15

### Abstract

16 Purpose: The relation between stock market volatility and macroeconomic fundamentals for G-7  
17 countries is analyzed using monthly data over the period from July 1985 to June 2015.

18  
19  
20 Methodology: The empirical methodology is based on two steps: in the first step, we obtain the  
21 conditional volatilities of stock market returns and macroeconomic variables through the  
22 GARCH family of models. We also incorporate the impact of early 2000s dotcom and the global  
23 financial crises. In the second step, we estimate multivariate vector autoregressive (VAR) model  
24 to analyze the dynamic relation between stock markets return and macroeconomic variables.  
25  
26

27 Findings: The overall results for G-7 countries indicate a weak volatility transmission from  
28 macroeconomic factors to stock market volatility at individual level but the collective impact of  
29 volatility transmission is highly significant. Although, the results of block exogeneity indicate a  
30 bidirectional causality except for the UK, but the causal linkage is quite weak from stock market  
31 to macroeconomic variables. Moreover, the local financial variables excluding interest rate are  
32 closely integrated, and the volatility of industrial production growth and oil price are identified as  
33 the most significant macroeconomic factors that could possibly influence the directions of stock  
34 markets.  
35  
36

37 Originality: This research establishes the nature of the links between stock market and  
38 macroeconomic volatility. Research to date has been unable to satisfactorily establish the  
39 empirical nature of such links. We believe this paper begins to do this.

## 1. Introduction.

Over the past few decades, as international stock markets have surged significantly, the issue of stock market volatility has become more prominent, especially during high volatility periods. The analysis of financial market volatility is crucial for asset pricing, risk management and fund allocation (Martens and Zein, 2004). Officer (1973) mentions that US stock market volatility was unusually high from 1929 to 1939 when compared to periods before and after. This view is supported by Schwert (1989), who reports that stock market volatility was high during major episodes in US economic history such as WWI, the great depression of 1929, WWII, the OPEC oil shocks and similar events. Karunanayake, et al. (2010) and Manda (2010) also report similar results regarding stock market volatility during the global financial crisis of 2008. Apart from such major events that significantly affect stock market volatility, noise trading and investor overreaction to macroeconomic news can also impact such volatility (Liljeblom and Stenius, 1997; French and Roll, 1986). Thus, understanding the relations between stock market and macroeconomic volatility is of importance to investors and other stakeholders, including policy makers, in order to know which factors affect stock market volatility and of any subsequent impact on the economy (Corradi *et al.*, 2013). This issue forms the focus of the paper.

In relation to macroeconomic fundamentals, the initial work of, for example, Fama (1981), Schwert (1981), Geske and Roll (1983) and Pearce and Roley (1983) provides the theoretical underpinnings for the dynamic linkage between macroeconomic variables and stock market returns. Since then, an extensive discussion in the finance and economics literature on the sensitivity of stock markets to the macroeconomic uncertainty in both developed and emerging economies has occurred. The state of the literature is summed up aptly by Chen et al. (1986) who notes that we are yet unable to determine which economic variables are responsible for the

1  
2  
3 movement of stock returns. In contrast, however, Chan et al. (1998) dismiss the empirical  
4 relevance of macroeconomic fundamentals on security returns. They argue that such exogenous  
5 factors make a poor showing in asset pricing and are as useful as any randomly generated series.  
6  
7

8  
9  
10 Although, the connection between systematic risk factors and the volatility of stock  
11 returns is intuitively appealing and can be theoretically motivated (Boudoukh and Richardson,  
12 1993), there exists a large gap between the theoretical and empirical identification of such  
13 macroeconomic factors. The current study tries to bridge this gap by analyzing the volatility  
14 connectedness between stock returns and macroeconomic variables.  
15  
16  
17  
18  
19  
20  
21

22 A sizeable empirical work has been advanced to study the linkage between the volatility  
23 of stock returns and macroeconomic fundamentals. For example, Schwert (1989) examines the  
24 relation of stock market volatility with the volatility of real and nominal macroeconomic series,  
25 financial leverage and trading volume by using monthly data from 1857-1987 for the US.<sup>1</sup> He  
26 argues that although the volatilities of interest rate and corporate bond returns are correlated with  
27 the volatility of stock market returns, none of these play a dominant role in explaining the  
28 behavior of stock market volatility. Further studies examine the behavior of stock returns and  
29 inflation and the money supply (e.g., Fama, 1981; Geske and Roll, 1983; Pearce and Roley, 1983  
30 find a negative relation). Erdem, et al. (2005) find a negative volatility spillover impact of  
31 inflation and a positive spillover impact of interest rate, exchange rate, money supply and  
32 industrial production on stock prices.  
33

39  
40  
41  
42  
43  
44  
45  
46  
47

48 Like Schwert (1989), Morelli (2002) finds only a weak connection between stock market  
49 volatility and macroeconomic risk factors, notably industrial production index and money  
50 supply. Whereas, Diebold and Yilmaz (2007) report a positive linkage between macroeconomic  
51  
52  
53  
54

---

55  
56 <sup>1</sup> The initial work of Officer (1973), Black (1976), Shiller (1981), Fama (1981), Schwert (1981) Chen et al. (1986),  
57 Abel (1988), Campbell and Shiller (1988), French and Roll (1986) and Schwert (1989) laid the foundation for the  
58 work examining the nexus between stock market returns and macroeconomic uncertainty.  
59  
60

1  
2  
3 volatility and stock market volatility in a global perspective. Similarly, Chinzara (2011) finds a  
4  
5 positive volatility spillover from the T-bill rate, exchange rate and gold price while negative  
6  
7 volatility spillovers arise from inflation. Narayan and Gupta (2015) find that the oil price is a  
8  
9 significant predictor of stock returns. By using monthly data over the period of one and half  
10  
11 century long for US, they find that negative oil price shocks are more significant in predicting  
12  
13 stock returns as compared to positive shocks. Diaz et al., (2016) also document a negative  
14  
15 response of stock market volatility to oil price volatility.  
16  
17  
18

19  
20 The main motivation of our research is to examine how macroeconomic volatility affects  
21  
22 stock market volatility in G-7 countries. Our research will thus compliment and extend the  
23  
24 existing literature (e.g., Wongbangpo and Sharma, 2002; Diebold and Yilmaz, 2007; Yartey,  
25  
26 2008; Diaz, et al., 2016), which will also provide a point of comparison, especially given the  
27  
28 number of crises that have occurred over the last 30-years period.<sup>2</sup> Of perhaps particular  
29  
30 relevance is the impact of the two most recent crises that began with the bursting of the dotcom  
31  
32 bubble as well as the global financial crisis. Moreover, while the work of Diebold and Yilmaz  
33  
34 (2007) covers a wide range of markets, none of the previous research considers the impact of  
35  
36 crisis periods on aggregate stock market returns in the framework of macroeconomic  
37  
38 fundamentals.  
39  
40  
41  
42

43 The present study contributes in several ways; first, it uses an updated monthly data set  
44  
45 covering the last 30-years for the G-7 countries, except France and Italy.<sup>3</sup> The use of both  
46  
47 monthly data and a long sample period should ensure robust results that would help financial  
48  
49  
50

---

51  
52 <sup>2</sup> The most prominent crises that took place during our sample period are OPEC collapse in 1986, Black Monday on  
53  
54 October 19, 1987, early 1990s recession, Japan stock market collapse in early 1992, Asian financial crises, Russian  
55  
56 and Brazilian financial crises, Argentina economic depression, dotcom bubble crash, 9/11 terror attacks, global  
57  
58 financial crises of 2008, Russian oil market crash and the euro debt crisis.

59 <sup>3</sup> Data availability problem restricted us to use 30-years data for France and Italy. For France, we have used data for  
60  
almost 25-years monthly data that starts from January 1990 to June 2015 while for Italy we have used 18.5-years  
monthly data that covers from December 1997 to June 2015.

1  
2  
3 analysts and policy makers in improved decision-making. Second, we consider the effect of  
4 crisis periods through the inclusion of two dummy variables for the early 2000s crisis and global  
5 financial crisis of 2008 respectively. Third, we investigate the relation between the volatilities of  
6 stock market and macroeconomic variables (industrial production, money supply, interest rate,  
7 inflation, exchange rate and oil price) in a multiple country perspective, allowing us to make  
8 comparisons. Overall, we hope that the findings of this study will be of interest to investors,  
9 financial analysts and policy makers.

## 30 **2. Data**

### 31 *2.1. Data and variables*

32 The stock markets data used in this study are comprised of monthly indices of aggregate stock  
33 markets of G-7 countries.<sup>4</sup> The data is obtained over the time-period from July 1985 to June  
34 2015. The time series plots of the stock market indices are displayed in Figure 1 and indicates  
35 that stock market indices follow a random walk pattern. As can be observed, while there are  
36 numerous up and down movements there are two noticeable downward swings for all G-7  
37 countries except Japan, which has experienced less stock market growth since the 1980s. These  
38 coincide with the early 2000s dotcom crash and the global financial crisis.

55  
56 <sup>4</sup> Dow Jones Industrial Average (DJIA) Index for USA, Financial Times Stock Exchange 100 Index for UK, Toronto  
57 Stock Exchange Index for Canada, Nikkei225 Index for Japan, German Deutscher Aktien Index(GDAXI) for  
58 Germany, CAC40 Index for France and FTSE MIB-30 Index for Italy. The data is obtained from DataStream.  
59  
60

1  
2  
3 consumer price Index (CPI), broad money supply (M2), treasury bill rate (TBR),<sup>5</sup> exchange rate  
4 with respect to the US dollar (ER)<sup>6</sup> and crude oil price in local currency (OIL).<sup>7</sup> This selection of  
5 the variables is based on the theoretical relevance of these variables to the stock market index as  
6 supported by the existing literature (Schwert, 1989, Morelli, 2002; Flannery and Protopapadakis,  
7 2002; Gan, et al. 2006; Chinzara, 2011; Hsing and Hsieh, 2012; Su et al., 2014; Kumari and  
8 Mahakud, 2015). All the data series are converted into growth form by using first-difference  
9 logarithmic transformation ( $\Delta \text{Ln}Y_t = \text{Ln}Y_t - \text{Ln}Y_{t-1}$ ). Majority of macroeconomic data series and  
10 stock market indices for G-7 countries are collected from the online Thomson Reuters  
11 DataStream and CEIC global data base.<sup>8</sup> We also used Organization of Economic Co-operation  
12 and Development (OECD) data source to collect the missing data on short term interest rate for  
13 Japan, France and Italy.

## 32 *2.2. Stability diagnostics for G-7 stock markets return*

33  
34 Our data for the G7 stock markets covers a history of three decades. Therefore, it is possible that  
35 the data contains structural breaks. For this purpose, we estimate the recursive residuals from an  
36 AR model (discussed below) with plus/minus two standard errors, which are displayed in Figure  
37 2. Evident in the plots of the recursive residual are various low and high extremes. Of particular  
38 interest are those that cross the standard error bounds, which appear evident during the stock  
39 market crash in 1987, Asian financial crisis, early 2000s crisis and the global financial crisis.  
40  
41  
42  
43  
44  
45  
46  
47  
48  
49  
50  
51

---

52 <sup>5</sup> Six months Treasury Bill rate has been used for USA, UK, Canada and Italy and Short term interest rate collected  
53 from OECD website (<https://data.oecd.org/>) for Japan, Germany and France.

54 <sup>6</sup>Exchange rate for USA has been taken as units of USD per Euro

55 <sup>7</sup>Oil Price is the WTI spot price in local currency, which is calculated using the exchange rate as per USD.

56 <sup>8</sup>CEIC is a European institutional investor company founded in 1992 that provides most expansive and accurate  
57 economic and financial data about the emerging and developed markets. The CEIC global database was accessed  
58 from the School of Management, university of Chinese Academy of Sciences Beijing, China.  
59  
60

Therefore, the current study uses dummy variables to captures the impact of crises periods.<sup>9</sup>

For consistency, we also consider a similar exercise for the macroeconomic variables, to illustrate Figure 3 reports the plots for the US. As can be observed from this figure, we can see the potential for breaks occurring over the same time-period as those for the stock returns. Notably, this is for the financial crisis period and, to a lesser extent, the bursting of the dotcom bubble. Thus, the dummy variables we include, as noted above, appear to be appropriate for the macroeconomic series.<sup>10</sup>

### 2.3. Descriptive summary and unit root tests

Descriptive statistics and unit root test results for the stock returns and macroeconomic growth rates are presented in Table 1. The results indicate that the average of stock market return is highest for US and Germany, followed by Canada, UK, France, Japan and Italy. The average stock market return for Italy not only stands lowest in the list of G-7 countries but is in fact negative, while Italy also has the highest standard deviation. The stock markets of the US, UK and Canada have a relatively lower standard deviation compared to the markets of Japan and Germany. Overall, we can nonetheless observe the usual characteristics whereby the financial data are more volatility than the macroeconomic data. For unit root testing, both the Augmented-Dickey Fuller (ADF) and Phillips-Perron (PP) tests show that all the growth series are stationary.<sup>11</sup> Ljung-Box (LB) tests for return series and squared return series were also performed to check the serial correlation and ARCH effect, and the results of these tests justify the

---

<sup>9</sup> The current study only uses two dummy variables that captures the impact of early 2000s crisis period and the global financial period of 2008 for all G-7 countries. Although, for Japan there appears to be no stability problem during the early 2000s, but for sake for uniformity of dummy selection, we include this dummy for Japan. The insignificance of the dummy variable for Japan during the early 2000s crisis period will also serve as a validity check for this dummy variable.

<sup>10</sup> The plots for the remaining countries are available upon request.

<sup>11</sup> For the sake of completeness, the levels of the series all contain a single unit root.

application of GARCH models to capture the volatility of monthly data series for stock market returns and other macroeconomic variables.

### 3. Methodology

To analyze the dynamic relation between stock market volatility and macroeconomic risk factors we use a vector autoregressive (VAR) model. A significant body of the literature (Liljeblom and Stenius, 1997; Errunza and Hogan, 1998; Morelli, 2002; Chinzara, 2011; Kumari and Mahakud, 2015) has previously considered this approach. Prior to the application of the VAR model, we first capture the stock market and macroeconomic volatilities using a GARCH model.

#### 3.1. GARCH model specifications

The autoregressive conditional heteroscedasticity (ARCH) model was introduced by Engle (1982) before Bollerslev (1986) extended the model to the generalized ARCH (GARCH) model. This model employs a maximum likelihood procedure and allows the conditional variance to vary over time. This model is now widely used to capture the volatility clustering effect observed in many data series. In the application of the model here, we include two dummy variables to capture the effect of the crises noted above.<sup>12</sup> The GARCH(p,q) model is specified as follows:

$$r_t = \mu_t + \sum_{i=1}^k a_i r_{t-i} + \varepsilon_t, \quad \varepsilon_t / I_{t-1} \square N(0, h_t) \quad (1)$$

<sup>12</sup> *Dum*<sub>1</sub> is used to account for the early 2000s crises originating from the US dotcom bubble crash and the 9/11 terror attacks. The dummy covers the period from March 2000 to October 2002, and almost all G-7 countries were affected over this period. *Dum*<sub>2</sub> is used to capture the global financial crisis (GFC) that cover the period from July 2007 to June 2009. In terms of other possible dummies, an obviously period would be 1987. However, we do not include a dummy here. This is because, although, there was a market crash on October 19, 1987 and the Dow Jones industrial average index plunged about 500 points, the market partially rebounded the next day. Moreover, there was no lasting economic effect, as economic growth continued to be positive. Hence, this period differs from the dotcom and financial crisis periods that had a longer lasting economic impact.

$$h_t = \omega_i + \sum_{i=1}^p \alpha_i \varepsilon_{t-i}^2 + \sum_{j=1}^q \beta_j h_{t-j} + \gamma_1 Dum_1 + \gamma_2 Dum_2 \quad \text{and } \omega > 0, |\alpha_i + \beta_j| < 1 \quad (2)$$

Where, equation (1) is an appropriate mean equation with  $\mu_i$  constant and  $\alpha_i$  coefficient of lagged returns. The current innovation term,  $\varepsilon_t$  is conditioned on a previous information set  $I_{t-1}$  with zero mean, a variance  $h_t$  and is serially uncorrelated,  $r_t$  and  $r_{t-i}$  denote the current and lagged returns respectively. Equation (2) is a GARCH(p,q) variance equation, where  $h_t$  is the conditional variance,  $\omega_i$  is constant,  $\alpha_i$  is the coefficient of the lagged squared residuals from the mean equation and  $\beta_j$  is the coefficient for the lagged conditional variance.  $Dum_1=1$  for the early 2000s crises period, otherwise 0,  $Dum_2=1$  if for the GFC period, otherwise 0 and  $\gamma_1$  and  $\gamma_2$  are the coefficients of dummy variables respectively.

One assumption underlying the standard GARCH model is the symmetry of shocks on volatility. However, it is argued that negative shocks should have a greater impact on volatility than positive shocks of an equal magnitude. Therefore, we consider the exponential-GARCH (EGARCH) model of Nelson (1991). The model is given by:

$$\log(h_t) = \omega_i + \sum_{i=1}^q \alpha_i \left[ \frac{\varepsilon_{t-i}}{\sqrt{h_{t-i}}} - E\left(\frac{\varepsilon_{t-i}}{\sqrt{h_{t-i}}}\right) \right] + \sum_{k=1}^m \gamma_k \frac{\varepsilon_{t-k}}{\sqrt{h_{t-k}}} + \sum_{j=1}^p \beta_j \log h_{t-j} + \varphi_1 Dum_1 + \varphi_2 Dum_2 \quad (3)$$

Where  $\gamma_k$  is the coefficient of asymmetric component and if it is significant and negative then negative (or bad news) brings higher volatility compared to positive news of the same magnitude. In the empirical application below we consider both the GARCH and EGARCH models and select the preferred model according to Akaike Information Criterion (AIC).

### 3.2. VAR Models

The specification of the VAR model to analyze the relation between the conditional volatility of stock markets and macroeconomic variables is as follows.

$$h_{it} = C_i + \sum_{s=1}^m A_s h_{it-s} + \varepsilon_{it}, \text{ and } i = 1, 2, 3, \dots, 7 \quad (4)$$

Where,  $h_{it}$  is the time varying column vector of stock market volatility and macroeconomic variables volatilities of G-7 countries.  $c_i$  is a  $7 \times 1$  deterministic component of a constant,  $m$  is the lag length for  $7 \times 7$  matrix coefficients and  $\varepsilon_{it}$  is  $7 \times 1$  residual vector which is not correlated to the past values of  $h_{t-s}$  contemporaneously.

Although, the VAR model is a very useful technique to examine interrelations between variables, the interpretation of the results can become complicated when the coefficient sign on variable changes across lags. Thus, to determine the impact on future values on other variables in the VAR system we examine the impulse response functions (IRFs) and the forecast variance decompositions.

## 4. Empirical Results and Discussion

### 4.1. GARCH models results and discussion

GARCH models are estimated for all stock markets return and macroeconomic variables for the G-7 countries with the results are presented in Table 2. The conditional mean model (not reported) was estimated according to an ARMA specification.<sup>13</sup> The results of the volatility models with dummy variables show evidence volatility persistence in all the stock return and macroeconomic growth series except for exchange rate and oil prices for France and CPI and exchange rate for Italy. The results of EGARCH model show clear evidence of asymmetry in all the stock markets return except UK. In case of macroeconomic variables, the asymmetry coefficient ( $\gamma$ ) of industrial production, short-term interest rate and oil price is significant for

---

<sup>13</sup> In most of the series we only added a AR(1), MA(1) or ARMA(1,1) in the mean equation in order to ensure a white noise error term although in a few cases the AIC and SIC values were lowest at higher order ARMA process.

1  
2  
3 most G-7 countries. Whereas, the asymmetry coefficient of money supply, inflation and  
4 exchange rate is insignificant for all countries except for CPI for UK that has significant  $\gamma$ . The  
5 results of EGARCH model show that the overall response the volatilities of stock market returns  
6 and macroeconomic variables to the market news is identical. The significant and negative value  
7 of asymmetry coefficient indicates that the negative news has a greater impact on the volatility of  
8 stock markets return and macroeconomic variables, than positive news of same magnitude.  
9 These results are consistent with findings within the literature (e.g., Schwert, 1989; Campbell  
10 and Hentschel, 1992; Koutmos and Booth, 1995; Chinzara, 2011, Kumari and Mahakud, 2015).

11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21  
22 The dummy coefficients are significant in all the stock markets return except UK. For the  
23 macroeconomic variables, industrial production index has structural breaks for all countries. M2  
24 TBR and CPI also have structural breaks for all countries except for M2 for the UK. Similarly,  
25 exchange rate has structural breaks for all countries except France and Germany. Finally, the  
26 results of oil price data do not indicate any structural break for USA, Canada, Japan, France and  
27 Germany. Most of the significant coefficients of dummy variables are negative which indicate  
28 that during the crisis period volatility is much higher as compared to non-crisis period.

39  
40

### 41 *3.2 VAR models results and discussion*

42  
43 Having obtained the conditional volatilities for the stock market and macroeconomic series from  
44 the appropriate GARCH model, we now estimate a system of simultaneous equations using the  
45 vector autoregressive (VAR) framework. The appropriate lag length is selected by AIC lag  
46 selection criteria.<sup>14</sup> After selecting the lag length, we estimate block exogeneity (F-statistics) to  
47 analyze the causal connection between the volatilities of the macroeconomic variables on stock  
48  
49  
50  
51  
52  
53  
54

---

55  
56 <sup>14</sup> In addition to the AIC we also consider the BIC and FPE (final prediction error). In each case the AIC and FPE  
57 choose the same lag length, as does the BIC for three markets. For the remaining markets the BIC chooses a shorter  
58 lag length. We opt for the AIC/FPE lag length to avoid the potential issue of selecting too short a lag length.  
59  
60

1  
2  
3 market returns. One important issue concerns the identification of the VAR in which the ordering  
4 of variables is important (Mills and Mills, 1991). To consider this, we estimate various  
5 combinations of the given variables in our VAR system, while the reported results are the ones  
6 that are robust with respect to different possible orderings of the variables. The results of the  
7 block exogeneity tests for volatility transmission between the macroeconomic and stock markets  
8 variables are presented in Table 3.  
9  
10  
11  
12  
13  
14  
15  
16

17 The results in *Panel-3A* of Table 3 show the volatility transmission from macroeconomic  
18 factors to stock market returns. These results indicate that the volatility of industrial production  
19 growth and money supply significantly influence US stock market volatility. For the UK, only  
20 CPI is found to significantly affect stock market volatility, while for Canada, Japan, Germany,  
21 France and Italy the volatility of the monetary variables (money supply and CPI) significantly  
22 impact stock market volatility. The volatility of industrial production growth is also a significant  
23 macroeconomic factor for stock market volatility for France and Italy. These results partly  
24 confirm those previously reported in the literature (e.g., Erdem, et al. 2005; Diebold and Yilmaz  
25 2007 and Chinzara, 2011). Oil price volatility is also identified as an important determinant of  
26 stock market volatility in Canada and Japan. As oil is a major input for economic activity, it is  
27 plausible that oil price fluctuations would influence the level of output through production costs  
28 and the prices of consumer goods, which in turn will affect household consumption and  
29 profitability of firms. Of the markets considered here, Canada is the largest exporter of oil, while  
30 Japan is the second largest importer of oil, after the US, which is also an oil producer and thus,  
31 less impacted by oil price fluctuations. Diaz et al., (2016) also report a strong connection  
32 between oil price volatility and stock market returns in their study on G-7 countries.  
33

54

55 In case of Japan, the volatility of money supply, inflation, exchange rate and oil price are  
56  
57  
58  
59  
60

1  
2  
3 significant factors affecting stock market volatility. Thus, we observe more interaction from the  
4  
5 macroeconomic variables. This may be because the Japanese economy has faced a difficult  
6  
7 situation for the past two decades, starting from the late 1980s and which has been accompanied  
8  
9 by unorthodox monetary policy. A possible reason for the stronger integration between the  
10  
11 volatility of the monetary and stock market variables could be accredited with the fact that the  
12  
13 exchange rate (yen/dollar) was a dominant factor affecting monetary policy and trade tensions  
14  
15 between the US and Japan, especially in the first decade of our sample period. Indeed, the  
16  
17 exchange rate was subject to political influence, which affected market expectations (McKinnon  
18  
19 and Ohno, 1997).  
20  
21  
22  
23

24  
25 The above results provide evidence of significant macroeconomic volatility transmission  
26  
27 to the volatility of stock market returns for all G-7 countries. The results of volatility  
28  
29 transmission from stock market to macroeconomic variables are presented in *Panel-3B* of Table  
30  
31 3. The findings of the block exogeneity test indicate volatility transmission from stock market to  
32  
33 macroeconomic variables for all G-7 countries except the UK. The results for UK indicate that  
34  
35 there is a unidirectional volatility transmission moving from macroeconomic variables to stock  
36  
37 market return, while for the rest of countries it is bidirectional. The results of causality linkage  
38  
39 between the volatilities of stock markets return and macroeconomic variables for the UK are in  
40  
41 line with Morelli (2002), who also reports a weak volatility connection between macroeconomic  
42  
43 variables and stock market returns for the UK.  
44  
45  
46  
47

48  
49 To analyze the speed, direction and persistence of stock market volatility in response to  
50  
51 macroeconomic shocks, we estimate 24-month impulse response functions, which are reported in  
52  
53 Figure 4.<sup>15</sup> Generally, the response of stock market volatility to the innovations of  
54  
55

---

56  
57 <sup>15</sup> Results of remaining IRFs of other macroeconomic variables were also estimates in the VAR system, but for  
58  
59 space interest, all results are not reported here and can be made available on request.  
60

1  
2  
3 macroeconomic variables is quite persistent. There is a positive response of stock market  
4 volatility to the one standard deviation innovation of industrial production volatility (VOLIP)  
5 over the 24-months horizon period for all G-7 countries except Canada and Japan. In case of  
6 Canada, the response is initially positive and then after one year it becomes negative while for  
7 Japan it is insignificant and negative. We note that for the US and Italy, the positive impact of  
8 VOLIP on stock market volatility becomes significant and sustainable after the 12<sup>th</sup> and 20<sup>th</sup>  
9 month respectively, while for UK, Germany and France it remains insignificant over the 24-  
10 months horizon period. The results are similar to Schwert (1989) and Morelli (2002).  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21

22 The response of stock market volatility to money supply volatility (VOLM2) shocks is  
23 positive for all countries except France where it is initially positive but over the long run it  
24 becomes negative. The literature has also reported mix results about the response of stock market  
25 to money supply.<sup>16</sup> The results for France are in the line with (Grossman, 1981; Urich and  
26 Wachtel, 1981; Pearce and Roley, 1983; Gan, et al. 2006 and Adjasi, 2009). The negative  
27 response of stock market volatility to money supply growth volatility can be rationalized through  
28 the behavior of investors who assume that the central bank will tighten monetary policy when  
29 inflationary expectations rise. This anticipation of restrictive monetary policy would trigger  
30 investors to sell their securities leading to a higher expected future rate of return.<sup>17</sup> That said,  
31 investors may have different expectations about the inflation when stock markets respond  
32 positively to the monetary shocks (Fama and Schwert, 1977 and Fama, 1981). A counter

49  
50 <sup>16</sup> Mukherjee and Naka (1995) argue that analyzing the impact of money supply shocks to stock markets is an  
51 empirical question and that results can vary depending upon the selections of sample data sets, countries, measures  
52 of variables used. So, the results can be different for different researchers and this argument was found to be true  
53 after examining the results of mentioned studies in the literature, some researchers have found positive relation  
54 while others have found negative between money supply and stock prices volatility.

55 <sup>17</sup> See Gan, Lee, Yong, and Zhang (2006) found a negative response of New Zealand stock market volatility to  
56 money supply (M1) shocks. Similarly, the consensus finding from the studies of Grossman, 1981; Urich and  
57 Wachtel, 1981; Pearce and Roley, 1983) is that they all have associated the higher interest rate to the high  
58 unexpected money growth and that would lead to lower the stock prices.  
59  
60

1  
2  
3 argument in favor of a positive response of stock market volatility to money supply has also been  
4  
5 made (e.g., Friedman and Schwartz, 2008; Muradoglu and Metin, 1996; Bailey, 1988; Maysami  
6  
7 and Koh, 2000). This line of research argues that money growth would lead to an increase in  
8  
9 liquidity and the purchasing power of consumers that would ultimately lead to an increase in the  
10  
11 price of stocks.  
12  
13

14  
15 The results of impulse response functions of stock market volatility with respect to one  
16  
17 standard deviation innovations in the Treasury bill (VOLTBR) indicate a negative response for  
18  
19 all stock markets except the Nikkei 225 for Japan. This negative response is consistent with  
20  
21 Chinzara (2011), who reports similar results for South Africa. The positive response of Japanese  
22  
23 stock market volatility to VOLTBR is in line with the findings of Kumari and Mahakud (2015)  
24  
25 for India. That said, the stock market volatility response in this case is only significant for the US  
26  
27 and Canada in short-run otherwise. The response of stock market volatility to inflation shocks is  
28  
29 positive and mainly significant over the short and medium term for all countries except the US  
30  
31 and Italy. Once again, the challenge of mixed results is persistent because Adjasi, (2009) among  
32  
33 others finds a negative response of stock market volatility to inflation rate while positive  
34  
35 response to the interest rate shocks.  
36  
37  
38  
39

40  
41 A mixed response of stock market volatility to exchange rate volatility (VOLER) is also  
42  
43 observed. For the US and UK, it appears positive over the horizon period while for rest of the  
44  
45 countries the spontaneous response of stock market volatility is negative but over the long run it  
46  
47 also becomes positive. However, the response of the Japanese market is opposite to the other  
48  
49 stock markets. In short run, the response of the Japanese market is positive, but over the long run  
50  
51 it becomes negative. A possible reason for this behavior can be given by McKinnon and Ohno  
52  
53 (1997), who argue that the underlying factors of exchange rate (yen/dollar) movements certainly  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 affect market behavior, while policy failed to provide direction for the exchange rate.  
4  
5 Wangbangpo and Sharma (2002) also find a mixed relation between stock prices and exchange  
6  
7 rate for some emerging Asian economies (Malaysia, Indonesia, Singapore, Thailand and  
8  
9 Philippine). Surprisingly, the response of stock market volatility to oil price volatility (VOLOIL)  
10  
11 is insignificant and positive for the US, UK and Germany. These results are contradictory to  
12  
13 Diaz et al., (2016), who find a negative response of G-7 stock markets to an increase in oil  
14  
15 prices. For Canada, Japan, France and Italy, the response of stock market volatility is negative to  
16  
17 VOLOIL, but it significant only for Canada and Japan. The overall results of impulse response  
18  
19 functions are in line with the block exogeneity results in Table 3. Moreover, it can be observed  
20  
21 from the impulse response functions that the relation between stock market volatility and  
22  
23 macroeconomic factors is indeed bidirectional.<sup>18</sup> Thus, there is also evidence of significant  
24  
25 volatility response of macroeconomic variables to the volatility of stock markets returns for all  
26  
27 G-7 countries.  
28  
29  
30  
31  
32  
33

34 In order to provide further analysis of our results, we now consider the variance  
35  
36 decompositions, which reveal proportion of stock market volatility that is explained by the  
37  
38 macroeconomic volatility and vice versa. For this purpose, we estimate 12-period forecast for the  
39  
40 variance decomposition with the results presented in Table 4.<sup>19</sup>  
41  
42  
43

44 Examining these results, it can be observed that the movement of volatility of stock  
45  
46 market returns, for most the G-7 countries, arises from their own shocks. However, it is  
47  
48 noticeable that some macroeconomic variables contribute to stock return volatility. At the 12<sup>th</sup>  
49  
50 period lag, about 38% of the variation in US stock market volatility is explained by the volatility  
51  
52  
53

---

54  
55 <sup>18</sup> The results of IRFs are only reported here partially; the complete results are available with the authors and can be  
56 made available to the reviewers on demand.

57 <sup>19</sup> The results of 12 periods forecast variance decomposition are only reported here for stock markets of G-7  
58 countries. The complete results are not reported here due to space reasons and can be made available upon request.  
59  
60

1  
2  
3 of other macroeconomic variables. For the other markets, the equivalent figures are about 20% of  
4  
5 the variation in UK and Japanese stock return volatility, 34% of the variations in the Canadian  
6  
7 and Italian stock market and 26% and 30% for German and French markets respectively.  
8  
9

10 Examining these results in greater detail, for the US the main contributing factors are oil  
11 (VOLOIL) and industrial production (VOLIP), contributing 15% and 13.35% respectively. For  
12  
13 the UK, the highest contribution is made by consumer prices (VOLCPI), however, this is only  
14  
15 6.64%, with more than 80% of the variation arising from the stock market itself. For Canada oil  
16  
17 and money supply (VOLM2) are the main factors, explaining 5.45% and 13.31% of the variation  
18  
19 in stock market volatility. In case of Japan and Germany, money supply and consumer prices are  
20  
21 the highest contributing factors, while for France, consumer prices and industrial production are  
22  
23 the main contributing series. Finally, for Italy VOLIP and VOLM2 contribute 17% and 8%  
24  
25 respectively to stock market volatility.  
26  
27  
28  
29  
30

31 In terms of the reverse effect, the 12-period forecast variance decomposition reveal a  
32  
33 weak contribution from stock market volatility to macroeconomic volatility. For Canada, stock  
34  
35 market volatility contributes 8.6% of the movement in money supply growth volatility. For  
36  
37 Japan, we observe 12% and 6% from stock market volatility to VOLIP and VOLOIL  
38  
39 respectively, while only 6% of the variation in VOLTBR arises from stock market volatility for  
40  
41 Germany. Overall, these results reveal a weak contribution of macroeconomic volatility to stock  
42  
43 market volatility and vice versa for our markets. This weak connection has previously been  
44  
45 observed by Schwert (1989). Whereas, Chinzara (2011) and Kumari and Mahakud (2015)  
46  
47 reported a strong feedback connection from stock market volatility to macroeconomic  
48  
49 uncertainty for emerging markets (i.e. South Africa and India).  
50  
51  
52  
53  
54

55 To summarize, the empirical linkage between stock market volatility and the systematic  
56  
57  
58  
59  
60

1  
2  
3 risk factors remains unclear. Although the collective impact of systematic risk factors to stock  
4 market volatility is significant as shown by block exogeneity results, it is weak at the individual  
5  
6 market volatility is significant as shown by block exogeneity results, it is weak at the individual  
7  
8 macro-series level. Of note, it would appear unexpected to find no significant relation arising  
9  
10 from short-term interest rates. Generally, short-term interest rates are considered as perhaps the  
11  
12 most important factor in stock market volatility as interest rate play a crucial role in determining  
13  
14 both macroeconomic health and firm level decisions around the appropriate capital structure and  
15  
16 investment plans. That said, the volatility of money supply growth is identified as the most  
17  
18 dominant factor of macroeconomic volatility. Further, the significant dummy coefficients in  
19  
20 EGARCH model for stock market returns and most of the macroeconomic variables indicate the  
21  
22 potential for structural breaks. It may be that issues surrounding stability within the data can have  
23  
24 a strong influence on the potential stock market and macroeconomic volatility nexus.  
25  
26  
27  
28  
29  
30  
31

### 32 **5. Concluding Remarks.**

33  
34 This paper considers the relation between stock market and macroeconomic volatility for the G-7  
35  
36 markets using monthly data over the period July 1985 to June 2015. In conducting the analysis,  
37  
38 we take explicit account of two major crisis periods (the dotcom crash and the global financial  
39  
40 crisis). We obtain the conditional volatilities of both stock market and macroeconomic variables  
41  
42 by estimating GARCH-type models. The volatilities are then used in a VAR model in order to  
43  
44 consider the linkages. The GARCH models reveal the usual characteristics of volatility  
45  
46 persistence, with asymmetric behavior in the stock market returns as well as some of the  
47  
48 macroeconomic variables (industrial production, short-term interest rate and oil price).  
49  
50 Furthermore, the GARCH results reveal a significant impact of the crisis periods on the majority  
51  
52 of the volatility series.  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 The VAR results reveal that the volatility transmission impact of industrial production,  
4 money supply and inflation is positive, for interest rates it is insignificant and negative for all  
5 countries except Japan, while for the exchange rate and oil prices the spillover impact is mixed  
6 across the different markets. The relation between stock market volatility and macroeconomic  
7 volatility unidirectional for UK, while for the rest of G-7 countries, causality is bidirectional,  
8 although it may not always be strong. Of particular note, money supply and exchange rate  
9 volatility has strong bidirectional causality with stock market volatility for the majority of  
10 countries.  
11  
12  
13  
14  
15  
16  
17  
18  
19  
20  
21

22 Overall, the bidirectional causality highlights the nature of interdependence of  
23 macroeconomic fundamentals and stock market returns. This, in turn, is important for policy  
24 makers, investors and risk managers who should incorporate these interrelations into their  
25 decision making. As a final point, we have included dummy variables to account for the dotcom  
26 and financial crisis periods. Our results show that accounting for these periods is important. An  
27 extension to this work could be to consider further periods of market stress at both the local and  
28 regional as well as global level. This should further improve our understanding of the nature of  
29 the linkages between the stock market and the macroeconomy.
