A series of experiments was carried out on verbal short-term memory for lists of words. In the first experiment, participants were tested via immediate serial recall and word frequency and list set size were manipulated. With closed lists the same set of items was repeatedly sampled, with open lists no item was presented more than once. In serial recall, effects of word frequency and set size were found. When a serial reconstruction of order task was used, in a second experiment, robust effects of word frequency emerged but set size failed to show an effect. The effect of word frequency in order reconstruction were further examined in two final experiments. The data from these experiments revealed that the effects of word frequency are robust and are apparently not exclusively indicative of output processes. A multiple mechanisms account is adopted in which word frequency can influence both retrieval and pre-retrieval processes.

Serial reconstruction of order and serial recall in verbal short-term memory

One of the most well-known techniques for studying verbal short-term memory is to present a short list of words to a person and then get them to report back the words in the order in which they were presented. This is known as the *immediate serial recall task*. To perform well in the task, participants must remember both the actual words (i.e., the *items*) and the order in which the words occurred. Many models of short-term memory, as defined relative to immediate serial recall, incorporate distinct mechanisms for maintaining the two types of information (e.g., Brown, Neath, & Chater, 2007; Brown, Preece, & Hulme, 2000; Burgess & Hitch, 1992; Farrell & Lewandowsky, 2002; Henson, 1998; Page & Norris, 1998) and it has been suggested that different brain regions are involved in dealing with these, respectively (Majerus, 2009). In this vein, attempts have been made to establish whether different factors differentially influence memory for item vs. order information. For example, it has often been suggested that the deleterious effect of having similar sounding words within a list, selectively disrupts memory for the order of the items (e.g., Baddeley, 1986).

In order to align the effects of other variables with the operations of specific mechanisms in models of memory, other tasks have also been used, and the present concerns are with something known as the *order reconstruction task*. In this task, the to-be-remembered (TBR) words that have just been presented are re-presented at test in a new random order, and the participant attempts to reconstruct the order of the words' presentation. A simple assumption is that the order reconstruction task is nothing other than a test of item order information, or, as Whiteman, Nairne and Serra (1994) stated, the reconstruction task "provides a relatively pure index of position memory" (pp. 276-277).

1  
2  
3 To investigate such a possibility, Whiteman et al. (1994) manipulated word  
4 frequency – a variable that reflects item knowledge – in a *free reconstruction of order*  
5 *task*. In this task, participants are free to reconstruct the original sequence in any  
6  
7 manner they wish. For example, and unlike in the serial recall task, participants might  
8 reconstruct the list in reverse order starting with the last item and then filling in the  
9  
10 other items. Whiteman et al. (1994) failed to find an effect of frequency and went on  
11  
12 to suggest that word frequency affects item information but not order information.  
13  
14  
15  
16  
17

18  
19 Several models of serial recall posit that word frequency influences the  
20 processes responsible for maintaining item information (e.g. Page & Norris, 1998;  
21 Burgess & Hitch, 1992) and thus do not predict an effect of word frequency on  
22  
23 measures of order memory. For instance, such models do not predict an effect of word  
24  
25 frequency on the number of order errors in serial recall. Although a number of papers  
26  
27 have reported such a null effect (e.g. Allen & Hulme, 2006; Miller & Roodenrys,  
28  
29 2012; Poirier & Saint-Aubin, 1996; Stuart & Hulme, 2000), others have found a  
30  
31 significant effect of frequency on order information in serial recall (Hulme, Stuart,  
32  
33 Brown, & Morin, 2003; Roodenrys, Hulme, Lethbridge, Hinton & Nimmo, 2002).  
34  
35  
36  
37

38  
39 In addressing this theoretical issue, it is arguable that examination of the effect  
40 of word frequency via order reconstruction provides a stronger test of whether word  
41  
42 frequency can affect memory for order than does any experiment on serial recall.  
43  
44 Consequently, Whiteman et al.'s (1994) null result provides apparently strong  
45  
46 evidence against the conclusion that word frequency can affect order memory. Some  
47  
48 caution is warranted, however, because we may question whether their experiment  
49  
50 reflects on the same memory mechanisms as those underpinning immediate serial  
51  
52 recall. Their procedure deviated from the standard immediate serial recall task in two  
53  
54 ways; first, it involved free reconstruction rather than a requirement to re-produce the  
55  
56  
57  
58  
59  
60

1  
2  
3 list from beginning to end, and, second, testing was not immediate as there was a 12  
4  
5 second, filled delay between presentation and test.  
6

7  
8 Other studies have also examined the effect of frequency in reconstruction  
9  
10 tasks, but, again, some caution is warranted in considering these. For instance, Thorn,  
11  
12 Frankish, and Gathercole (2009) reported data from a paradigm that bears some  
13  
14 similarities with the immediate serial recall task. Unfortunately, it is difficult to  
15  
16 recover critical details of these experiments because few are provided. Nonetheless, it  
17  
18 is reported that words were presented as spoken lists and, at test, the items were re-  
19  
20 presented visually. The participant had to say each item in turn in the same order as  
21  
22 originally presented. Two datasets are presented and in neither case, is a simple  
23  
24 evaluation of the frequency effect given. Although the authors report a diminished  
25  
26 frequency effect in reconstruction in comparison to recall, the data as presented  
27  
28 appear to show no effect of frequency for reconstruction.  
29  
30

31  
32 A number of other studies on order reconstruction, have used very slow  
33  
34 presentation rates (in comparison to the typical immediate serial recall task) and have  
35  
36 included delays between presentation and test (e.g., DeLosh & McDaniel, 1996;  
37  
38 Merritt, DeLosh & McDaniel, 2006). In some cases effects of word frequency have  
39  
40 emerged (DeLosh & McDaniel, 1996; Merritt, DeLosh & McDaniel, 2006) and in  
41  
42 others not (Whiteman et al., 1994). As a consequence, it is very difficult to draw any  
43  
44 straightforward conclusions about the effects that word frequency may exert in order  
45  
46 reconstruction tasks. It is particularly notable, though, that evidence from paradigms  
47  
48 composed of a simple serial presentation of the TBR items followed by an immediate  
49  
50 test of memory is lacking.  
51  
52

53  
54 In the present experiments, the effect of word frequency was examined in both  
55  
56 serial recall and reconstruction tasks. A starting point for the experiments is the earlier  
57  
58  
59  
60

1  
2  
3 work by Roodenrys and Quinlan (2000). They examined two variables; (i) word  
4 frequency, and, (ii) word set size (or more simply, *set size*), where ‘set size’ refers to  
5 how the words within a list were sampled. With *open sampling*, each word was only  
6 sampled once in an experiment; with *closed sampling*, words were sampled  
7 repeatedly across trials, but no word was repeated within a list. The design of the  
8 experiments was based on a factorial combination of open vs. closed lists of high vs.  
9 low frequency words. The procedure was serial recall, and across two experiments the  
10 findings were clear and consistent. Whereas low frequency words were better recalled  
11 from closed vs. open sets there was no effect of set size for the high frequency words.  
12 There was also a standard word frequency effect such that high frequency word lists  
13 were better recalled than low frequency word lists.  
14

24  
25  
26

27           In the same way that we may consider the effects of word frequency across  
28 recall and reconstruction tasks, we may also ask how set size effects vary across these  
29 tasks. Neath (1997) compared performance with open and closed lists in a variant of  
30 the free reconstruction of order task and found that closed lists were more accurately  
31 reconstructed than were open lists. Neath’s procedure was much more involved than  
32 that typically used in immediate serial recall tasks. Each TBR word was presented for  
33 1 second and before the next item was presented, participants undertook a mental  
34 addition problem. Sequences of single digits were presented followed by a target sum  
35 and participants had to verify whether the sum of the digits matched the total. This  
36 filler addition task lasted for approximately 5 s before the next TBR item occurred. In  
37 total the presentation duration of one list took around 37 s and there was a 3 s blank  
38 delay before the test was initiated. As before, we may be concerned about the degree  
39 to which similar mechanisms are being tapped in this case and in the more standard  
40 immediate tests of serial recall. Nonetheless, the nature of the set size effect reported  
41

1  
2  
3 by Neath (1977) is qualitatively the same as that found by Roodenrys and Quinlan  
4  
5 (2000) in their tests of serial recall. This at least suggests that set size operates  
6  
7 similarly across recall and reconstruction tasks.  
8

9  
10 The primary aim of the experimental work reported here was to examine word  
11  
12 frequency and set size in reconstruction tasks in a bid to understand better the  
13  
14 relations between serial recall and reconstruction. In the first experiment, we include a  
15  
16 replication of Roodenrys and Quinlan (2000) in which word frequency and set size  
17  
18 variables were examined in a serial recall task. The experiment was configured as a  
19  
20 web application and a link to the application was disseminated via email. The aim  
21  
22 here was to replicate the Roodenrys and Quinlan (2000) findings so as to demonstrate  
23  
24 the integrity of data collected over the web. Experiment 2, comprised a serial  
25  
26 reconstruction of order task. Again, the data were collected over the web, and,  
27  
28 significant effects of word frequency did emerge. This word frequency effect was  
29  
30 then explored in two remaining experiments that established the generality and  
31  
32 robustness of the phenomenon.  
33  
34  
35

### 36 Experiment 1

#### 37 38 *Method*

39  
40 The experimental tasks were configured using the Qualtrics software in which  
41  
42 the corresponding experimental scripts were disseminated via web links. In this way,  
43  
44 there was no control over where, or when, participants were tested. The general  
45  
46 advice to participants was to undertake the experiment in a quiet place away from  
47  
48 distractions. Experiment 1 comprised a replication of Roodenrys and Quinlan (2000),  
49  
50 and provides a proof of concept that the novel web-based testing does produce data  
51  
52 that are robust and are systematically similar to previous findings.  
53  
54

#### 55 56 *Design.*

57  
58  
59  
60

1  
2  
3           Ninety-six high frequency and 96 low frequency words were selected as the  
4 stimulus materials and were controlled on several variables known to influence recall  
5 performance (taken from Miller & Roodenrys, 2012, see Appendix A). Memory for  
6 high frequency and low frequency words was tested in separate testing sessions for  
7 every participant. Every participant was tested over two sessions and the order of the  
8 word frequency sessions was counterbalanced across the participants. In each session  
9 16 lists of 6 words were presented. There were 16 high frequency and 16 low  
10 frequency lists. If the testing involved open lists, then the items were selected without  
11 replacement across the lists. Hence a given participant would see every item but only  
12 once across all the lists. If the testing involved closed lists, then at the start of the  
13 testing six items were randomly selected from the 96 and these were repeatedly  
14 sampled across all lists. The order of presentation of the words was determined  
15 randomly prior to the start of a trial.

16  
17  
18           Participants either completed testing sessions comprising open lists or  
19 comprising closed lists. Hence set size was a between-participants factor with - Group  
20 1 – open, and Group 2 - closed. More particularly, there were four sub-groups in total  
21 as the order of frequency testing was balanced across Groups 1 and 2. Word  
22 frequency was a two-leveled factor (high vs. low) and list position was a six-leveled  
23 factor.

#### 24           *Participants.*

25           The experiment was run as an online (web-based) laboratory practical and  
26 members of the second-year Psychology degree at The University of York were tested  
27 as participants. Data from only native English speaking students were examined  
28 further and for several participants it was clear that they had failed to follow the  
29 instructions properly. For instance, they tested themselves twice with the high  
30

2  
3 frequency lists instead of running separate sessions for the high and low frequency  
4  
5 lists. Consequently, the eventual data sets comprised 33 Group 1 - open participants,  
6  
7 and, 41 Group 2 - closed participants.  
8

9  
10 *Procedure.*

11  
12 Once the web link was launched a preliminary information screen was  
13  
14 presented giving generic instructions about the kind of memory task to be undertaken.  
15  
16 Next, they were asked to provide explicit consent to testing. Finally, participants were  
17  
18 asked in indicate their age, nationality and to input their unique participant number.  
19  
20 The participant number determined whether open or closed lists would be used. The  
21  
22 overall cohort of students was divided roughly so that each of the groups was  
23  
24 assigned the same  $n$ . Finally, a start screen was presented which instructed the  
25  
26 participant to initiate the experiment when ready.  
27  
28

29  
30 At the start of each trial a screen displaying the message “Next list” was  
31  
32 presented for 1 s. Then the sequence of six TBR words unfolded. Each word was  
33  
34 visually presented for 1s and once the list terminated there was a 1 s blank delay  
35  
36 before list testing began. Next a screen containing a text box was presented with the  
37  
38 message “Input item  $n$ ” where  $n$  (i.e., 1 – 6) indicated the item position currently  
39  
40 being requested. The participant entered their response and moved onto the next  
41  
42 screen by pressing <Return>. Blank entries were possible by simply pressing  
43  
44 <Return>. There was no time constraint on how long a participant could take to enter  
45  
46 a response. Six such screens were presented in sequence. A final <Return> key press  
47  
48 moved the experiment onto the next trial.  
49  
50

51  
52 *Results and Discussion*

53  
54 All responses were scored strictly so that an item had to be reported correctly  
55  
56 in its correct position. As a consequence, each list position was scored as a total  
57  
58  
59  
60

1  
2  
3 correct over the 16 lists and expressed as a proportion. (Descriptive statistics for all  
4  
5 conditions of interest in all of the experiments are provided in tabular form in  
6  
7 Appendix B.)  
8

9  
10 Figure 1 provides a graphical illustration of the summary data for the  
11 conditions of interest. The data were entered into a split-plot ANOVA in which word  
12 frequency (high vs. low), and item position (1-6) were entered as fixed repeated  
13  
14 measures factors. Set size (open vs. closed) was entered as a fixed between-  
15  
16 participants factor and participants was entered as a random factor. This analysis  
17  
18 revealed statistically significant main effects of both word frequency,  $F(1, 72) =$   
19  
20  $57.98, p < .001$ , partial  $\eta^2 = .446$ , and, item position,  $F(5, 360) = 150.47, p < .001$ ,  
21  
22 partial  $\eta^2 = .676$ . The main effect of set size failed to reach statistical reliability,  $F(1,$   
23  
24  $72) = 1.97, p = .164$ , partial  $\eta^2 = .027$ .

58  
59  
60

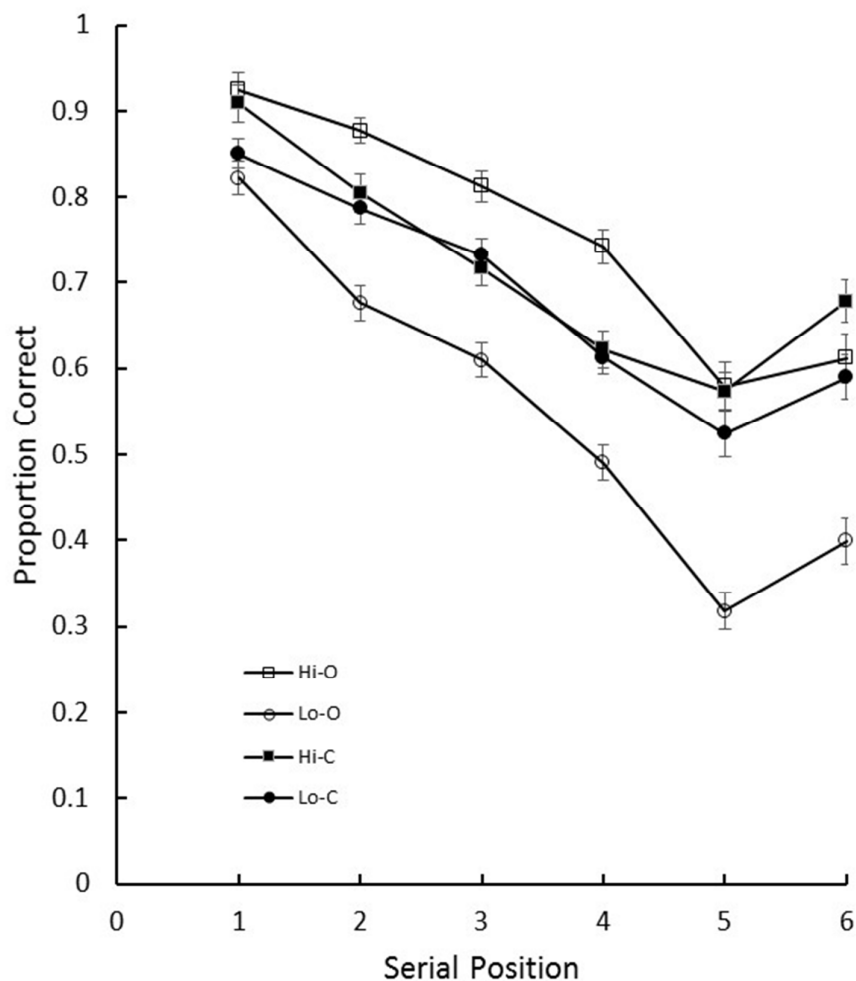

Figure 1. Serial position curves for the four serial recall conditions of interest in Experiment 1. Error bars reflect 1 SE of the particular condition mean. In the notation used, Hi-O stands for high frequency words open set lists, Hi-C stands for high frequency words closed set lists, Lo-O stands for low frequency words open set lists, and Lo-C stands for low frequency words closed set lists.

All of the two-way interactions also reached statistical significance,  $F(1, 72) = 29.37, p < .001$ , partial  $\eta^2 = .290$ , for the word frequency x set size interaction;  $F(5, 360) = 5.68, p < .001$ , partial  $\eta^2 = .073$ , for the item position x set size interaction; and,  $F(5, 360) = 2.83, p < .05$ , partial  $\eta^2 = .038$ , for the word frequency x item

1  
2  
3 position interaction. Finally, the word frequency x item position x set size interaction  
4  
5 was also statistically reliable,  $F(5, 360) = 12.87, p = .001$ , partial  $\eta^2 = .055$ .

6  
7 These patterns of statistical difference replicate those reported by Roodenrys  
8 and Quinlan (2000). Although further comparisons are possible, for the sake of  
9 brevity and, as the focus of the current research is on the reconstruction task, no  
10 further subsidiary analyses of the recall data are reported. Given that the data replicate  
11 those previously reported by Roodenrys and Quinlan (2000), we have shown that the  
12 novel web-based testing conditions are reliable and, therefore, that we can approach  
13 the data from the ensuing order reconstruction task with some confidence.

21

## 22 Experiment 2

23  
24 In Experiment 2 a serial order reconstruction task was used. The choice of the  
25 particular task was in part influenced by consideration of some recent results reported  
26 by Clarkson, Roodenrys, Miller and Hulme (2016). Clarkson et al. (2016) examined  
27 performance in a paradigm, in which on each trial and following the serial  
28 presentation of a list of words, the words were re-presented in a new random order.  
29 Participants had to write down the first word as presented, then the second, then the  
30 third and so on until they had attempted to re-create the original presentation order of  
31 the words.  
32  
33  
34  
35  
36  
37  
38  
39  
40  
41

42 Across a series of experiments, Clarkson et al. (2016) examined the effect of  
43 phonological neighborhood size. For instance, in their Experiment 2 word lists  
44 comprised words solely from either *dense neighborhoods* or *sparse neighborhoods*. A  
45 word from a dense neighborhood shares sets of phonemes with many other words  
46 whereas a word from a sparse neighborhood shares them with few words. In this way,  
47 phonological neighborhood size is a variable that reflects long-term knowledge about  
48 how words are phonologically related to one another.  
49

1  
2  
3           On the assumption that order reconstruction does not rely on accessing such  
4 item information because the items themselves are represented at test, then there is no  
5 reason to predict that the phonological neighborhood size should influence  
6 performance. However, Clarkson et al. (2016) found that participants were more  
7 accurate in reconstructing list of items taken from dense neighborhoods than they  
8 were in reconstructing lists of items taken from sparse neighborhoods. Without  
9 attempting to provide a detailed explanation of this pattern of results here, it suffices  
10 to note that Clarkson et al. (2016) have provided more evidence of how the process of  
11 order reconstruction is affected by item information despite the items being  
12 represented at test (cf. Neath, 1977).

24

25           On the grounds that serial order of reconstruction has been shown to be  
26 effective in exposing effects of item information in immediate verbal memory, the  
27 intention here was to use this in the next experiment. As discussed, the data from  
28 order reconstruction tasks concerning effects of word frequency is mixed and, in some  
29 cases, it is difficult if not impossible to recover what the exact nature of the testing  
30 conditions were. Here we examined effects of word frequency and set size when  
31 participants were forced, in an immediate test, to reconstruct the order of the items in  
32 the same sequence as at presentation. An intention was to examine performance under  
33 conditions that closely matched those typically used in immediate serial recall.  
34 Indeed, the identical presentation conditions to those used in Experiment 1 were used  
35 in Experiment 2. In this way, we can begin to construct a clearer picture of the  
36 differences in memory when testing is either by serial recall or serial reconstruction.

#### 51 *Method*

52           In Experiment 2 performance in a serial reconstruction of order was examined  
53 with the materials used in Experiment 1. Again, the Qualtrics software was adapted to  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 run the experiment and testing was carried out over the web in the manner described  
4 for Experiment 1. At test, the original words were re-presented as a single list on the  
5 screen. The order of the items on the screen was determined on a random basis at the  
6 start of each trial and differed from the presentation order. The page also contained  
7 the message “Input item n” where n (i.e., 1 – 6) and a text box for typing a word.  
8 Participants were therefore forced to type in their responses in sequential order. Once  
9 they typed a response pressing <Return> moved the experiment onto the next screen.  
10 This screen retained the word list (as just described) and instructions to make their  
11 next response.

23 The materials were the same as in Experiment 1 and the design mirrored that  
24 for Experiment 1. Participants were tested twice – once with high frequency word  
25 lists and once with low frequency word lists – and the order of testing was  
26 counterbalanced across participants. Although the primary aim was to examine the  
27 influence of word frequency on order reconstruction, the design also incorporated the  
28 set size manipulation from Experiment 1. In this way, both variables were examined  
29 in concert. As before, therefore, set size (open vs. closed) was tested as a between-  
30 participants factor and the word frequency and item position factors were as used in  
31 Experiment 1.

### 43 *Participants*

44  
45 Participants were sourced from the cohort of first year undergraduates at the  
46 University of York. A blanket email was sent to the cohort and the volunteer  
47 participants were enrolled on agreeing to take part. All participants were provided  
48 with course credit for taking part. Only native English speakers were tested and the  
49 sample size was determined by the number of respondents that signed up and agreed  
50 to be tested in a two-week period prior to the end of the Spring term. Although 57

participants were tested, due to a variety of web glitches, 50 data sets were analyzed in total. Group 1 (the open group) comprised 23 participants and Group 2 (the closed group) comprised 27 participants.

*Results and Discussion*

*Figure 2.* Serial position curves for the four serial reconstruction conditions of interest in Experiment 2. Error bars reflect 1 SE of the particular condition mean. In the notation used, Hi-O stands for high frequency words open set lists, Hi-C stands for high frequency words closed set lists, Lo-O stands for low frequency words open set lists, and Lo-C stands for low frequency words closed set lists.

60

A graphical illustration of the summary data of interest is provided in Figure 2. The data were scored and analyzed in the same manner as in Experiment 1. This analysis revealed statistically significant main effects of both word frequency,  $F(1, 48) = 14.94, p < .001$ , partial  $\eta^2 = .231$ , and, item position,  $F(5, 240) = 69.23, p < .001$ , partial  $\eta^2 = .591$ . The main effect of set size failed to reach statistical reliability,  $F < 1.0$ . The only other test to reach statistical significance was of the word frequency x item position interaction,  $F(5, 240) = 2.88, p < .05$ , partial  $\eta^2 = .057$ ;  $F(1, 48) = 2.53, p = .118$ , partial  $\eta^2 = .050$ , for the word frequency x set size interaction;  $F < 1.0$ , for the item position x set size interaction; and,  $F(5, 240) = 1.10, p = .356$ , partial  $\eta^2 = .022$ , for the three-way, frequency x item position x set size interaction. So, in sum, the data reveal no effects of set size but robust effects of word frequency and item position.

Of prime interest is that when memory was tested via serial reconstruction of order, effects of word frequency occurred. Participants were better in reconstructing the order of high frequency word lists than low frequency word lists. On these grounds, the data sit comfortably with the view that participants ‘do remember and use item information to complete the test’ (Neath, 1997, p. 262). This particular finding is followed up in the remaining experiments.

Aside from this positive result, there is the null result regarding set size. The data failed to show any systematic difference in performance across the open and closed lists. This null finding contrasts with the findings in the serial recall task (see Roodenrys & Quinlan, 2000, and Experiment 1 here) and with the robust effects reported by Neath (1997). In order to examine the null effect in more detail the data were examined further using Bayesian methods (Rouder, Morey, Speckman &

1  
2  
3 Province, 2012). From Roodenrys and Quinlan (2000) and the serial recall task  
4  
5 reported above, the effects of set size emerged most strongly and consistently with  
6  
7 low frequency but not high frequency words. This set size effect is not present in the  
8  
9 data from Experiment 2. To examine this null effect further the data from the low  
10  
11 frequency lists were examined in a Bayesian repeated measures ANOVA (JASP  
12  
13 Team, 2017) in which the factors were list position and set size as defined for the  
14  
15 traditional ANOVA just reported.  
16  
17

18  
19 Relative to the null model (in which equality is assumed across all cells in the  
20  
21 design) a model comprising just the set size factor generated an inverse Bayes factor  
22  
23 of 0.280. The null model provided an adequate account of the data and a model  
24  
25 including the set size factor failed to provide a statistically better fit, that is, there was  
26  
27 substantial evidence in favor of the null model relative to a model including the set  
28  
29 size factor (Wetzels, Matzke, Lee, Rouder, Iverson, & Wagenmakers, 2011). As a  
30  
31 consequence, we conclude that the data provide *substantial* evidence that there was no  
32  
33 effect of set size in the data for the low frequency lists in the serial reconstruction of  
34  
35 order task.  
36  
37

38  
39 In discussing performance in their serial recall task, Roodenrys and Quinlan  
40  
41 (2000) argued that the set size variable reflected repeated access of particular lexical  
42  
43 entries for items in closed but not in open sets. Critically they assumed that the serial  
44  
45 recall task in important respects reflects the operation of long-term memory priming.  
46  
47 That is, the repeated presentation of an item primes its lexical entry such that it  
48  
49 becomes more readily accessed. Such priming is likely to benefit low frequency  
50  
51 lexical entries more than corresponding high frequency lexical entries. High  
52  
53 frequency lexical entries are generally more readily accessed than low frequency  
54  
55 entries and this may be explained in terms of different resting levels of activation  
56  
57  
58  
59  
60

1  
2  
3 (Morton, 1969). On these grounds, low frequency lexical entries benefit more from  
4  
5 temporary priming than do high frequency items because it makes them more  
6  
7 competitive at recall, effectively limiting the set of alternative items that could be  
8  
9 recalled in all positions.  
10

11           The lack of an effect of set size in the reconstruction task in Experiments 2 is  
12  
13 consistent with the explanation of the set size effect in serial recall offered above as  
14  
15 the reconstruction task limits the set of possible responses in each position to only  
16  
17 those presented in the list. However, it stands in contrast to the results of Neath  
18  
19 (1997), who did find an effect of set size in a *free* reconstruction of order task.  
20  
21

22           Aside from differences in the actual paradigms used in the two cases, the  
23  
24 kinds of items used in the two cases are very different. Neath (1977) used closed lists  
25  
26 comprising items repeatedly sampled from color names ('black', 'blue', 'brown',  
27  
28 'green', 'red', 'white') while the open lists comprised unrelated words. This is  
29  
30 important given the evidence that lists containing categorically related items are  
31  
32 generally better remembered than are lists containing unrelated items (Poirier &  
33  
34 Saint-Aubin, 1995; Wetherick, 1975). In this regard, it seems that the closed vs. open  
35  
36 list manipulation used by Neath (1997) is confounded with semantic relatedness  
37  
38 which may be producing the pattern in his data. This possibility is given added  
39  
40 plausibility by data from another of his experiments in which he found that  
41  
42 reconstruction performance was sensitive to word concreteness - a "semantic"  
43  
44 variable that reflects item knowledge.  
45  
46  
47  
48

49           Of course, such speculations do provide pointers to future research, but given  
50  
51 the lack of a set size effect in the reconstruction task reported here, this variable is not  
52  
53 examined further. It appears that the priming effect of repeatedly presenting a small  
54  
55 set of items is nullified by the re-presentation of items in the response phase. The  
56  
57  
58  
59  
60

1  
2  
3 finding of a frequency effect under the same circumstances suggests the two effects  
4  
5 reflect the operation of different processes. Indeed, having established a word  
6  
7 frequency effect in a serial reconstruction of order task in Experiment 2, the final two  
8  
9 experiments build on this finding and establish its robustness and generality. In both  
10  
11 experiments a variant on the serial reconstruction of order test was used. Experiment  
12  
13 3 reports on a basic replication of the effect whereas in Experiment 4 its robustness is  
14  
15 tested in a more complex design.  
16  
17

### 18 Experiment 3

20  
21 In Experiment 3 the generality of the word frequency effect is explored when  
22  
23 participants experienced both high frequency and low frequency word lists at  
24  
25 presentation in an intermixed fashion. In Experiment 2, participants were consistently  
26  
27 presented with high or low frequency word lists within a given block of trials. We  
28  
29 have shown that under these conditions, effects of word frequency in order  
30  
31 reconstruction do obtain. However, this experiment was prompted by the findings of  
32  
33 Merritt et al. (2006) that the effect in reconstruction of order only occurs when  
34  
35 participants experienced lists blocked by condition at presentation and not when they  
36  
37 were intermixed. We tested this in the next experiment in which high and low  
38  
39 frequency word lists were randomly intermixed.  
40  
41  
42

#### 43 *Methods*

##### 44 *Participants.*

45  
46 Participants were 138 third-year undergraduate students in the University of  
47  
48 Wollongong Psychology program delivered in Singapore, who took part in the  
49  
50 experiment as part of a class exercise. Almost all students in Singapore are bilingual  
51  
52 but complete all their schooling in English.  
53  
54

##### 55 *Stimuli and design.*

56  
57  
58  
59  
60

1  
2  
3 The stimuli used in this experiment were taken from Miller, Roodenrys and  
4 Arcioni (under review). Two sets of 30 CVC (consonant-vowel-consonant) stimuli  
5 were constructed so that each contained word pairs with the same consonants (see  
6 Appendix A). Vowels were selected to create high frequency and low frequency  
7 stimuli, respectively. For example, the high frequency stimuli ‘mouth’, ‘team’, ‘gun’,  
8 ‘book’, ‘head’, ‘wife’ were counterparts to the low frequency stimuli ‘moth’, ‘tame’,  
9 ‘gown’, ‘beak’, ‘hood’, ‘wharf’. High frequency stimuli ( $M = 198.33$ ,  $SD = 124.45$ )  
10 had reliably greater frequency than low frequency stimuli ( $M = 4.80$ ,  $SD = 3.92$ ),  
11 Mann-Whitney  $U = 0.00$ ,  $z = -6.66$ ,  $p < .001$ . These word sets were also controlled on  
12 concreteness, Mann-Whitney  $U = 427.50$ ,  $z = -0.33$ ,  $p = .739$ , biphone frequency,  
13 Mann-Whitney  $U = 441.50$ ,  $z = -0.13$ ,  $p = .900$ , phonological neighborhood, Mann-  
14 Whitney  $U = 445.50$ ,  $z = -0.07$ ,  $p = .947$ , and vowel length (short, long, and  
15 diphthong),  $\chi^2 = 2.66$ ,  $p = .265$ .

25  
26  
27  
28  
29  
30  
31  
32 *Procedure.*

33  
34 The experimental session was run during tutorial classes and was controlled  
35 by a bespoke computer program. Participants were given instructions regarding the  
36 serial reconstruction task; for each trial, they would see a fixation cross on the  
37 computer screen and after 1000ms the list would be presented, one item at a time in  
38 the center of the screen in 24pt Times New Roman font for 1000ms each. After the  
39 final item was presented, all items would appear in a random order on the screen from  
40 left to right. Using the computer mouse participants were asked to check off the items  
41 in the order they appeared in the list by selecting a box adjacent to each word. Once  
42 an item was selected a participant could not unselect it and all items had to be selected  
43 to complete a trial. The experiment was self-paced with the participant initiating each  
44 trial by pressing a ‘Next’ button on the computer screen.  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 Prior to the testing phase participants performed 2 practice trials. Each  
4  
5 experimental session comprised thirty, 6-item lists of each frequency condition. For  
6  
7 each participant, items were randomly arranged into lists; each item appeared across a  
8  
9 list set 6 times, but no item appeared in a list more than once. The order of high- and  
10  
11 low-frequency lists was randomized in a single block.  
12

### 13 *Results and Discussion*

14  
15  
16 The data were entered into 2 x 6 repeated measures ANOVA in which word  
17  
18 frequency (high vs. low) and item position (1-6) were entered as fixed factors and  
19  
20 participants acted as a random factor. The analysis was clear in showing statistically  
21  
22 reliable main effects of both word frequency,  $F(1, 137) = 205.38, p < .001$ , partial  $\eta^2$   
23  
24 = .600, and, item position,  $F(5, 685) = 255.24, p < .001$ , partial  $\eta^2 = .651$ , and a  
25  
26 statistically significant word frequency x item position interaction,  $F(5, 685) = 21.04$ ,  
27  
28  $p < .001$ , partial  $\eta^2 = .133$ . Figure 3 provides a graphical illustration of this pattern of  
29  
30 effects.  
31  
32

33  
34 The data quite clearly reveal a robust effect of word frequency in a serial  
35  
36 reconstruction of order task. It is of particular note that, in this case, the effect  
37  
38 emerged when pure lists of high and low frequency were randomly intermixed at  
39  
40 presentation. In this respect, the data are more indicative of the importance of the  
41  
42 constraints at testing rather than those at presentation: the effect of word frequency  
43  
44 has emerged under conditions of both blocked (in Experiment 2) and intermixed (in  
45  
46 Experiment 3) list presentation conditions.

60

*Figure 3.* Serial position curves for the two serial reconstruction conditions of interest in Experiment 3. Error bars reflect 1 SE of the particular condition mean. In the notation used, Hi stands for high frequency word lists, and Lo stands for low frequency word lists.

#### Experiment 4

In our final experiment, we again adopted tests of serial reconstruction of order (i.e., the testing method was as used in Experiment 3), but now we combined these with tests of serial recall. Following the presentation of a list of words, memory was tested either by serial recall or serial reconstruction of order. The type of test was

1  
2  
3 randomized across trials so that participants were unaware of which kind of test  
4  
5 would be administered until the time of the test itself. Merritt et al. (2006) reasoned  
6  
7 that this kind of procedure guarantees that the manner in which the participants  
8  
9 encode the items is the same for both forms of testing. As a consequence, any  
10  
11 contingent difference in performance across the two tasks cannot, therefore, be due to  
12  
13 differences in item encoding. As in Experiment 3, list type (high- vs low-frequency)  
14  
15 was randomly intermixed at presentation.  
16  
17

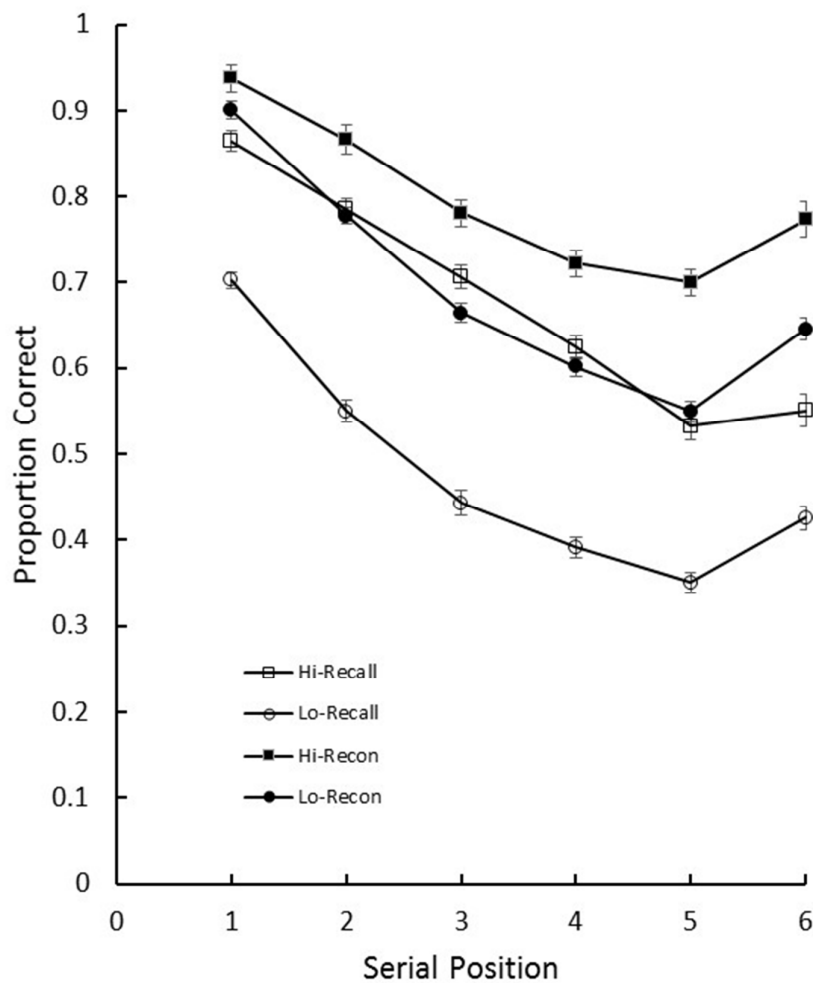

### 18 *Methods*

#### 19 *Participants.*

20  
21 Participants were 108 third-year undergraduate students the University of  
22  
23 Wollongong Psychology program delivered in Singapore who completed the  
24  
25 experiment as a subject requirement. The data from 17 students were omitted from the  
26  
27 final data set because the pattern of their responses indicated that they were not  
28  
29 attempting to recall the lists in full and so were not starting recall at the first item.  
30  
31  
32

#### 33 *Procedure.*

34  
35 The stimuli were identical to those used in Experiment 3 and the procedure  
36  
37 was very similar to that for Experiment 3 except that participants now performed 15  
38  
39 trials each of serial recall and serial reconstruction for both high- and low- frequency  
40  
41 words. The presentation of items replicated the procedure in Experiment 3. However,  
42  
43 recall or reconstruction was post-cued by the response screen that appeared after the  
44  
45 presentation of the final item in the list. Reconstruction trials were completed as per  
46  
47 Experiment 3. Serial recall trials were prompted by a screen comprising 6 horizontally  
48  
49 aligned text boxes that constrained participants to type their responses according to  
50  
51 strict serial recall protocol. Practice trials in Experiment 4 included both  
52  
53 reconstruction and recall forms to familiarize participants with each type of response.  
54  
55  
56  
57  
58  
59  
60

*Results and Discussion*

*Figure 4.* Serial position curves for the four conditions of interest in Experiment 4.

Error bars reflect 1 SE of the particular condition mean. In the notation used, Hi-Recall stands for high frequency word lists tested via serial recall, Hi-Recon stands for high frequency word lists tested via serial reconstruction of order, Lo-Recall stands for low frequency word lists tested via serial recall, Lo-Recon stands for low frequency word lists tested via serial reconstruction of order.

1  
2  
3 A graphical illustration of the summary data for the conditions of interest is  
4 provided in Figure 4. The data were entered into 2 x 2 x 6 repeated measures ANOVA  
5 in which type of task (recall vs. reconstruction), word frequency (high vs. low) and  
6 item position (1-6) were entered as fixed factors and participants acted as a random  
7 factor. The analysis revealed that all tests were statistically reliable:  $F(1, 90) =$   
8  $345.63, p < .001$ , partial  $\eta^2 = .793$ , for main effect of type of task;  $F(1, 90) = 421.46,$   
9  $p < .001$ , partial  $\eta^2 = .824$ , for main effect of word frequency;  $F(5, 450) = 175.74, p <$   
10  $.001$ , partial  $\eta^2 = .661$ , for main effect of item position;  $F(1, 90) = 55.70, p < .001,$   
11 partial  $\eta^2 = .382$ , for the type of task x word frequency interaction;  $F(5, 450) = 5.43, p$   
12  $< .001$ , partial  $\eta^2 = .057$ , for the type of task x item position interaction;  $F(5, 450) =$   
13  $9.26, p < .001$ , partial  $\eta^2 = .093$ , for the word frequency x item position interaction;  
14 and,  $F(5, 450) = 8.39, p < .001$ , partial  $\eta^2 = .085$ , for the type of task x word  
15 frequency x item position interaction.

32 The statistically significant three-way interaction shows that the effect of word  
33 frequency was expressed differently across the item positions in the recall and  
34 reconstruction tasks. Subsidiary analyses were carried out via simple main effects  
35 tests of the word frequency effect at each of the item positions across the two tasks.  
36 These revealed that the effect of word frequency was smaller in the data for the  
37 reconstruction task than the recall task in the earlier serial positions. Given the  
38 relatively high level of performance in the reconstruction task and the reduced  
39 variability in the data in these earlier positions, it seems likely that the three-way  
40 interaction is due to the influence of a ceiling effect in earlier positions. The  
41 frequency effect in the serial order reconstruction data is therefore remarkably similar  
42 to that in the recall data.

1  
2  
3 Overall, the data are clear in showing robust effects of word frequency in both  
4 the recall and reconstruction tasks. The data also show that the effects of word  
5 frequency in the serial reconstruction of order tasks reported here (i.e., Experiments 2  
6 and 3) cannot be attributed to some form of special item encoding that comes about  
7 when participants know that order memory will be tested in the upcoming trial.  
8 Indeed, the nature of the word frequency effect in the reconstruction tasks in  
9 Experiments 3 and 4 are remarkably similar. When expressed in terms of Cohen's  $d$ ,  
10 the word frequency effect size in Experiment 3 is 1.218 (95% CI spans 1.419 to  
11 1.017; Kirby & Gerlanc, 2013) and in Experiment 4 it is 1.096, (95% CI spans 1.342  
12 to 0.858). This provides some grounds for concluding that the effect of word  
13 frequency was essentially the same across these experiments despite the difference in  
14 the nature of the list presentation conditions.

### 30 General Discussion

31  
32 We have reported four experiments concerning performance in verbal short-  
33 term memory tasks. Across these experiments, we have been able to establish clear  
34 effects of word frequency in both serial recall and serial reconstruction of order tasks.  
35 Critically, we have been able to establish that the word frequency effects in  
36 reconstruction tasks are readily apparent when serial order of reconstruction is tested  
37 across a range of different presentation conditions. We have also been able to show  
38 differential effects of stimulus set size depending on the task requirements. Set size  
39 effects are readily apparent in the data for serial recall tasks but are seemingly absent  
40 when reconstruction of order is tested.

41  
42 Experiment 1 comprised a simple replication of the serial recall experiments  
43 reported by Roodenrys and Quinlan (2000). The variables of primary interest were  
44 word frequency and set size. The data from the serial recall task replicate those

1  
2  
3 reported by Roodenrys and Quinlan (2000), who argued that the particular pattern of  
4 findings is readily accounted for by processes concerning redintegration at test.  
5

6  
7 According to such an account, performance depends on attempting to reinstate the  
8 transitory short-term memory traces of the TBR items with corresponding long-term  
9 memory representations. Given that retrieval from long-term memory is easier for  
10 high frequency than low frequency items (Freedman & Loftus, 1971), the idea is that  
11 redintegration is correspondingly more efficient for sequences of common vs. rare  
12 words. Although more recent research has determined that the redintegrative potential  
13 of a word within a list appears to be a function of list composition (Stuart & Hulme,  
14 2000; Hulme et al., 2003) and item arrangement (Miller & Roodenrys, 2012) rather  
15 than specific to the individual item, the same argument holds.  
16  
17

18  
19 Roodenrys and Quinlan (2000) also argued that the effect of set size was only  
20 apparent in the data for the low frequency words because, in a sense, the long-term  
21 advantage for high vs. low frequency words far outweighed any additional benefit due  
22 to repeating items across the lists. The set size effect was, therefore, only present in  
23 the data for the low frequency words. Regardless of these details, the general point is  
24 that both variables are seen to influence processes operating at *output* rather than  
25 during an earlier stage of processing. As discussion proceeds, we question whether  
26 this account provides a useful framework for thinking about the current data.  
27  
28

29  
30 In Experiment 2, when simple serial presentation was followed by immediate  
31 serial reconstruction, a robust effect of word frequency was found. This finding was  
32 followed up in Experiments 3 and 4 which involved serial reconstruction of order  
33 with different constraints on how participants might encode the lists. In Experiment 3  
34 participants performed only the reconstruction task so were able to encode lists  
35 however they chose. In Experiment 4 the intermixing of recall and reconstruction  
36

57  
58  
59  
60

1  
2  
3 trials in a post-cued procedure ensured that item encoding and maintenance must be  
4  
5 the same for both tasks. Robust effects of word frequency were found in both cases.  
6  
7  
8 Indeed, the comparability of performance in the reconstruction tasks in Experiments 3  
9  
10 and 4 suggests strongly that common processes were being tapped in these two  
11  
12 experiments.

13  
14 In contrast to the inconsistent findings of word frequency effects in order  
15  
16 reconstruction in the literature, the effects of word frequency in the current  
17  
18 experiments are robust and orderly. When immediate tests of order memory for short  
19  
20 lists (equivalent in length to typical serial recall tasks) were used here, the pattern is  
21  
22 clear and more readily explained. The previous apparently ‘relevant’ studies have  
23  
24 used longer presentation times, longer retention intervals, and more complicated  
25  
26 methodologies. As a consequence, a full understanding of those data can only be  
27  
28 gained by further research. It is, therefore, most sensible to limit the following  
29  
30 discussion to consideration of the data reported here.  
31  
32

33  
34 The absence of a set size effect in serial order reconstruction suggests very  
35  
36 strongly that the set size effect seen in serial recall is one related to the retrieval of  
37  
38 item information during output. However, we do not wish to claim that effects in the  
39  
40 order reconstruction task cannot provide insights into processes concerning item  
41  
42 retrieval. Despite item information being re-presented at retrieval, performance in  
43  
44 serial reconstruction is not perfect, because the processes used to produce the next  
45  
46 item in sequence (i.e., the same processes that drive serial recall), sometimes fail (see  
47  
48 Neath, 1997, for more on this). We suggest that these processes are not open to  
49  
50 introspection, although the result of the process is. Sometimes the result is the correct  
51  
52 item: Sometimes it is an incorrect item and a number of possibilities then arise. It  
53  
54 may be that an explicit comparison of the retrieved item against the items re-presented  
55  
56  
57  
58  
59  
60

1  
2  
3 at test reveals to the participant which item should have been retrieved. At other  
4  
5 times, it may be that the trace of the item is so degraded that nothing is retrieved or  
6  
7 what does enter awareness does not discriminate between some of the items. At that  
8  
9 point, the task demands that the participant choose a response, and errors will ensue.  
10  
11 In agreement with Neath (1997), we conclude that even though an item is re-  
12  
13 presented at test this does not mean that all appropriate item information will be  
14  
15 reinstated in memory. We also accept that “reconstruction of order tests do not offer a  
16  
17 pure measure of order memory” (Neath, 1997, p. 262).  
18  
19

20  
21 The present experiments show a clear dissociation between set size and word  
22  
23 frequency as manipulations of item familiarity, and, therefore, an implication is that  
24  
25 these effects have different loci. The notion that set size influences recall through a  
26  
27 process of redintegration during the output phase of the recall task remains a plausible  
28  
29 explanation (as argued by Roodenrys & Quinlan, 2000). Indeed, it remains plausible  
30  
31 that the effect of word frequency in the serial recall task also reflects characteristics of  
32  
33 item redintegration. However, we suggest that the word frequency effects in the  
34  
35 reconstruction tasks reflect something else.  
36  
37

38  
39 In this regard, we agree with Thorn et al. (2009) in accepting a multiple  
40  
41 mechanisms account in which long-term knowledge influences short-term memory in  
42  
43 a number of different ways. We accept that processes of redintegration reflect the  
44  
45 influence of long-term knowledge in the manner discussed (see Thorn et al., 2009),  
46  
47 for instance, in helping reconstruct partial traces in the store during serial recall.  
48  
49 However, it is difficult to see why such a process of reconstruction is needed when  
50  
51 the items themselves are re-presented at test. The problem facing the system is not the  
52  
53 reconstruction of item traces, but recovery of the item ordering from the items  
54  
55 themselves. One possibility is that word frequency influences pre-retrieval processes  
56  
57  
58  
59  
60

1  
2  
3 as well as item retrieval. For instance, Lewandowsky and Farrell (2000) adopted a  
4  
5 similar idea in allowing for lexical effects to emerge as a consequence of a benefit at  
6  
7 encoding for words relative to non-words and we suggest that word frequency may  
8  
9 play a similar role. Although they discussed effects of word frequency in terms of  
10  
11 different mechanisms, here we claim that word frequency may exert an effect during  
12  
13 item encoding.  
14

15  
16 Many models of serial recall incorporate distinct mechanisms for the retention  
17  
18 of item and order information. These models generally assume that the two types of  
19  
20 information are only recombined at output, thus leading to the prediction that serial  
21  
22 reconstruction will be immune to item-based effects. This conclusion sits  
23  
24 uncomfortably with the word frequency effects described here. It is possible that the  
25  
26 relative familiarity of high frequency words vs. low frequency words means that the  
27  
28 ordering of the particular items is more readily encoded for high vs. low frequency  
29  
30 words.  
31  
32

### 33 34 Conclusions

35  
36 In sum, the experiments allow us to conclude that word frequency effects  
37  
38 occur in both serial recall and serial order reconstruction tasks. Collectively, the data  
39  
40 strongly suggest that even when TBR items are re-presented at test, the recovery of  
41  
42 their order depends on accessing both the short-term memory traces of these items  
43  
44 and their corresponding long-term memory representations. The findings sit most  
45  
46 comfortably with a multiple mechanisms account in which word frequency influences  
47  
48 both retrieval and pre-retrieval processes.

*Note.* log(Freq.) – log (base 10) of word frequency; Conc. – concreteness, and PNS – phonological neighbourhood size.

\* Frequency values were adjusted for the effects of homophones. Concreteness values are the weighted averages by frequency count across homophones.

<sup>†</sup> Phonological similarity measures using the algorithm of Mueller, Seymour, Kieras & Meyer (2003)

*Note.*  $\log(\text{Freq.})$  –  $\log$  (base 10) of word frequency; Conc. – concreteness, and PNS – phonological neighborhood size.

\* Frequency values were adjusted for the effects of homophones. Concreteness values are the weighted averages by frequency count across homophones.

† Phonological similarity measures using the algorithm of Mueller, et al. (2003)
