Abstract—Radars operating at high millimetre and sub-millimetre wave frequencies are promising candidates for security applications such as people screening since they offer the possibility to form 3D images through clothing with sufficient resolution to detect concealed objects. High spatial resolution of order 1 cm can be achieved using practically sized antennas and high range resolution can be achieved using wideband FMCW chirps, e.g. 30 GHz, to yield 0.5 cm range bins. We present a 220 GHz test-bed ‘Pathfinder’ radar which achieves sub-cm³ voxel resolution with very high signal fidelity. The radar is used to de-risk technology under development for next generation people screening systems.

Keywords— Millimetre wave radar, security, FMCW, 3D imaging, high resolution

I. INTRODUCTION

Over the last decade millimetre wave security scanners have emerged as the dominant technology for passenger body screening and have become a near ubiquitous presence at major international airport hubs around the world [1]. Despite this commercial success, the requirement for security imaging technology that facilitates faster passenger throughput at screening locations remains a highly desirable goal.

Submillimetre wave 3D imaging radar with high (\sim cm³) voxel resolution offers the potential to resolve anomalous objects concealed under clothing. By using 3D shape information, intensity fluctuations caused by clothing and specular reflections are suppressed [2]. However, achieving high enough frame rates to yield reduced screening times remains a significant challenge for this technology.

The EU FP7 CONSORTIS (Concealed Object Stand-Off Real-Time Imaging for Security) project [3] aims to produce high resolution, real time security imaging with significantly improved throughput rates, and will combine a dual-band passive submillimetre wave imager and a 340 GHz 3D imaging radar. In order to de-risk critical technology and provide representative phenomenological data, St Andrews and Wasa have constructed a 220 GHz ‘Pathfinder’ radar imager to underpin the development of the future CONSORTIS radar.

II. HARDWARE DESCRIPTION

The ‘Pathfinder’ laboratory test-bed radar is a single-pixel imager based on a frequency multiplied transceiver and two-

axis gimbal plus PC-based data acquisition. Whilst slow to acquire imagery the purpose of the radar is to prove the wideband chirp generator and transceiver technology and to gather data with a sub-cm³ voxel resolution to support the development of automatic image processing algorithms. The radar is shown in Fig. 1.

A. Chirp Generator

The chirp generator has been designed specifically to achieve the required wide bandwidth performance for this radar. For a 30 GHz output chirp bandwidth, the chirp generator bandwidth is 1.25 GHz at 8.958 GHz i.e. 14%. Chirps are generated with a direct digital synthesis (DDS) chip clocked at 3.5 GHz which is upconverted onto a low phase noise stable local oscillator (STALO) to achieve high linearity, low phase noise, high speed, wideband chirps [4]. The phase noise of the chirp generator is dominated by that of the STALO, which in the experiments described below was an Anritsu MG3692C synthesiser. The chirp generator output power is $+7 \pm 2$ dBm, sufficient to drive the transceiver.

B. Transceiver

The transceiver uses x24 frequency multiplication in the sequence x4 MMIC - x3 Schottky - x2 Schottky. The final stage is configured as a self-mixing, balanced diode multiplier thus acting as the final transmit doubler and as a sub-harmonic mixer on receive [5]. The transceiver output power varies between +2 and +5 dBm over 200 to 230 GHz. The receive conversion loss is -17 dB.

C. Optics

The transceiver is coupled to free-space with a smooth-walled conical feedhorn, which points vertically downwards. A low return loss feedhorn is essential to ensure the correct operation of the waveguide hybrid at the front end of the self-mixing multiplier. A plane mirror at 45° deflects the beam forwards where it is focussed by a plano-convex lens made of HDPE. The lens focusses the beam to a tight spot a few metres from the radar. The lens design was optimised to achieve a symmetric beam with low sidelobes and a well-controlled

depth of field to maximise the radar image quality. Sidelobe level is principally a function of the illuminating feedhorn. The surfaces of the lens are not anti-reflection treated. The whole assembly is mounted on a two-axis elevation-over-azimuth gimbal with the pivot axis slightly behind the lens.

III. RANGE PROFILE PERFORMANCE

Wideband sub-millimetre wave radars based on frequency multiplication chains tend to exhibit quite badly degraded raw point responses [2, 6]. The range profile performance of the radar was characterised by measuring the point response obtained from a sub-beamwidth target placed at the beam focus. In contrast to these other groups, the raw point response of our radar is extremely clean given the large fractional bandwidth. This is attributed to a combination of the high linearity and good amplitude flatness of the chirp generator and the well-controlled group delay and good power flatness of the transceiver multiplier chain. As is the established practice for such wideband high frequency radars, residual nonlinearities in the transmitted chirp can be compensated for by calibrating the

point response from a reference target at a specific range and normalizing the received radar spectrum [2]. Whilst the calibration is strictly only valid at that range, it is effective over a reasonable range swath, and at least over the depth of field of the beam. Fig. 2 shows the raw and calibrated point response of the radar compared with that of a pure, numerical sinewave. It can clearly be seen that the corrected point response follows the theoretical resolution limit over a dynamic range of >60 dB.

IV. OPTICAL PERFORMANCE

The focussing characteristics of the radar beam were characterised by imaging a small sub-beamwidth target positioned at different distances. The resulting series of beam profiles is shown in Fig. 3 and reveals the plane of focus lies at a range of 1.55 m from the front of the radar.

The beam quality and spatial resolution at the focal plane are excellent. Fig. 4 shows the good beam symmetry and a two-way (radar) 3 dB width of $\pm 0.1^\circ$ which corresponds to a spot size of <1 cm when accounting for the gimbal geometry. The sidelobe level of -40 dB (two-way) is consistent with the sidelobes expected for the lens design when fed by the smooth-walled conical feedhorn.

The excellent spatial resolution was confirmed by imaging two closely-spaced sub-beamwidth targets as they are brought closer together. Fig. 5 shows lateral beam profiles for

separation of 20, 15 and 10 mm. Note that even at 10 mm separation there is still a 10 dB dip between the peaks.

V. 3D IMAGING RESULTS

The radar has been used to collect 3D imagery from a life-size mannequin and various test targets. Data acquisition is fully automated using a laptop which performs the gimbal positioning, IF output sampling and FMCW processing including range calibration. Point cloud extraction from the raw 3D data set is performed offline in MATLAB. Typical chirp settings are 30 GHz bandwidth and 100 μ s duration. Image acquisition is slow due to limitations of the data capture card so only static targets can be used. For example, a 0.6×0.6 m field of view image with 1 m range swath takes 90 minutes to acquire.

Fig. 6 shows side, front and isometric views of a 3D point cloud of the mannequin. The benefits of sub- cm^3 voxel resolution are evident as the fine details in the surface profile of the mannequin which are well resolved.

VI. CONCLUSIONS

We have presented the 'Pathfinder' 220 GHz test-bed radar capable of sub- cm^3 voxel resolution 3D imaging which demonstrates the high performance achievable with a wideband DDS-based chirp generator and self-mixing multiplier based transceiver. The raw point response of the radar is extremely

good and with minor calibration the range resolution is transform-limited over a >60 dB dynamic range. The test lens has demonstrated <1 cm spatial resolution enabling the clear distinction between point targets spaced as close as 1 cm.

The 'Pathfinder' radar de-risks critical technology for the CONSORTIS 340 GHz 3D imaging radar which is currently under development. That radar will acquire and process 3D imagery of the same high volumetric resolution as achieved with 'Pathfinder' but at a 10 Hz frame rate, suitable for high throughout security screening.

ACKNOWLEDGMENT

The authors thank Dr Ewan Finlay of InDepth Optics Ltd. for Zemax lens design and the University's Mechanical Workshop for fabricating the hardware.
