**Abstract** *Lichtheimia corymbifera* and *Aspergillus flavus* pulmonary coinfection has been rarely reported in immune-competent patients. We report case of a young male who presented with clinical features of pulmonary-renal syndrome and was later diagnosed to have bilateral polymicrobial fungal lung infection.

**Keywords** *Lichtheimia corymbifera* · *Aspergillus flavus* · Coinfection · Invasive mycosis

## Introduction

Invasive fungal infections have remained a major cause of morbidity and mortality in immunocompromised individuals, particularly those with hematological malignancies, solid organ transplant and neutropenia [1]. Polymicrobial pulmonary fungal infection is a rare entity reported mainly in severely immunodeficient patients [2–7]. *Aspergillus* species and mucoraceous molds have been implicated mainly as a cause of coinfection. Underlying risk factors in

these cases have varied from poorly controlled diabetes, chronic steroid use, leukemia, HIV and cardiac transplant [2–7]. Agents of mycosis reported in dual infections have been *Aspergillus fumigatus*, *Aspergillus flavus*, *Aspergillus alliaceus*, *Mucor species*, *Lichtheimia corymbifera*, mucoraceous mold (not speciated). Patient outcome with fungal coinfection has been poor with high mortality rates [2–7].

## Case Report

A 45-year-old male with no prior comorbid presented to the Emergency department with history of productive cough, high grade fever and dyspnea for a week and submassive hemoptysis for past one day. There was no history of smoking, and he denied history of other substance abuse. His past, family and drug history was not significant. He had no history of any previous infections or surgical intervention. On physical examination, he was awake and alert, had a pulse of 118 beats per minute, respiratory rate of 32 breaths per minute and blood pressure of 140/90 mmHg and was afebrile at the time of examination in emergency room. Blood oxygen saturation was 91% on 5 l of oxygen. On chest auscultation, there were bilateral coarse crackles till mid lung zones. Cardiovascular, abdominal and neurological examination was normal. Laboratory data revealed creatinine of 3.5 mg/dl, blood urea of 96 mg/dl and WBC count of  $23 \times 10^9/l$ . His blood sugars were normal. Chest

radiograph showed bilateral alveolar infiltrates which were denser in lower lung zones (Fig. 1). Blood and sputum cultures were obtained, and he was treated as severe community acquired pneumonia with imipenem, vancomycin and levofloxacin.

The chest X-ray and hypoxemia worsened within 24 h of admission requiring intubation and transfer to the intensive care unit. High-resolution CT of the chest and abdomen without contrast showed multiple patchy areas of consolidation and ground glass opacities in both lungs with underlying cystic and cavitary changes without mediastinal or hilar lymphadenopathy or pleural effusion (Fig. 2), while the abdominal examination was reported as normal. Intravenous contrast was not given due to deranged renal parameters. Bronchoscopy revealed inflamed bronchial mucosa and blood in the right bronchial tree. Multiple urinalyses showed microscopic hematuria and no red blood cell casts. A clinical diagnosis of pulmonary-renal syndrome was made due to rapid deterioration of both respiratory and renal functions. Sequential bronchial lavage was not done due to high oxygen requirement. Nephrology and Infectious Disease consult was obtained, and they agreed with the diagnosis of pulmonary-renal syndrome. He was commenced on intravenous pulse steroids along with plasmapheresis.

Meanwhile microscopic examination of bronchoalveolar lavage (BAL) in mycology laboratory and cytopathology revealed presence of septate hyphae. Aseptate hyphae were not seen on initial microscopic examination. Gram, acid fast and

immunofluorescent stain for *Pneumocystis jirovecii* were negative. Based on microscopic findings, the patient was started on amphotericin B. Bacterial and fungal cultures were set up in the laboratory; for fungi, Sabouraud dextrose agar plates were incubated at 25 and 37 °C, potato agar and Mycosel agar were also used for fungal growth. For bacterial growth, chocolate, sheep blood and MacConkey's agars were used and incubated at 36 °C for 48 h. There was growth of two types of molds on all non-selective plates and no bacterial growth 48 h later. These two molds were phenotypically identified 72 h later as *L. corymbifera* and *A. flavus*. At this point, voriconazole was added to the regimen, and steroids and

plasmapheresis were stopped. Laboratory results of ANA, anti-dsDNA, c-ANCA, p-ANCA, (done by ELISA, DiaSorin, Italy), HIV, Hepatitis B and C virus were reported as negative. Bacterial and mycobacterial cultures in BAL were finally reported as negative. Blood cultures; the first set drawn before the administration of antibiotics and urine cultures were also reported as negative for any bacterial or fungal pathogens. The antibacterial drugs were stopped on day seven.

Patient eventually improved and was extubated after two days of ICU stay. His creatinine levels were normal (1 mg/dl) when he was shifted out of the ICU. The steroids were gradually tapered off. He was sent home in a stable clinical state without supplemental oxygen. The lung infiltrates on chest radiograph had completely resolved and renal function improved on a clinic follow-up after 2 weeks of hospital discharge (Fig. 3).

### Microbiological Diagnosis

Fungal and bacterial cultures were performed using standard methodology [8]. After 24 h of incubation culture plates inoculated with BAL revealed abundant growth of whitish floccose colonies typical of a mucoraceous with a colorless reverse. Growth of a second type of mold with flat, granular, greenish colonies was also noted in Sabouraud dextrose agar

**Fig. 4** Microscopic morphology of *Lichtheimia corymbifera* (a) and *Aspergillus flavus* (b). a Broad ribbon-like aseptate hyphae and sporangium of *Lichtheimia corymbifera*. b Thin, septate hyphae and head of *Aspergillus flavus* (arrow)

(both plates incubated at 25 and 37 °C), potato agar (to induce sporulation), blood and chocolate agar plates. Identification was made on the basis of gross appearance of colonies on plates and microscopic examination. *Aspergillus flavus* was identified by the presence of typical rough conidiophore, uniseriate and biseriata phialides covering entire vesicles (Fig. 4a) [9]. *Lichtheimia corymbifera* was identified on the basis of typical colony morphology, branching sporangio-phore bearing small sporangia with funnel-shaped bases and a conical columella (Fig. 4b) [9].

### Discussion

Invasive pulmonary mycosis has been rarely reported in patients with no apparent risk factors [10–16]. In

most instances, extensive environmental exposure to fungal spores during occupational or recreational activities has been identified as an initiating event. Mixed pulmonary mycosis due to *A. fumigatus* and *Rhizopus species* in a previously healthy patient has reported in one patient with after near drowning [17]. This patient had a history of aspiration of muddy water after being submerged for several minutes. In addition to fungi, multiple bacteria were also isolated from sputum and bronchoalveolar lavage of this patient. Patient recovered fully with prolonged treatment with liposomal amphotericin B. Another report also highlighted invasive fungal infection with pulmonary involvement due to *Rhizomucor pusillus* and *Aspergillus niger* in an immunocompetent patient. This patient had a history of trauma and was successfully treated by multiple surgical debridement and liposomal amphotericin B [18]. In contrast, in our patient exposure to soil or dust or trauma was not found. An extensive workup for immunodeficiency was not done as his previous history was unremarkable for recurrent infections. His blood glycemic levels remained normal throughout the course of treatment despite being in severe sepsis hence HbA<sub>1C</sub> levels were never obtained.

Diagnosis of invasive mycosis is challenging due to low sensitivity of currently available diagnostic modalities. Culture and histopathology require invasive sampling approaches such as bronchoscopy with BAL, transbronchial lung biopsy, computed tomographic-guided transthoracic needle biopsy and video-assisted thoracoscopic surgery may be required to make a diagnosis. Classic signs and patterns on radiology for invasive mycosis, although are well documented for immunocompromised patient but are less commonly seen and reported in immunocompetent individuals [19]. Antigen detection and PCR-based methods are usually not available in settings with limited resources. All these factors lead to either misdiagnosis or a delayed diagnosis in immunocompetent patients.

In our patient, culture and microscopy of the BAL fluid yielded growth of *A. flavus* and *L. corymbifera*. Both of these fungi are a common cause of invasive mycosis and have been reported to cause illness in immune compromised as well as immune-competent patients. Drug of choice to treat invasive pulmonary aspergillosis is voriconazole and for pulmonary mucormycosis is amphotericin B [19]. In our patient,

amphotericin B was started after the microscopy and cytology report and voriconazole was subsequently added to this regimen. The patient improved on this therapy with complete resolution of lung infiltrates in two weeks. The deranged renal function was likely due to acute renal injury secondary to sepsis which led to the presentation similar to pulmonary-renal syndrome. The use of corticosteroids in this case was justified due to high suspicion of life-threatening vasculitis which later turned out to be a fungal infection. To our knowledge, pulmonary coinfection with *A. flavus* and *L. corymbifera* in an immunocompetent patient presenting as a pulmonary-renal syndrome has not been reported previously. Clinicians should be aware of such cases for prompt appropriate diagnosis and management.
