven families,  
200 namely Brachodidae (little bear moths), Cossidae (cossid millers or carpenter millers),  
201 Dudgeoneidae, Metarbelidae, Ratardidae (Oriental parnassian moths), Sesiidae (clearwing  
202 moths) and Castniidae (van Nieukerken *et al.*, 2011). Initially, Minet (1991) had placed the

203 Castniidae in the superfamily Sesiioidea together with Sesiidae and Brachodidae, but recent  
204 molecular studies grouped the Sesiioidea with some Cossoidea in a large, near-monophyletic  
205 (but internally unresolved) assemblage that included Cossoidea, Sesiioidea and Zygaenoidea  
206 (Regier *et al.*, 2009; Mutanen *et al.*, 2010). Many species in this heterogeneous group are  
207 diurnal.

208 Castniids are interesting Lepidoptera in the following respects:

209 (1) The Neotropical species of castniids remarkably mimic many butterflies living in the  
210 same area in form, colours and habits, and form a truly Batesian mimicry association (Miller,  
211 1986). The levels of mimicry between butterflies and castniids, two groups of  
212 phylogenetically-distant lepidopterans, are unparalleled in the order Lepidoptera and this has  
213 granted to castniids the term ‘butterfly-moths’.

214 (2) Castniid males are territorial and display perching behaviour as butterfly males (Sarto i  
215 Monteys *et al.*, 2012), and references therein), which is also an unparalleled trait in moths.

216 (3) Most importantly, and in contrast to other known moths including day-flying moths,  
217 castniid females appear to have lost their abdominal pheromone glands, so that they do not  
218 release long-range pheromones to attract conspecific males. This evolutionary breakthrough  
219 was first hypothesised by Sarto i Monteys and Aguilar (2005), based on numerous field  
220 observations of the behaviour of *Paysandisia archon*, a large castniid moth (Fig. 3) which had  
221 been introduced into Europe from Argentina, as cited above, becoming a pest of palm trees  
222 (Sarto i Monteys, 2002). Experimental evidence brought forward to confirm the hypothesis  
223 that *P. archon* females do not release long-range pheromones to attract conspecific males was  
224 provided by Sarto i Monteys *et al.* (2012) and Riolo *et al.* (2014), although not without debate  
225 (Delle-Vedove *et al.*, 2014) (see below). The fact that castniids mostly rely on visual cues for  
226 partner-finding, as most butterflies do (see above), was already noticed in the early 1900s by  
227 the German naturalist Adalbert Seitz (Seitz & Strand, 1913).

228

**229                   Territoriality and perching/patrolling behaviour in castniids**

230 *P. archon* males usually perch on palm leaves or cut rachises around the trunk close to the  
231 crown (Fig. 3) (Sarto i Monteys & Aguilar, 2005). When a perching male watches another  
232 male approaching his territorial spot, he immediately takes off towards the intruder and a  
233 pursuit begins. The pursuit flight is very powerful and rapid, and the flight path is generally  
234 straight although right/left shifts may also occur (Sarto i Monteys & Aguilar, 2005). If the  
235 flying pair cross the territory of another male, this third one would immediately join the  
236 pursuit so that the flying group would now be constituted by three individuals, and so on.  
237 These pursuit flights are not long-lasting and males soon fly back to their perching spots.  
238 Most males behave like perchers, i.e. they are faithful to a territory or spot they ‘defend’.  
239 These spots are located within palm-infested plots, where females would be flying around  
240 after emergence and detected by perching males. In Catalonia, NE of Spain, the areas of these  
241 plots are not large (usually less than 3,000 m<sup>2</sup>), and it is unclear how the territorial spots are  
242 shared by competing males, especially when infestation is high. It is likely that males with no  
243 ‘territory’ move away in search of new plots to colonise and females to mate. In this case,  
244 they would behave as patrollers, as supported by our occasional observations of lone-flying  
245 males. As in other castniids, the territoriality of *P. archon* is poorly understood, and thus  
246 several questions remain unanswered, such as: who wins the territorial spot?; how large are  
247 the territorial spots?; or what drives the likely migration of males and females to other palm  
248 plots?. Based in our observations, the mating behaviour of *P. archon* cannot be properly  
249 performed in nature unless large areas are available to the moths, and so studies carried out  
250 only in small insectaries or cages are not suitable for fully understanding the behaviour of  
251 these insects and may lead to wrong conclusions.

252

**253                   Do female castniids have pheromone glands in their ovipositors?**

254 Several morphological, chemical and ethological facts combined appear to demonstrate that  
255 *P. archon* females have apparently lost their pheromone glands. These facts are the following:  
256 (1) The territorial male behaviour described above does not support that female castniids use  
257 long-range pheromones for partner-finding, with vision playing a determinant role in this task.  
258 (2) Hexane extracts of *P. archon* female ovipositors and other female body parts have yielded  
259 no compounds with putative pheromone activity (Acín, 2009; Sarto i Monteys *et al.*, 2012).  
260 Also, analysis of ovipositor extracts of 1- and 24-h virgin females of *P. archon* (N=10) in  
261 hexane resulted in the identification of 24 different compounds but none of them elicited any  
262 significant GC-EAD (gas chromatography-electroantennographic detector) responses on male  
263 antennae (Riolo *et al.*, 2014). The GC-EAD system allows determination of the  
264 electrophysiological activity of every compound eluting from the capillary column when the  
265 outlet of the column is split in a specific ratio (usually 1:1) between the GC detector and the  
266 male antenna.

267 (3) In most Lepidoptera, when female moths adopt the ‘calling’ position, the glandular area  
268 containing the sex pheromone gland is exposed and the pheromone is released (Percy-  
269 Cunningham & MacDonald, 1987; Hallberg & Poppy, 2003). A well-defined periodicity for  
270 calling is widespread in nocturnal and diurnal moths that use long-range chemical  
271 communication (e.g. (Haynes *et al.*, 1983) and references therein). For instance, females of  
272 the nocturnal tobacco budworm *Heliothis virescens* (Fabricius) call during the period 23:30-  
273 02:30 h (Sparks *et al.*, 1979), whereas those of the artichoke plume moth *Platyptilia*  
274 *carduidactyla* (Riley) call mainly between 2 and 6.5 h after the onset of the scotophase  
275 (Haynes *et al.*, 1983). In the diurnal gypsy moth *Lymantria dispar* (Linnaeus), females call  
276 continuously from 10:00 to 22:00 h but some females may continue calling at night during the  
277 scotophase and early photophase (Charlton & Cardé, 1982). In diurnal burnet moths of the  
278 genus *Zygaena*, most females may call for 5 to 10 h per day (A. Hofmann pers. com.).  
279 Therefore, in diurnal moths the periodicity of pheromone release and calling appear to be not

280 as discrete as in the nocturnal moths, but in all cases, females expose their glandular area  
281 during several hours to release the pheromone. Nothing similar has been observed in *P.*  
282 *archon* females. We have frequently noticed that females quickly extrude/retract their  
283 ovipositors for some seconds, but never adopt a typical ‘calling’ position that implies keeping  
284 ovipositors extruded for a long period of time. Riolo et al. (2014) have also reported that  
285 females perform the extrude/retract action very often throughout their lives, but it appears not  
286 to be related to calling behaviour. These authors concluded that ovipositor extrusion might be  
287 involved in the female physiological state (i.e. egg load) or in thermoregulation activity, as  
288 observed in the hawk moth *Eumorphia achemon* (Drury).

289 (4) The antennae of castniids and butterflies are strikingly similar, with no apparent sexual  
290 dimorphism. The antennae are the ‘noses’ of moths and butterflies and their morphology and  
291 sensilla are suited to their needs (Hansson, 1995; Hallberg & Poppy, 2003). Moth antennae  
292 are generally sexually dimorphic, and those of males contain a certain population of sensilla  
293 housing olfactory receptor neurons (ORNs) sensitive to the pheromone components.  
294 Butterflies, in turn, possess thin and clubbed antennae and display no sexual dimorphism.  
295 They use sex pheromones only for close-range communication and therefore lack the highly  
296 sensitive detection system found in male moths. In a Scanning Electron Microscopy (SEM)  
297 study of male and female antennal sensilla of several day-flying Lepidoptera, namely sesiids,  
298 butterflies (pierids and skippers) and castniids (*P. archon*), Sarto i Monteys *et al.* (2012)  
299 concluded that *P. archon* male antennae were unsuited to detect long-range pheromones.

300 (5) The abdominal tip (segments 8 and 9-10) of female Lepidoptera forms a telescope-type  
301 oviscap, commonly called ‘ovipositor’. In most Cossioidea, the intersegmental cuticle  
302 connecting segments 8 and 9 is long when the ovipositor is fully extended. Below that cuticle  
303 are located the glandular epithelial cells that produce pheromones. In sesiids, which are very  
304 closely related to castniids, such cuticle shows many buds, each topped with one thin and  
305 curved ‘hair’ (Fig. 4) that is supposed to help release the pheromone (Tatjanskaitė, 1995).

306 However, SEM studies on *P. archon* ovipositors showed that the 8-9 intersegmental cuticle  
307 was devoid of such structures, and instead multiple longitudinal smooth folds could be seen,  
308 simply allowing for ovipositor expansion, as if there were no pheromone glands underneath  
309 (Figs. 5, 6) (Sarto i Monteys *et al.*, 2012). More recent histological studies confirmed this  
310 assumption as there was no evidence of pheromone gland tissues below the intersegmental  
311 cuticle of the *P. archon* ovipositor (Riolo *et al.*, 2014).

312 The latter five facts combined appear to clearly indicate that, as in female butterflies, *P.*  
313 *archon* females do not possess any abdominal gland to release a volatile pheromone to attract  
314 conspecific males, and this may likely be widespread in Castniidae. However, against this  
315 assumption, Delle-Vedove *et al.* (2014) claimed that *P. archon* females ‘call’ males using a  
316 pheromone identified as (E,Z)-2,13-octadecadien-1-yl acetate from ovipositor extracts of  
317 sexually mature females but no further details were given. They also concluded that the insect  
318 displays a “moth-butterfly hybrid” strategy relying on both chemical and visual clues. The  
319 chemical thought to be the female sex pheromone of *P. archon* had been identified in females  
320 of a number of Sesiidae, especially of the genus *Synanthedon* Hübner, and in females of the  
321 leopard moth *Zeuzera pyrina* (Linnaeus) (Cossidae) (El-Sayed, 2014). In this respect, it  
322 should be noticed that this pheromone was used in one-day field tests carried out at two sites  
323 in Catalonia to check a possible attractant effect on *P. archon* males. The tests took place in  
324 sunny days of mid-July and observations lasted continuously from 12 to 15 h, when *P. archon*  
325 males are particularly active. Three filter papers and three paper dummies depicting an adult  
326 of *P. archon* were impregnated with 1 µg of *Z. pyrina* pheromone dissolved in hexane. Such  
327 gadgets were set spaced 8 m apart on palm trunks (*Trachycarpus fortunei* (Hook.) H. Wendl.  
328 and *Chamaerops humilis* Linnaeus) within commercial gardens heavily infested by *P. archon*.  
329 At both sites not a single *P. archon* male approached to either lure suggesting that this  
330 pheromone does not attract males of this castniid (Vassiliou & Sarto i Monteys, 2014).

331

332 **Mating behaviour of *P. archon* at close range**

333 The courtship behavioural sequence of *P. archon* was first described in detail by Sarto i  
334 Monteys *et al.* (2005, 2012) as the following six consecutive steps: **1. Localization/pursuit.**

335 A territorial perching (or maybe patrolling) male locates a flying female that has entered his  
336 territory and pursues her. The pair fly together along the palm rows close to each other (about  
337 10-15 cm) and at heights near the palm crowns. **2. Alighting.** Then, the pair alight, led by the  
338 female, facing up on upright surfaces (a palm leaf or crown, the sides of a mesh tent, etc.).

339 The female may walk shortly until reaching a spot where she can rest comfortably, folding her  
340 wings in the common noctuid position, and if the male is accepted, she will remain still for  
341 the rest of the courtship. **3. Orientation.** The male, which alighted a few cm below the female  
342 and has been closely following her movements, moves up and approaches to her with his  
343 wings folded. There is no male flickering. **4. Thrusting.** While approaching the female, the  
344 male usually touches the edges of her wings with his head/antennae, sometimes inserting the  
345 antennae briefly under her wings. Also, his antennae and/or legs may also make contact with  
346 the side of the female. Both sexes keep their wings fully folded. **5. Attempting.** The male  
347 curls his abdomen and opens up his clasping genital valvae in order to contact and grasp the  
348 female copulatory orifice to accomplish the copula. **6. Copulation.** While in copula, both  
349 sexes stay motionless, facing up side by side, and with the male in a lower position than the  
350 female.

351 Recently, the courtship behaviour of *P. archon* has received further attention (Delle-Vedove  
352 *et al.* 2012, 2014; Riolo *et al.*, 2014) with both research groups providing a deep quantitative  
353 analysis of the behaviours involved (up to 14 defined by the former authors and 20 by the  
354 latter). Both groups also provided kinetic diagrams of courtship behaviour indicating, for each  
355 behavioural step, the frequency of transitions to other courtship steps. They basically  
356 confirmed the main six behavioural steps described above, including in the sequence analysis  
357 all types of behaviours displayed by both sexes during courtship. One of such behaviours was

358 the ovipositor extrusion. According to Delle-Vedove *et al.* (2014) the extrusion (1-10 times  
359 during periods of 13-48 s each before displaying another behaviour type) was synonymous to  
360 ‘calling’, i.e. females emitting a sex pheromone to attract males. In contrast, according to  
361 Riolo *et al.* (2014), extrusion of the ovipositor was not related to calling but possibly to the  
362 female physiological state or to thermoregulation activity, as cited above.

363 Other behaviours during *P. archon* courtship which deserve special mention are **antenna**  
364 **cleaning** (in both sexes) and **male ‘scratching’**. Females clean their antennae about 3 times  
365 more often than males, regardless of courtship outcome (Riolo *et al.*, 2014), and because  
366 females have a higher olfactory sensory surface area in their antennae than males (Sarto i  
367 Monteys *et al.*, 2012), this suggests that the perception of volatiles is highly important to *P.*  
368 *archon* females – probably more than it is for males whose antennae are unsuited for detecting  
369 long-range pheromones (see above).

370 Male ‘scratching’ is an interesting behaviour introduced by Frérot *et al.* (2013) and Delle-  
371 Vedove *et al.* (2014). When performed, the male walks and scratches/rubs its midlegs rapidly  
372 on the substrate, supposedly helping the release of a male pheromone produced and/or held in  
373 the midlegs (see below) and inducing the female to take-off and initiate a hovering flight. The  
374 authors, however, do not provide any evidence that such ‘scratching’ implies releasing  
375 pheromone from the male midlegs nor its unambiguous association to some kind of response  
376 by the female.

### 377 **Castniids androconia and likely role of *P. archon* male putative pheromones**

378 The structures presumed to be involved in the reproductive behaviour of castniid males have  
379 been poorly studied, although four types have been so far identified in the Neotropical species  
380 of the subfamily Castniinae: (1) a complex and very large abdominal (sternal) androconial  
381 organ with a brush in the hindlegs, formed by long, soft, pale scaling on the inner surface of  
382 femur, tibia and basitarsus, which supposedly helps distribute the gland secretion over the  
383 sternites in the abdomen; (2) large paronychial (i.e. bristle-like structures) on the pulvilli of

384 midlegs pretarsi; (3) notably enlarged midlegs basitarsi, generally (but not exclusively) in  
385 combination with large midlegs pretarsal paronychia (see Fig. 7A-D); (4) alar androconial  
386 organs located either on the underside of the forewings or the upperside of the hindwings  
387 (Jordan, 1923; Le Cerf, 1936). Whereas structures 3 and 4 seem to be common to most  
388 castniids, those individuals bearing structure 1 lack structure 2, and viceversa (Jordan, 1923);  
389 *P. archon* for instance holds structures 2, 3, and 4.

390 Very few reports have been found in the literature about the possible presence of sex  
391 pheromones in the Castniidae family and only concern those of females (Rebouças *et al.*,  
392 1999). It was not until 2012 that three putative male pheromones were reported for the first  
393 time from *P. archon* male wings (Sarto i Monteys *et al.*, 2012). The compounds were  
394 identified as (Z,E)-3,7,11-trimethyl-2,6,10-dodecatrienal ((Z,E)-farnesal), the corresponding  
395 E,E isomer ((E,E)-farnesal), and (E,Z)-2,13-octadecadienol, which elicited significant GC-  
396 EAD responses on female antennae. Farnesals were found in the forewings and hindwings of  
397 males only (Fig. 8), although the relative amount detected in both types of wings was highly  
398 variable. The biological significance of farnesals in the male wings of *P. archon* is unknown,  
399 but it is noteworthy that both isomers of the chemical were identified in male glands located  
400 in the forewings of the rice moth *Corcyra cephalonica* and elicited walking attractancy on  
401 females (Zagatti *et al.*, 1987). We could hypothesise that these chemicals may be used by *P.*  
402 *archon* females for sexual selection, as occurs in the nymphalid butterfly *Bicyclus anynana*  
403 whose females use n-hexadecanal, one specific component of the male sex pheromone, for  
404 that purpose (Nieberding *et al.*, 2012).

405 In female castniids, sexual selection may also be likely influenced by their monandrous  
406 condition. Thus, it is known that most *P. archon* females behave monandrously with only a  
407 few of them (6%) mating twice, always before laying their first eggs (Delle-Vedove *et al.*,  
408 2012). This is probably due to their low fecundity: *P. archon* and other castniid females only  
409 lay about 110-130 eggs in their lifetime (Sarto i Monteys & Aguilar, 2005). Therefore, the

410 monandrous female must choose which type of males can help her reproduce successfully,  
411 and she will likely prefer virgin to non-virgin males, since the former are likely to provide  
412 bigger spermatophores with higher amounts of sperm, proteins and lipids to be used in egg  
413 production (Lauwers & Van Dyck, 2006). In the speckled wood butterfly, *Pararge aegeria*,  
414 also a territorial species, copulations with non-virgin males lasted on average 5 times longer  
415 than with virgin males, resulting in a 3 times smaller spermatophore (Lauwers & Van Dyck,  
416 2006). The number of eggs laid and the female life span were not affected by the mating  
417 status, but there was a significant effect on the number of living caterpillars as copulations  
418 with virgin males resulted in higher larval offspring.

419 It is known that males from several lepidopteran families, either moths (e.g. Arctiinae-  
420 Noctuidae) or butterflies (Danainae and Ithomiinae-Nymphalidae), accumulate substances  
421 from the host plant at the larval stage as a defence mechanism against predators (Schulz *et al.*,  
422 2004). Many of these chemicals can be subsequently used as pheromone precursors (Eisner  
423 & Meinwald, 1987; Trigo *et al.*, 1994). Farnesals are present in plants of the families Araceae,  
424 Orchidaceae, Cactaceae, Rubiaceae and others, but have not yet been found as such in palm  
425 trees (Arecaceae). The latter, which are the only food plants of *P. archon* larvae, contain,  
426 however, relatively large amounts of (Z) and (E)- $\beta$ -farnesenes (see f.i. Knudsen, 2002), and  
427 these compounds could be biosynthetic precursors of the farnesals found in *P. archon* through  
428 the corresponding intermediate farnesols.

429 The presence of (E,Z)-2,13-octadecadienol in *P. archon* was also noticed by Frérot *et al.*,  
430 (2013) in surprisingly huge amounts ( $\mu\text{g}$ ) from male midlegs. This compound was identified  
431 by its NMR spectrum and GC-MS, and the authors suggested that the midlegs basitarsi were  
432 probably the sites of emission. This dienol is a component of the female sex pheromone or  
433 attractant of some Lepidoptera, namely some species of the family Tineidae, such as the  
434 common clothes moth, *Tineola bisselliella* (Hummel), some species of *Prochoreutis*  
435 Diakonoff & Heppner (Choreutidae), and several clearwing moths (Sesiidae), this latter

436 family closely related to that of castniids (El-Sayed, 2014). The role of the dienol in the  
437 chemical communication of *P. archon* is likely different to that of the farnesals. Because the  
438 alcohol triggers significant responses in male and female antennae (Sarto i Monteys *et al.*,  
439 2012), it might act as a ‘territorial’ pheromone, i.e. males could use it to let other males know  
440 about its presence, either around where they are perching and/or when they alight close to the  
441 female in the close-range phase of the courtship.

442 Females, in turn, may perceive the dienol on flight during the pursuit phase of the courtship  
443 or while approaching a male territory. Since male and female *P. archon* antennae are not  
444 suited to detect long-range pheromones, as cited above, the latter option would apply only at  
445 rather short distances.

446 In summary, we have reviewed the partner-finding strategies of three day-flying lepidopteran  
447 groups, namely butterflies (superfamily Papilionoidea) and the moth families Zygaenidae and  
448 Castniidae, and compared their mating behaviour with that of other typical diurnal and  
449 nocturnal moth families. Day-flying moths have been subject to analogous evolutionary  
450 pressures than those of butterflies, and consequently, at least in some of them, females behave  
451 as if they had lost their pheromone glands, not releasing long-range pheromones to attract  
452 conspecific males. In fact, as in butterflies, female castniids appear to have lost their  
453 pheromone glands, an attribute with no parallel in the world of moths, and this certainly  
454 represents an evolutionary breakthrough to what has been known about sexual communication  
455 in Lepidoptera. However, as pointed out, we are still far from fully understand the chemical  
456 communication of day-flyers, particularly of castniids, and more work should be devoted to  
457 unveiling the function of the diverse structures allegedly involved in their reproductive  
458 behaviour and the specific role of their sex pheromones. Knowledge of the chemical  
459 communication of day-flying Lepidoptera is also important in natural resource management,  
460 both for control of new invasive species, like *P. archon*, or to protect specific endangered  
461 populations.

462

463

**Acknowledgments**

464 We thank CSIC for a postdoctoral contract to C.Q. We thank J.-B. Peltier for help with  
465 literature and *P. archon* cocoons, L. Aguilar for providing information on *P. archon*'s infested  
466 plots in Catalonia. We also acknowledge A. Hofmann and G. Tarmann for helpful literature  
467 and/or comments provided on Zygaenidae reproductive behaviour. This work was partially  
468 supported by MINECO (AGL2012-39869-C02-01) with assistance from the European  
469 Regional Development Fund.

**Table 1. Generalized comparison of partner-finding strategies, pheromone uses and other related traits in nocturnal and diurnal lepidopteran groups**

	FLIGHT PERIOD				
	NOCTURNAL <sup>1,2</sup>	DIURNAL <sup>1</sup>			
Lepidoptera group	Most moth families	Some moth families	<b>Zygaenidae</b> moths ( <i>Zygaena</i> genus) <sup>3</sup>	<b>Castniidae</b> moths	<b>Butterflies</b> (excluding hedyliids)
Partner-finding strategy	Moth-like	Moth-like	Dual or moth-like	Butterfly-like	Butterfly-like
Female-released long distance pheromones to attract males	Yes	Yes	Yes, but may not use them in the morning	Most likely absent but evidence is still lacking	No
Presence of female pheromone glands in the ovipositor <sup>4</sup>	Yes	Yes	Yes	No	No
Perching and/or patrolling behaviour in males	No	No	Yes, though males patrol only in the morning	Yes	Yes
Main sense used by males to detect females at long distance	Olfaction	Olfaction	Vision in the morning, olfaction in the afternoon	Vision	Vision
Clubbed antennae + very reduced olfactory sensory surface on antennae	No	No	No	Yes	Yes
Male-released pheromones in close range courtship	Yes	Yes	Most likely (evidence still lacking)	Most likely (evidence still lacking)	Yes

<sup>1</sup>Some species within a 'nocturnal' or 'diurnal' family have adapted to fly in the twilight or prefer to fly in shaded environments

<sup>2</sup>Some species within a typical 'nocturnal' family have adapted to fly in day time

<sup>3</sup>Except *Zygaena nocturna* and some related species

<sup>4</sup>Exceptionally some groups have ovipositor-like pheromone glands in other parts of the abdomen or thorax
