23 **Abstract**

24 Recent human fatalities from avian-origin H10N8 influenza virus infection raise
25 concerns about the threat of this virus subtype to public health. To investigate genetic
26 adaptation of H10 avian influenza viruses in mammals, we generated
27 a mouse-adapted avian H10N7 variant (A/mallard/Beijing/27/2011-MA, [BJ27-MA])
28 through nine serial passages in mice. Mice infected with BJ27-MA virus died by 6
29 days post-infection and showed neuronal infection in contrast to parental virus which
30 elicited no overt symptoms. Sequence analysis showed the absence of the widely
31 recognized mammalian adaptation markers of E627K and D701N in PB2 in the
32 mouse-adapted strain; instead five amino acid mutations were identified: E158G and
33 M631L in PB2, G218E in HA (H3 numbering), and K110E and S453I in NA.
34 Neurovirulence of BJ27-MA virus necessitated the combined presence of the PB2 and
35 NA mutations. Mutations M631L and E158G of PB2 and K110E of NA were required
36 to mediate increased virus replication and severity of infection in mice and
37 mammalian cells. PB2-M631L was functionally the most dominant mutation in that it
38 strongly up-regulated viral polymerase activity and played a critical role in the
39 enhancement of virus replication and disease severity in mice. K110E mutation in NA,
40 on the other hand, significantly promoted NA enzymatic activity. These results
41 indicate that the novel mutations in PB2 and NA genes are critical for the adaptation
42 of avian H10N7 influenza virus in mice, which could serve as molecular signatures of
43 virus transmission to mammalian hosts including humans.

45 **Importance**

46 The increasingly prevalent H10 subtype of avian influenza virus in China has
47 recently been a source of human fatalities. We demonstrated that an avian H10N7
48 virus can readily be adapted to become highly pathogenic and neurotropic in mice.
49 Mutations in PB2 and NA from the mouse-adapted virus (BJ27-MA) were the major
50 determinants of enhanced pathogenicity of which mutation PB2-M631L was
51 functionally most dominant. Although BJ27-MA virus lacked the well-known
52 mammalian adapted mutations (namely PB2-E627K and PB2-D701N), PB2-M631L
53 mutation enhanced viral polymerase activity, replication and pathogenicity of
54 BJ27-MA virus in mice, indicating a novel adaptation strategy. These observations
55 affirm the public health threat of avian H10 subtype influenza viruses and have
56 implications in the assessment of potential mutant viruses that may cause severe
57 infections in humans.

58

59 **Introduction**

60 Presently, avian influenza viruses (AIVs) cause great economic losses to the global
61 poultry industry, which historically were major contributors to the 1918 H1N1, 1957
62 H2N2 and 1968 H3N2 virus pandemics (1). H5N1 and H9N2 influenza viruses, as the
63 two principal subtypes circulating in poultry, are high on the list of candidates that
64 could potentially cause another major human influenza outbreak (2, 3). However,
65 recent human cases of emergent avian H7N9 virus infection challenge our
66 understanding of the main subtypes of possible future pandemic human virus (4).
67 Thus, contingency planning in the prevention and management of avian influenza
68 virus infections in human should be based on a broad range of possible subtypes.

69 Between November 2013 and February 2014, two fatal and one severe cases of
70 human infections with a novel reassortant H10N8 virus in Jiangxi, China, were
71 reported for the first time (5-7). Avian H10 virus subtype was firstly isolated from
72 chickens in Germany in 1949 (8, 9); subsequently viruses bearing H10 hemagglutinin
73 (HA) and different neuraminidase (NA) subtypes have become widely prevalent in
74 wild birds and domestic poultry around the world (10-12). Since 1984, repeated
75 infections or deaths of mammals with this subtype have been reported, such as the
76 outbreaks of H10N4 virus in minks (13), H10N5 virus in domestic pigs (14), H10N8
77 virus in feral dogs (15) and H10N7 virus in harbor seals (16-18). Human cases of H10
78 virus infections had occurred sporadically in several other countries. For example,
79 H10N7 viruses had caused a number of human infections in Egypt in 2004 (19). In
80 March 2010, H10N7 virus infection was identified in two abattoir workers in a

81 commercial poultry farm in Australia who showed conjunctivitis and minor upper
82 respiratory tract symptoms (12). In the USA, serological evidence of exposure to H10
83 virus subtype was confirmed in turkey workers (20). The repeated human cases of
84 H10 virus infections coupled with the prevalence of H10 viruses in birds raise
85 concerns that this particular subtype could pose increasing threat to human and animal
86 health. However, the molecular adaptations of H10 influenza viruses in mammals are
87 largely unknown.

88 Adaptation is considered to be a primary driver in evolution, and the process of
89 natural selection of influenza A viruses in experimental mice appears also to hold true
90 for humans (21). Several adaptation studies of human H3N2, pandemic 2009 H1N1,
91 avian H9N2 and H6N6 influenza viruses in mice have provided better understanding
92 of molecular determinants of virus pathogenicity in mammals including humans
93 (22-26). Here, to explore the genetic adaptations of H10 AIV subtype in mammals, we
94 serially passaged a low-pathogenicity avian-derived H10N7 virus in mice. We found
95 that mouse-adapted H10N7 virus acquired high pathogenicity status causing fatal
96 infection and neurovirulence. The well-known mammalian adaptation markers
97 PB2-E627K and PB2-D701N (27, 28) were not found in the mouse-adapted strain, but
98 amino acid substitution PB2-M631L was a dominant contributor to virus virulence.

99

100 **Materials and methods**

101 **Ethics statement**

102 All animal work was approved by the Beijing Association for Science and

103 Technology (approval ID SYXK [Beijing] 2007-0023) and conducted in accordance
104 with the Beijing Laboratory Animal Welfare and Ethics guidelines, as issued by the
105 Beijing Administration Committee of Laboratory Animals, and in accordance with the
106 China Agricultural University Institutional Animal Care and Use Committee
107 guidelines (ID: SKLAB-B-2010-003).

108 **Viruses and cells**

109 The H10N7 virus A/mallard/Beijing/27/2011 (BJ27) was isolated in Beijing, China
110 and propagated in the allantoic cavities of 10-day-old specific-pathogen-free (SPF)
111 embryonated chicken eggs (Merial, Beijing, China) at 37°C for 72 h. Allantoic fluid
112 containing virus was harvested, aliquoted and frozen at -80°C for later use. Viruses
113 were titrated in MDCK cells to determine the 50% tissue culture infectious dose
114 (TCID₅₀) by the Reed and Muench method (29). Human embryonic kidney (293T),
115 human pulmonary adenocarcinoma (A549), Madin Darby canine kidney (MDCK) and
116 mouse neuroblastoma N2a (N2a) cells were maintained in Dulbecco's modified
117 Eagle's medium (DMEM, Gibco) supplemented with 10% fetal bovine serum (FBS,
118 Gibco), 100 units/ml of penicillin, and 100 µg/ml of streptomycin at 37°C in 5% CO₂
119 atmosphere.

120 **Adaptation of the BJ27 virus in mice**

121 Six 6-week-old female BALB/c mice (Beijing Experimental Animal Center) were
122 anesthetized with Zoletil 50 (tiletamine-zolazepam; Virbac S.A., Garros, France) and
123 inoculated intranasally with 50 µl of allantoic fluid containing BJ27 virus. At 3 days
124 post-inoculation (dpi), three mice were euthanized and the lungs were harvested and

125 homogenized in 1 ml of sterile cold phosphate-buffered saline (PBS). The
126 homogenate was centrifuged at $6,000 \times g$ for 5 min at 4°C and filtered through a
127 0.22- μm -pore-size cellulose acetate filter (Millipore, USA). Fifty μl of filtered
128 homogenate were used as inoculum per mouse for the next passage (passage 2 [P2]).
129 The remaining three mice were monitored daily for clinical symptoms. At 9 passages
130 (P9), the virus in the lung homogenate was subjected to three rounds of plaque
131 purification in MDCK cells, and the cloned virus, designated BJ27-MA, was
132 amplified once in 10-day-old SPF embryonated eggs for 72 h at 37°C, as previously
133 described (30).

134 **Sequence analysis**

135 Viral RNA was extracted from allantoic fluid containing plaque-purified BJ27-MA.
136 The eight virus genes were amplified by reverse transcription-PCR (RT-PCR) and
137 sequenced. Adaptive mutations arising from serial passage were identified by
138 comparing consensus BJ27-MA and wild type BJ27 sequences.

139 **Plasmid construction and virus rescue**

140 The eight gene segments of BJ27 and BJ27-MA were amplified by RT-PCR and
141 cloned into the expression plasmid, PHW2000. Mutations of interest in the PB2, HA
142 and NA gene were introduced by PCR-based site-directed mutagenesis with primer
143 pairs containing point mutations. All constructs were sequenced to confirm mutational
144 changes.

145 Reassortant viruses between BJ27 and BJ27-MA were generated by reverse
146 genetics as described previously (31). Briefly, 0.5 μg of each gene segment plasmid

147 was mixed together and incubated with 8 μ l of TransIT-LT1 reagent (Mirus Bio, USA)
148 at 20°C for 30 min. The TransIT-LT1-DNA mixture was transferred to 70% confluent
149 293T/MDCK co-cultured monolayers and incubated at 37°C with 5% CO₂. Six hours
150 post-transfection, the supernatants were replaced with 2 ml of Opti-MEM containing
151 2 μ g/ml TPCK-treated trypsin (Sigma-Aldrich). Forty-eight hours post-transfection,
152 the cell supernatants were harvested and inoculated into 10-day-old SPF embryonated
153 eggs and incubated for 72 h at 37°C to prepare a virus stock. Viral RNA was extracted
154 and analyzed by RT-PCR, and each viral segment was sequenced to confirm identity.
155 Virus titers were determined by TCID₅₀ assay on MDCK cells.

156 **Mouse experiments**

157 Groups of eleven 6-week-old female BALB/c mice (Beijing Experimental Animal
158 Center) were anesthetized with Zoletil 50 (tiletamine-zolazepam; Virbac S.A., Garros,
159 France) and inoculated intranasally with 10^{5.5} TCID₅₀ of viruses in 50 μ l PBS. Three
160 mice in each group were euthanized at 3 and 5 dpi; lungs, brains, spleens, kidneys and
161 livers were collected for virus titration in MDCK cells. The remaining five mice in
162 each group were monitored for weight loss and mortality for 14 days. Mice that lost
163 more than 30% of their body weight were humanely euthanized. To determine the
164 fifty percent mouse lethal dose (MLD₅₀), groups of three 6-week-old female mice
165 anesthetized with Zoletil 50 and inoculated intranasally with 50 μ l of 10-fold serial
166 dilutions of viruses in PBS. The mice were monitored for 14 days. MLD₅₀ was
167 calculated and expressed in TCID₅₀. For histopathology and immunohistological
168 analysis, mouse lungs and brains collected at 5 dpi were fixed in 10%

169 phosphate-buffered formalin, embedded in paraffin, then cut into 5 mm-thick sections
170 and stained with haematoxylin and eosin (H&E) or immunostained with a mouse
171 monoclonal antibody specific for influenza A virus NP (Biorbyt, UK).

172 **Viral growth kinetics**

173 Selected recombinant viruses were inoculated onto MDCK cell monolayers (at
174 multiplicity of infection [MOI] of 0.01), A549 cell monolayers (at MOI of 0.1) or N2a
175 cell monolayers (at MOI of 0.1) in serum-free DMEM containing 1 µg/ml
176 TPCK-treated trypsin and incubated at 37°C with 5% CO₂ atmosphere. Cell
177 supernatants were harvested at 12, 24, 36, 48, 60 and 72 hours post-inoculation (hpi)
178 and titrated on MDCK cells in 96-well plates. Three independent experiments were
179 performed for each virus.

180 **Polymerase activity assay**

181 The PB2, PB1, PA and NP gene segments of BJ27, BJ27-MA and BJ27-PB2
182 mutants were individually inserted into pCDNA3.1 plasmid. PB2, PB1, PA and NP
183 plasmids (125 ng each) were transfected to sixty percent confluent 293T cells,
184 together with fire-fly luciferase reporter plasmid pYH-Luci (10 ng) and internal
185 control plasmid expressing renilla luciferase (2.5 ng). After 24 hours of transfection,
186 cell lysate was prepared with Dual Luciferase Reporter Assay System (Promega) and
187 luciferase activity was measured using GloMax 96 microplate luminometer
188 (Promega).

189 **Western blotting**

190 PB2 expression levels in different transfection groups were determined by Western

191 blotting. Total cell protein lysates were extracted from transfected 293T cells with
192 CA630 lysis buffer (150 mM NaCl, 1% CA630 detergent, 50 mM Tris base [pH 8.0]).
193 Cellular proteins were separated by 12% sodium dodecyl sulfate-polyacrylamide gel
194 electrophoresis (SDS-PAGE) and transferred to a polyvinylidenedifluoride (PVDF)
195 membrane (Amersham Biosciences, Germany). Each PVDF membrane was blocked
196 with 0.1% Tween 20 and 5% nonfat dry milk in Tris-buffered saline and subsequently
197 incubated with a primary antibody. Primary antibodies used were specific for
198 influenza A virus PB2 (ThermoFisher, USA) and β -actin (Beyotime, China).
199 Secondary antibody was horseradish peroxidase (HRP)-conjugated anti-rabbit or
200 -mouse antibody (Beyotime, China). HRP presence was detected using a Western
201 Lightning chemiluminescence kit (Amersham Pharmacia, Freiburg, Germany),
202 following the manufacturer's protocols.

203 **Neuraminidase (NA) activity assay with substrate 4-MU-NANA**

204 NA activity assays using the soluble substrate MUNANA (Sigma, Germany) were
205 performed as previously described (32). Briefly, virus was diluted to 10^6 TCID₅₀/ml
206 and 50 μ l was added to each well of a black 96-well plate (CoStar). Concentrations of
207 MUNANA substrate ranging from 2.0 μ M to 200 μ M were used. When cleaved by
208 the viral NA, MUNANA produces a fluorescent product. Fluorescence was quantified
209 using a Biotek Synergy H1 plate reader every 3 minutes over the course of 45 minutes.
210 Fluorescence curves were then fitted to the Michaelis-Menton equation to determine
211 values of V_{\max} and K_m . Each experiment comprised triplicate samples of each virus.

212 **Statistical analyses**

213 All statistical analyses were performed using GraphPad Prism Software Version
214 5.00 (GraphPad Software Inc., San Diego, CA, USA). Statistically significant
215 differences between experimental groups were determined using the analysis of
216 variance (ANOVA). Differences were considered statistically significant at $P < 0.05$.

217 **Nucleotide sequence accession numbers**

218 The nucleotide sequences of the eight gene segments of H10N7 are available from
219 GenBank under accession numbers: KX898962 for PB2, KX898963 for PB1,
220 KX898964 for PA, KX898965 for HA, KX898966 for NP, KX898967 for NA,
221 KX898968 for M, and KX898969 for NS.

222

223 **Results**

224 **Adaptation of avian H10N7 influenza virus in mice**

225 To mimic the adaptation of avian H10 subtype influenza virus in mammalian hosts,
226 A/mallard/Beijing/27/2011 H10N7 virus (BJ27) was serially passaged in murine host
227 by intranasal inoculation of $10^{5.5}$ TCID₅₀ of virus per mouse. Mice at passage 1 (P1)
228 infected with wild type BJ27 did not show overt clinical sign. At P5, infected mice
229 showed mild clinical signs, including decreased activity and ruffled coat. At P9 and
230 P10, mice displayed severe clinical symptoms of respiratory distress, inactivity and
231 inappetence; all infected mice died by 5 dpi (data not shown), indicating significant
232 increase in pathogenicity. P9 virus from lung homogenate was plaque purified three
233 times in MDCK cells and designated BJ27-MA.

234 **Mouse-adapted H10N7 virus exhibited enhanced pathogenicity and** 235 **neurovirulence**

236 BALB/c mice were infected, in two groups of eleven mice each, with $10^{5.5}$ TCID₅₀
237 of BJ27 or BJ27-MA virus to compare virus pathogenicity. BJ27-MA virus caused

238 dramatic weight loss in infected mice and all were dead by 6 dpi, while mice infected
239 with BJ27 showed modest weight loss of 8.7% and recovery weight gain from 7 dpi
240 (Fig. 1A and B). To determine whether the differences in pathogenicity between BJ27
241 and BJ27-MA virus were due to altered virus replication, groups of three BALB/c
242 mice were euthanized at 3 and 5 dpi respectively, and virus titers in lung and brain
243 were determined. As shown in Fig 1C and D, mouse-adapted BJ27-MA virus
244 replicated to higher titers in the lungs than wild type BJ27 virus at 3 and 5 dpi.
245 Furthermore, BJ27-MA virus was isolated from brains of infected mice in rising titers
246 from mean titer of 2.1 log₁₀ TCID₅₀/ml at 3 dpi to 2.8 log₁₀ TCID₅₀/ml at 5 dpi. No
247 virus was isolated from brains of BJ27 virus infected mice. Therefore, the
248 mouse-adapted BJ27-MA virus has acquired neurotropism which would have
249 contributed to the severity of infection in mice.

250 **Genetic changes in adapted BJ27-MA virus**

251 To identify potential segments and amino acid substitutions that are responsible for
252 increased pathogenicity and replication of BJ27-MA virus in mice, the consensus
253 sequence of thirty virus clones was determined. Interestingly, the most common
254 mammalian adaptation determinants of PB2-E627K and PB2-D701N (27, 28), did not
255 appear in any of the thirty clones, indicating that other viable adaptations were present
256 in the BJ27-MA virus. Here, five conserved amino acid mutations that could be linked
257 to increased pathogenicity were identified in 3 virus segments of the BJ27-MA virus
258 as PB2-E158G, PB2-M631L, HA-G218E (H3 numbering), NA-K110E and
259 NA-S453I.

260 PB2-E158G mutation resides in the amino-terminal NP binding region (1–269aa)
261 (23), and PB2-M631L lies in the PB2-PB1 and PB2-NP interaction regions (25). HA
262 G218E is located near the 220-loop of the globular head HA1 domain (33).

263 NA-K110E and NA-S453I reside in the amino-terminal and carboxyl-terminal region
264 of NA protein, respectively; both are located in the interface of tetrameric structure of
265 NA protein (34).

266 **PB2 and NA segments in BJ27-MA virus conferred increased pathogenicity and**
267 **replication capacity in mice**

268 To identify virus segments from the BJ27-MA virus that confer increased
269 pathogenicity in mice, a series of recombinant viruses were generated by reverse
270 genetic based on wild type BJ27 (rBJ27) and BJ27-MA (rBJ27-MA) viruses.
271 Recombinant viruses rBJ27-PB2, rBJ27-HA and rBJ27-NA were constructed in rBJ27
272 virus background with the substituted segments of PB2, HA and NA, respectively,
273 from the rBJ27-MA virus. Mice infected with recombinant viruses were monitored
274 over 14 days for weight loss and survival rate. As shown in Fig. 2A and B, all of
275 rBJ27 and rBJ27-HA viruses infected mice, similar to wild type BJ27 virus infection,
276 survived with maximum 6.7% and 8.8% weight loss respectively. By contrast, mice
277 infected with rBJ27-MA and rBJ27-PB2 viruses resulted in 25% to 31% weight loss
278 and 100% mortality by 6 dpi. rBJ27-NA virus showed moderate increase in
279 pathogenicity with 40% mortality. The MLD₅₀ values also showed the same
280 descending order of virus virulence: rBJ27-MA, rBJ27-PB2 (both MLD₅₀, 4.75 log₁₀
281 TCID₅₀) > rBJ27-NA (5.75 log₁₀ TCID₅₀) > rBJ27 and rBJ27-HA (>6.5 log₁₀ TCID₅₀)
282 (Table 1). None of these segment recombinants was neurotropic although they were
283 recovered from lungs and extrapulmonary organs (kidney and/or spleen) (Table 1).
284 Thus, the adaptive PB2 and NA segments of BJ27-MA conferred increased virulence
285 in wild type BJ27 virus background in mice.

286 **Combined PB2 and NA segments of BJ27-MA virus contributed to**
287 **neurovirulence**

288 Influenza virus replication in the central nervous system (CNS) often leads to fatal
289 outcome (35-37). Although mouse-adapted BJ27-MA virus was able to efficiently
290 replicate in murine brain, none of the above single segment recombinant viruses was
291 found in the brain of infected mice (Table 1). Next, we generated three
292 double-segment recombinant viruses based on the rBJ27 backbone: rBJ27-PB2/HA
293 virus, rBJ27-PB2/NA virus and rBJ27-HA/NA virus. As shown in Table 2, only
294 rBJ27-PB2/NA virus was recovered from infected murine brains at 3 and 5 dpi which
295 produced MLD_{50} value and viral loads similar to those of rBJ27-MA virus at each
296 time point. Viral NP was readily detected in neurons of mice infected separately with
297 rBJ27-MA and rBJ27-PB2/NA viruses (Fig. 3A). These data demonstrated that the
298 combined PB2 and NA segments of rBJ27-MA contributed to its neurovirulence in
299 mice.

300 The ability of double segment recombinant viruses to replicate in neural tissue was
301 assessed in mouse neuroblastoma N2a cells which has been used to study the
302 replication of neurotropic viruses (38). Only rBJ27-MA and rBJ27-PB2/NA viruses
303 showed up to 15-fold increased virus output relative to rBJ27 virus at 24 and/or 36 hpi
304 (Fig. 3B). The other viruses (rBJ27-PB2/HA and rBJ27-HA/NA) showed no
305 significant difference in virus titers at all time points. Therefore, the combined PB2
306 and NA segments also enhanced the replication of rBJ27-MA virus in neural cells.

307 **PB2-M631L, PB2-E158G and NA-K110E contributed to severe BJ27-MA virus**
308 **infection**

309 To pinpoint the contribution of the single mutations in PB2 and NA to the increased

310 pathogenicity of BJ27-MA, four point mutant viruses were generated with the rBJ27
311 backbone as rBJ27-PB2/E158G, rBJ27-PB2/M631L, rBJ27-NA/K110E and
312 rBJ27-NA/S453I viruses. Virus rBJ27-PB2/M631L was most virulent in that all
313 infected mice died before 8 dpi (Fig. 2C and D). Virus rBJ27-PB2/E158G and
314 rBJ27-NA/K110E caused moderate weight loss of around 13.3% without fatality.
315 Virus NA-S453I and wild type rBJ27 were least pathogenic and caused little weight
316 loss. MLD₅₀ was highest with PB2-M631L virus (4.75 log₁₀ TCID₅₀) relative to all the
317 other viruses (>6.5 log₁₀ TCID₅₀) (Table 1). Compared with rBJ27, the viral titers of
318 rBJ27-PB2/M631L, rBJ27-PB2/E158G and rBJ27-NA/K110E in murine lungs were
319 significantly higher at 3 and/or 5 dpi (Table 1). Virus rBJ27-PB2/M631L produced
320 the highest virus titers. However, none of the four point mutation viruses showed
321 extrapulmonary infection in liver, spleen, kidney or brain.

322 Histopathological findings of lung tissues taken at 5 dpi gave a severity picture that
323 was similar to the pathogenicity results (Fig. 2E). Virus rBJ27-PB2/M631L and
324 rBJ27-MA elicited the most severe lung lesions of edema, inflammatory infiltrates,
325 interstitial pneumonia and bronchopneumonia. Lungs from rBJ27-PB2/E158G and
326 rBJ27-NA/K110E virus infection showed less severe bronchopneumonic changes.
327 Almost no lung lesion was detected from infection with rBJ27 and rBJ27-NA/S453I
328 viruses except for some thickening of alveolar wall and mild infiltration of
329 inflammatory cells.

330 We next compared the replication of the four mutant viruses in MDCK and A549
331 cells, infected at MOI of 0.01 or 0.1 respectively, over 72 h. In MDCK cells (Fig. 4A),

332 rBJ27-MA virus showed higher output (up to 56-fold higher) than the parental rBJ27
333 from 24 to 72 hpi, and PB2/M631L mutation increased the replication of rBJ27 virus
334 at 36 hpi (both $P < 0.05$). Replication of rBJ27-PB2/E158G, rBJ27-NA/K110E and
335 rBJ27-NA/S453I viruses was similar to that of rBJ27 virus. In A549 cells, the
336 rBJ27-MA virus also showed higher output from 24 to 60 hpi, and rBJ27-PB2/M631L,
337 rBJ27-PB2/E158G and rBJ27-NA/K110E viruses produced more progeny virus at 24
338 or 36 hpi than rBJ27 virus (all $P < 0.05$) (Fig. 4B). Therefore, in summary,
339 PB2-M631L, PB2-E158G and NA-K110E mutations in rBJ27 virus backbone
340 conferred more severe infection than wild type rBJ27 virus in mice and mammalian
341 cells, with PB2-M631L mutation being the most potent determinant.

342 **PB2-M631L and PB2-E158G mutations enhanced polymerase activity of**
343 **BJ27-MA virus**

344 PB2 is one of the components of ribonucleoprotein (RNP). RNP polymerase
345 activity has been shown to catalyze viral transcription and genomic replication, which
346 correlate with viral replication and pathogenicity in hosts (39). To evaluate whether
347 the mutations of PB2-E158G and PB2-M631L affect viral polymerase activity, we
348 generated two mutant RNP complexes under the background of the RNP of rBJ27,
349 and measured their polymerase activities in 293T cells by a luciferase minigenome
350 assay (Fig. 5). RNP polymerase activity with single E158G or M631L mutation was
351 28 or 62 times higher, respectively, than that of wild type rBJ27 RNP complex;
352 combined E158G and M631L PB2 mutations induced 75 times higher activity than
353 with the rBJ27 RNP complex (all $P < 0.05$). Western blotting, based on protein lysates

354 derived from 293T cells transfected with the different PB2 mutant plasmids in RNP
355 polymerase assays, showed comparable PB2 protein expression, which indicated that
356 the differences in polymerase activity were not due to levels of protein expression
357 (Fig. 5). Collectively, the raised polymerase activity conferred by PB2-M631L and
358 PB2-E158G mutations correlate with their severity of virus replication in mice and
359 mammalian cells, and suggest that elevated polymerase activity, rather than protein,
360 mediated the increased replication of BJ27-MA virus; the single M631L mutation in
361 PB2 appeared as a major contributor.

362 **NA-K110E increased NA enzymatic activity**

363 NA enzymatic activity is associated with influenza virus replication and
364 pathogenicity (40). The two amino acid mutations (K110E and S453I) in the
365 BJ27-MA NA protein were evaluated for NA enzymatic activity as described
366 previously (32). Based on K_m values, we found that the NA-K110E mutation caused a
367 significant increase as did the mutant segment (rBJ27-NA with double mutations) in
368 substrate affinity (Table 3). Similarly, V_{max} , which was determined by both the specific
369 activity and the amount of enzyme in the reaction mixture, was significantly higher
370 with the K110E mutation than with wild type rBJ27 virus ($P < 0.05$). The V_{max} of
371 rBJ27-NA/S453I virus was increased but not significantly higher than rBJ27 virus.
372 Thus, NA-K110E mutation improved NA enzymatic activity, which would have
373 contributed to the increased replication and pathogenicity of rBJ27-MA virus in mice.

374 **Discussion**

375 In this study, serial passage of avian H10N7 virus in mice resulted in dramatic

376 acquisition of pathogenicity in terms of increase virus replication, virus dissemination
377 that extended to the brain and high mortality rate. Five conserved mutations were
378 identified in PB2, HA and NA genes of the passaged BJ27-MA virus (PB2-E158G,
379 PB2-M631L, HA-G218E, NA-K110E and NA-S453I). The mutations in PB2 and NA
380 genes significantly up-regulated viral polymerase activity and NA enzymatic activity
381 respectively; their combined presence in BJ27-MA virus was necessary for
382 neurovirulence. In particular, M631L mutation in PB2 was a major molecular
383 determinant for the overall increase in virulence of the mouse-adapted H10N7 virus.

384 PB2 gene plays important roles in the adaptation of influenza viruses from avian to
385 mammals through increasing polymerase activity and viral replication (41).
386 Polymerases of avian-origin generally have impaired function in human and other
387 mammalian cells (39). To overcome this natural restriction, avian polymerases need to
388 acquire mutations that lead to improved activity in mammalian hosts. E627K or
389 D701N in PB2 is a common adaptive change of avian influenza viruses that cause
390 mammals and human infections (27, 28, 42). In our mice adaptation study, in place of
391 these reported mutations in the PB2 gene, E158G and M631L were identified to
392 mediate the promotion of polymerase activity, virus pathogenicity and replication in
393 mice. PB2-E158G was reported to be a pathogenic determinant of pandemic H1N1
394 and avian H5 influenza viruses in mice (24). PB2-M631L is a novel and dominant
395 pathogenic mutation not previously described. The structure of PB2 shows that
396 position 631 is close to position 627 and located at the PB2-PB1 and PB2-NP
397 interaction regions (22). From the isolates of human infection cases, PB2 sequence

398 analysis found that nine avian H5N1 and two pandemic H1N1/2009 viruses possessed
399 PB2-M631L but not E627K or D701N mutation, implying that PB2-M631L could be
400 functionally important independent of E627K or D701N. Likewise, during the
401 pH1N1/2009 virus outbreak in humans, the PB2-E627K mutation was absent; instead
402 PB2-G590S/Q591R mutation was responsible for increased polymerase activity in
403 human cells (43). Therefore, PB2-M631L could be a novel functional mutation in
404 H10N7 virus adaptation in mammalian hosts.

405 NA cleaves sialic acid from glycans on host cell and emerging virions, thus
406 allowing unhindered release of progeny virus from infected cells (40). Several studies
407 found that amino acid mutations or deletions in NA can affect NA enzymatic activity,
408 which correlate with virus replication and pathogenicity *in vitro* or *in vivo* (44-46).
409 Here, NA-K110E in BJ27-MA virus, acting as a novel mammalian mutation,
410 significantly increased NA activity and viral replication in mice. We found that the
411 two NA mutations (K110E and S453I) are located in the interface of tetrameric
412 structure of NA (34) which may affect the formation of tetramer.

413 Neurovirulence is not commonly observed in the adaptation of avian influenza
414 viruses in mice (21-23, 42). Besides our H10N7 virus, another related virus (H10N8)
415 was reported to acquire neurotropism after two passages in mice (42), suggesting that
416 H10 subtype might be more able to gain the ability to replicate in mammalian brain.
417 Clinically, CNS disease is a common extra-respiratory complication in humans
418 induced by influenza virus. Patients with CNS manifestations are more likely to
419 experience severe illness (35-37). In Australian and Texas, USA, 9.7% and 8.8%

420 hospitalized children, respectively, infected with pH1N1/2009 virus had neurological
421 complications (47, 48). Ying et al. also found that viruses with high replication ability
422 in murine brain also possess high pathogenicity (49). The collective evidence
423 indicates that high pathogenicity and neurovirulence could cooperate to promote
424 fatalities in human cases of H10N8 virus infection. Molecular mechanism of influenza
425 virus causing infection in the CNS is unclear. HA, NA and PB2 genes have been
426 separately found to be critical to the neurovirulence of H1N1 or H5N1 viruses in
427 mammalian hosts (50-53). However, in our present study, the viruses with single
428 adapted PB2 or NA segment could not cause brain infection although when combined
429 they replicated in the brain to a level comparable with rBJ27-MA virus which
430 indicates that the synergistic effect of PB2 and NA is important for H10N7
431 neurovirulence.

432 In summary, our mouse adaptation study clearly shows that avian H10N7 virus can
433 readily become highly virulent and neurotropic after limited passages in mice. We
434 demonstrated that this enhanced pathogenicity was mediated by specific mutations in
435 PB2 and NA genes; in particular PB2-M631L is a novel and critical determinant of
436 virulence.

640 **Figure legends**

641 **FIG 1** Pathogenicity and replication of wild type (BJ27) and mouse-adapted
642 (BJ27-MA) H10N7 viruses in mice. Six-week-old female BALB/c mice were
643 inoculated with $10^{5.5}$ TCID₅₀ of the indicated viruses or mock infected with PBS. (A)
644 Body weight changes over a 14-day period were plotted as percentage of body weight
645 at 0 dpi (n = 5 per group). Data are presented as means \pm SD of five individual mice.
646 (B) Survival data expressed as percentage of mice infected with indicated virus. Mice
647 that lost > 30% of their baseline weight were euthanized. BJ27 and BJ27-MA virus
648 titers were determined in lungs (C) and brains (D) of infected mice (n = 3 per group).
649 Data are presented as means \pm SD of three individual mice. * , the value is
650 significantly different from that of BJ27 ($P < 0.05$, ANOVA).

651

652 **FIG 2** Relative virulence of different recombinant and mutant BJ27 (H10N7) viruses
653 in mice. (A and C) Body weight changes in mice (n = 5) infected with $10^{5.5}$ TCID₅₀ of
654 indicated viruses over a 14-day period, plotted as percentage of body weight at 0 dpi.
655 Data are presented as means \pm SD of five individual mice. (B and D) Survival data
656 expressed as percentage of mice infected with indicated viruses. Mice that lost more
657 than 30% of baseline weight were euthanized. (E) H&E examination was performed
658 on the lungs of mice infected with indicated viruses at 5 dpi. Virus rBJ27-PB2/M631L
659 and rBJ27-MA infection caused severe bronchopneumonia; rBJ27-PB2/E158G and
660 rBJ27-NA/K110E infections produced moderate bronchopneumonia ; rBJ27 and
661 rBJ27-NA/S453I infection caused almost no lung lesion. Scale bar, 200 μ m.

662 **FIG 3** Neurovirulence of recombinant BJ27 (H10N7) viruses. (A) Sections of brains
663 taken from mice 5 dpi with $10^{5.5}$ TCID₅₀ of indicated viruses were immunostained for
664 viral NP (open arrow). Scale bar, 400 μ m. (B) Growth kinetics of recombinant viruses
665 in neuronal N2a cells. Confluent N2a cells were infected with indicated viruses at 0.1
666 MOI. Data are presented as means \pm SD of three independent experiments. *, the
667 value is significantly different from that of rBJ27 ($P < 0.05$, ANOVA).

668

669 **FIG 4** Growth kinetics of recombinant H10N7 viruses in MDCK and A549 cells.
670 Confluent MDCK (A) or A549 (B) cells were infected with viruses as indicated at
671 MOI of 0.01 or 0.1 respectively. Data are presented as means \pm SD of three
672 independent experiments. *, the value is significantly different from that of rBJ27 (P
673 < 0.05 , ANOVA).

674

675 **FIG 5** Polymerase activity of BJ27 with different PB2 mutations in minigenome
676 assays. Luciferase activities were relative to wild type BJ27 set at 100%. Expression
677 of PB2 and β -actin was detected by Western blotting. Data are presented as means \pm
678 SD of three independent experiments. *, the value is significantly different from that
679 of BJ27 ($P < 0.05$, ANOVA).

TABLE 1 Pathogenicity and replication of BJ27 (H10N7) recombinant and mutant viruses in mice

Virus	MLD ₅₀ (log ₁₀ TCID ₅₀)	Average virus titer in sample ^a

^a Mean virus titer in sample (log₁₀ TCID₅₀/ml) ± SD. The lower limit of detection was 10^{0.75} TCID₅₀/ml for each sample. ^{*}, virus titer of corresponding strains was significantly higher than that of rBJ27 ($P < 0.05$, ANOVA).

^b The number of samples with recovered viruses versus the number of total collected samples.

^c The number(s) shows the virus titer in an individual infected mouse.

TABLE 2 Pathogenicity and replication of double-segment recombinant H10N7 viruses in murine brain

Virus	MLD ₅₀	Average virus titer in brain ^a	
		3 dpi	5 dpi
rBJ27	>6.5	0/3 ^b	0/3
rBJ27-MA	4.75	2.1±0.4	2.8±0.6
rBJ27-PB2/HA	5.25	0/3	0/3
rBJ27-PB2/NA	4.75	1.8,2.3 ^c	2.5±0.5
rBJ27-HA/NA	5.5	0/3	0/3

^a Mean virus titer in sample (log₁₀ TCID₅₀/ml) ± SD. Lower limit of detection was 10^{0.75} TCID₅₀/ml in the brain.

^b The number of samples with recovered viruses versus the number of total collected samples.

^c The number(s) shows virus titer in an individual mouse.

TABLE 3 NA enzyme kinetics of mutant H10N7 viruses ^a

Virus	K_m (μM)	V_{max}	V_{max} ratio ^b
rBJ27	28.7±4.1	0.53±0.10	1.00
rBJ27-MA	14.8±1.8 [*]	0.90±0.09 [*]	1.70 [*]
rBJ27-NA	15.6±2.3 [*]	0.86±0.06 [*]	1.62 [*]
rBJ27-NA/K110E	17.8±1.5 [*]	0.78±0.02 [*]	1.47 [*]
rBJ27-NA/S453I	20.7±2.2	0.66±0.14	1.25

^a A standardized virus dose of 10⁶ TCID₅₀/ml was used for the NA kinetics assay. The enzyme kinetics data (standard deviation) were fit to the Michaelis-Menten equation by nonlinear regression to determine the Michaelis constant (K_m) and maximum velocity (V_{max}) of substrate conversion (in fluorescent units per second). ^{*}, the value of corresponding strains was significantly different from that of rBJ27 ($P < 0.05$, ANOVA).

^b The ratio of the recombinant viruses versus rH10N7 virus V_{max} values.
