One sentence summary: The anti-arrhythmic drug amiodarone, and one of its active metabolites interfere with the early steps of Ebola virus life cycle by blocking the fusion step between the viral envelope and the endosomal membrane.

Editor: Alfredo Garzino-Demo

ABSTRACT

Ebola virus disease (EVD) is one of the most lethal transmissible infections characterized by a high fatality rate, and a treatment has not been developed yet. Recently, it has been shown that cationic amphiphiles, among them the antiarrhythmic drug amiodarone, inhibit filovirus infection. In the present work, we investigated how amiodarone interferes with Ebola virus infection. Wild-type *Sudan ebolavirus* and recombinant vesicular stomatitis virus, pseudotyped with the *Zaire ebolavirus* glycoprotein, were used to gain further insight into the ability of amiodarone to affect Ebola virus infection. We show that amiodarone decreases Ebola virus infection at concentrations close to those found in the sera of patients treated for arrhythmias. The drug acts by interfering with the fusion of the viral envelope with the endosomal membrane. We also show that MDEA, the main amiodarone metabolite, contributes to the antiviral activity. Finally, studies with amiodarone analogues indicate that the antiviral activity is correlated with drug ability to accumulate into and interfere with the endocytic pathway. Considering that it is well tolerated, especially in the acute setting, amiodarone appears to deserve consideration for clinical use in EVD.

Keywords: amiodarone; haemorrhagic fever; ebola; cationic amphiphiles; dronedarone; filovirus

INTRODUCTION

Ebola virus disease (EVD) is a disease of human and non-human primates, caused by five genetically distinct mem-

bers of the *Ebolavirus* genus, *Filoviridae* family. So far Zaire, Sudan and Bundibugyo viruses have been responsible for most of the human EVD outbreaks (Feldmann and Geisbert 2011). Ebola virus (EBOV) infects a broad range of

cell types (Feldmann and Geisbert 2011). Binding and entry into target cells are mediated by the viral glycoprotein GP, a class I fusion protein composed of a receptor binding subunit (GP1) and a fusion subunit (GP2) (Lee et al. 2008; Lee and Saphire 2009). After initial internalization via macropinocytosis, virus particle trafficking into the endolysosomal pathway ends up into late endosomes, where the low-pH-dependent cysteine proteases cathepsins B and L allow processing of the GP1 into a 19 kDa fusogenic form (Chandran et al. 2005; Schornberg et al. 2006; Dube et al. 2009; Hood et al. 2010; Miller et al. 2012). Subsequently, the interaction between the processed GP1 and the late endosomal/lysosomal protein Neimann–Pick C1 (NPC-1) leads to GP2-dependent fusion of the viral envelope with the limiting membrane of the endosomes (Carette et al. 2011; Cote et al. 2011; Miller et al. 2012). NPC-1 protein is necessary for virus infectivity, as cells from patients with Neimann–Pick disease, due to lack or malfunction of the NPC-1 protein, are resistant to EBOV infection (Carette et al. 2011). In addition to the NPC-1, it has been recently demonstrated that EBOV entry into the target cells requires also the presence of the endosomal/lysosomal calcium channels called two-pore channels (Sakurai et al. 2015).

Multiple cationic amphiphiles have been reported to inhibit EBOV infection (Carette et al. 2011; Johansen et al. 2013; Shoemaker et al. 2013). In particular, it has been shown that the antiarrhythmic drugs amiodarone and dronedarone, multi-ion channel inhibitors, inhibit filovirus infection acting at an early step of viral life cycle (Gehring et al. 2014). Interestingly, amiodarone and dronedarone induce an NPC-like phenotype in several cell types (Morissette et al. 2009; Piccoli et al. 2011).

Here we found that (i) amiodarone inhibits the fusion of the *Zaire ebolavirus* glycoprotein (ZEBOV GP) with the endosomal membrane; (ii) amiodarone and its main metabolite monodesethyl amiodarone (MDEA) potently inhibit *Sudan ebolavirus* (SUDV) entry and progeny release from infected cells; (iii) the antiviral activity correlates with amiodarone ability of inducing an NPC-like phenotype.

Since all these effects were observed at concentrations close to those found in the sera of patients treated for arrhythmias, it appears that amiodarone could be an attractive candidate for the treatment of EVD.

MATERIALS AND METHODS

Cells, plasmids and compounds

Human embryonic kidney (HEK293T) cells and African green monkey kidney Vero cells were grown at 37°C with 5% CO₂ in Dulbecco's modified Eagle's medium (Life Technologies) supplemented with 10% heat-inactivated foetal bovine serum (Life Technologies).

The plasmid expressing the ZEBOV GP, pVR-1012-ZEBOV-GP, was kindly provided by Gary Nabel (Vaccine Research Center, NIH, Bethesda, USA). The plasmid expressing the vesicular stomatitis virus (VSV) glycoprotein (pVSV-G) was previously described (Salata et al. 2009).

Amiodarone was purchased from Sigma-Aldrich. Dronedarone was extracted from Multaq pills (Sanofi-Aventis) as previously described (Piccoli et al. 2011). Synthesis and characteristics of amiodarone analogues (Fig. 1) have been previously reported (Quaglino et al. 2004; Ha et al. 2005).

Infection assays with the GP-pseudotyped virus and SUDV

The recombinant VSV containing the gene encoding the green fluorescent protein in place of the VSV-G gene (VSVΔG-GFP) was provided by Michael Whitt, University of Tennessee, USA. ZEBOV GP pseudotyped VSVΔG-GFP (GP-pseudotyped virus) was generated as previously described (Whitt 2010). Briefly, HEK293T cells were transfected by Lipofectamine 2000 (Life Technologies) with 16 μg of pVR-1012-ZEBOV-GP plasmid and infected with the recombinant VSVΔG-GFP virus at the multiplicity of infection (MOI) of 4 fluorescent focus-forming units (FFU)/cell. After 48 h, virus was harvested and stored at –80°C. Viral titer was evaluated by cytofluorimetric analysis (FACS Calibur, Becton Dickinson) of Vero cells infected with limiting dilutions of viral stock, and data were analysed by CellQuest software.

In the antiviral activity assays, Vero cells were exposed to the appropriate compound for the time indicated. Next, cells were infected with recombinant viruses (MOI of 0.1 FFU/cell) and 24 h later GFP-positive cells were evaluated.

Infection with the SUDV was performed by adding the virus (MOI of 0.05 FFU/cell) to Vero cells. One hour later, unbound virus was removed and fresh medium with the appropriate compound was added. After 24 h, cells were fixed with ice-cold methanol/acetone at –20°C for 30 min. Cells were processed for immunofluorescence using an antibody targeting the viral nucleoprotein, as previously described (Weidmann et al. 2011). Viral progeny release was evaluated on supernatants collected 48 h post-infection by immunostaining of infected Vero cells. All the experiments with SUDV were performed in the biosafety level 4 laboratory at the Public Health Agency of Sweden, Solna, Sweden.

Fusion assay

Vero cells grown on 13-mm coverslips were kept in control medium or pretreated for 16 h with either 10 μM amiodarone or 20 μM U18666A. Subsequently, cells were incubated for 3 h with GP-pseudotyped virus (MOI of 20 FFU/cell). Next, cells were fixed for 20 min with 2% paraformaldehyde (Sigma-Aldrich), and permeabilized for 30 min with 0.1% Triton X-100 (Sigma Aldrich). VSV matrix (VSV-M) protein was detected by incubations for 30 min at 37°C with 23H12 antibody (Kerafast Inc.), and then with Alexa 568-conjugated antibody (Life Technologies). Cells were counterstained with DRAQ5TM (Cell Signaling Technology) to visualize the nuclei. Images were acquired using a Nikon A1 confocal microscope (Nikon Instruments).

Cathepsin B and L activity assay

Cathepsin B substrate (Z-Arg-Arg-MCA) and Cathepsin L substrate (Z-Phe-Arg-MCA), both from Sigma-Aldrich, were stored at –80°C as 10 mM in DMSO stocks, and diluted to 100 μM with 0.1% Brij (Sigma-Aldrich) just before use. 10 mM in DMSO stocks of cathepsin B inhibitor CA-074Me (Calbiochem) was prepared and stored at –80°C. The concentration was brought to 25 μM with reaction buffer just before use. To measure the effects of amiodarone on cathepsin activity, Vero cells were grown to semi-confluence in six well plates. Three wells were incubated for 12 h with 10 μM amiodarone, while three wells served as controls. At the end of the incubation, cells were rinsed with cold PBS, pooled by scraping in two Eppendorf tubes, washed two more times with cold PBS and lysed in 200 μl of 100 mM sodium

Figure 1. Amiodarone and analogues. (a) Amiodarone structural determinants: benzofuran moiety with butyl lateral group (I), diiodobenzoyl moiety (II) and diethylamino- β -ethoxy moiety with tertiary nitrogen atom (III). (b) Analogues listed in order of decreasing hydrophobicity; + or – indicate the ability of inducing an NPC-like phenotype and of inhibiting GP-mediated viral entry at the concentrations used in this work (0.3 μ M dronedarone, 0.3 μ M DDEA, 0.3 μ M B2-O-EtOH, 2 μ M MDEA, all other 10 μ M).

acetate, 1 mM EDTA, 0.5% Triton, pH 5.0 for 10 min in ice. Lysates were then centrifuged at 12 000 \times g for 6 min and the supernatants were stored at -80°C . Cathepsin assay (Ebert et al. 2002) was performed by using 0.5–5 μ g of protein lysates and 50 μ M of substrate in a total volume of 200 μ l by combining (a) 80 μ l of reaction buffer (100 mM sodium acetate, 1 mM EDTA, 4 mM dithiothreitol, pH 5.0) and 100 μ l of Z-Arg-Arg-MCA solution (cathepsin B assay); (b) 80 μ l of CA-074Me in reaction buffer (final concentration 10 μ M) and 100 μ l of Z-Phe-Arg-MCA (cathepsin L assay); (c) 80 μ l of reaction buffer and 100 μ l of Z-Phe-Arg-MCA (cathepsin B+L assay). The reaction, allowed to

proceed for 1 h at 37°C in the dark, was stopped by the addition of 200 μ l of cold reaction buffer. Fluorescence was measured by using a fluorometer with an excitation of 390 nm and an emission of 460 nm.

Statistical analysis

Data are expressed as mean \pm standard deviation (SD). Differences were analysed by a Student's 't' test. The level of accepted significance was $P < 0.05$.

RESULTS

Amiodarone and its metabolite MDEA inhibit EBOV infection *in vitro*

It has been recently reported that amiodarone inhibits flavivirus replication *in vitro*, while the mechanism of inhibition remains unclear (Gehring *et al.* 2014). In patients with arrhythmia chronically treated with 200–600 mg day⁻¹ amiodarone, drug plasma concentration ranges from 1.7 ± 0.6 to 5.1 ± 0.2 μM , while after intravenous administration, plasma levels can increase up to 11 μM (Ha *et al.* 2005; Breitenstein *et al.* 2008). We have previously reported that 16 h of incubation with 10 μM amiodarone induces a full-fledged NPC-like phenotype (Piccoli *et al.* 2011). In order to confirm the anti-ebolavirus activity of amiodarone and to analyse whether the NPC-like phenotype plays a role at this level, Vero cells were incubated for 16 h with 2, 5 or 10 μM amiodarone which previously displayed no appreciable cytotoxicity (Piccoli *et al.* 2011). Cells were then infected with recombinant VSV encoding for the green fluorescent protein (GFP) in place of the glycoprotein G (VSV ΔG -GFP), pseudotyped with either the envelope glycoprotein G of the VSV (VSV-recombinant virus) or the ZEBOV-envelope glycoprotein (GP-pseudotyped virus). A MOI of 0.1 FFU/cell was employed to achieve a percentage of infected cells which allows, with all the recombinant viruses tested, the evaluation of the antiviral effect without saturating the system. Two hours post-infection, cells were rinsed and incubated for additional 24 h in the presence of the appropriate drug concentration before evaluating GFP-positive cells by cytofluorimetry. The 2 h time frame was selected in order to ensure the adhesion to the target cells of all the used recombinant viruses, in the adopted experimental settings. Our results show that amiodarone inhibited GP-pseudotyped virus in a dose-dependent manner with an estimated IC₅₀ (half maximal dose inhibitory concentration) of 5.6 μM (Fig. 2a). By contrast, the drug did not display such an effect on VSV-recombinant virus.

Next, to further dissect the mechanisms by which amiodarone inhibit the infection, GP-pseudotyped virus (MOI of 0.1 FFU/cell) was incubated with Vero cells untreated (no drug) or exposed to amiodarone for 16 h before infection (*t* -16), during viral adhesion (*t* 2), before and after (*t* -16 + *t* 24) or only after adhesion (*t* 24) (Fig. 2b). Cell fluorescence was then measured. We found a significant reduction in GFP-positive cells both with amiodarone pretreatment (*t* -16) and when amiodarone was present during viral adhesion (*t* 2). Only a limited effect was observed when amiodarone was added after viral adhesion (*t* 24). These results suggest that amiodarone could interfere with infection both by a direct effect during viral entry and through the induction of an NPC-like phenotype.

The above findings were confirmed in an experimental setting in which SUDV was used to infect Vero cells (MOI of 0.05 FFU/cell) either untreated (no drug) or treated with 10 μM amiodarone 16 h before and 24 h after infection (*t* -16 + *t* 24), during 1 h of viral adhesion (*t* 1), during and 24 h after adhesion (*t* 1 + *t* 24), or after adhesion, i.e. immediately (*t* 24) or 3 h post-viral adhesion (*t* 21) (Fig. 3). Cells were then analysed by immunofluorescence. SUDV infection was significantly inhibited ($95.9 \pm 0.2\%$) in the *t* -16 + *t* 24 condition (Fig. 3). Furthermore, $91.7 \pm 2.9\%$ of inhibition was also achieved with the *t* 1 + *t* 24 condition, while the treatment performed only during the adhesion (*t* 1) caused an inhibition of $81.3 \pm 8.9\%$ (Fig. 3). However, when the drug was added after the adhesion step, the effect of amiodarone was smaller, especially when the drug was added with 3 h delay (*t* 21) (Fig. 3). Furthermore, the amiodarone effect was stronger

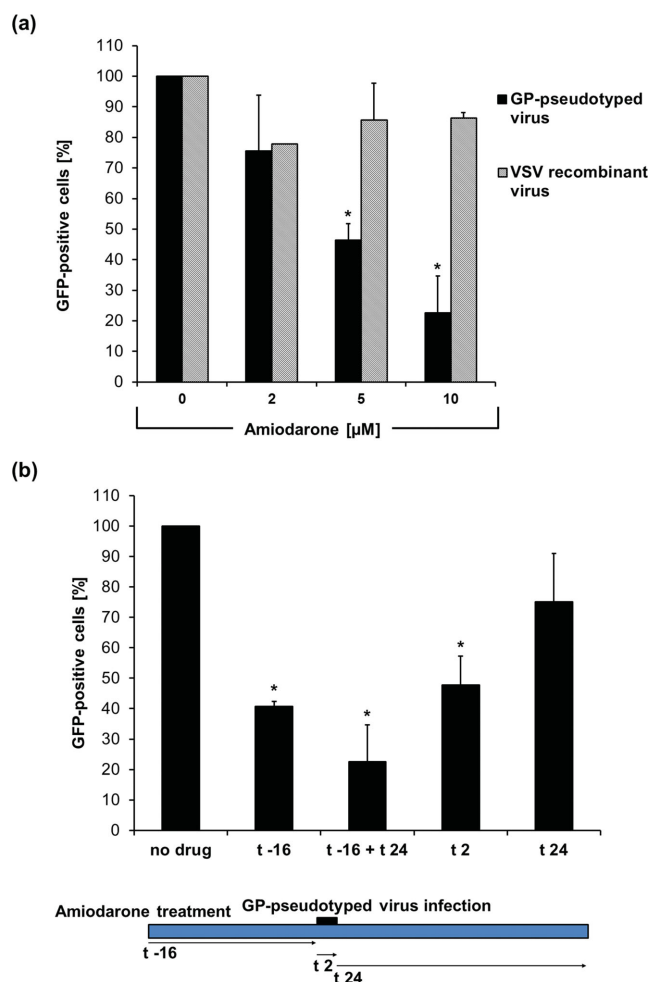

Figure 2. Amiodarone inhibits GP-mediated entry. (a) Vero cells treated for 16 h with amiodarone were infected for 2 h with the VSV ΔG -GFP virus (MOI of 0.1 FFU/cell) bearing its native glycoprotein (VSV-recombinant virus) or the EBOV GP glycoprotein (GP-pseudotyped virus). After 24 h, GFP-positive cells were assayed by cytofluorimetry. (b) Vero cells treated with 10 μM amiodarone, as indicated, were infected for 2 h with GP-pseudotyped virus (MOI of 0.1 FFU/cell). After 24 h, GFP-positive cells were quantified by cytofluorimetry. No drug indicates no amiodarone treatment, (*t* -16) indicates 16 h of treatment before infection, (*t* + 24) stands for 24 h of treatment after infection, (*t* 2) indicates treatment during viral adhesion. Data (mean \pm SD, *N* = 3 experiments in duplicate) are percentages of GFP-positive cells with respect to no drug, set as 100% (* = *P* < 0.05).

than the one observed in the presence of U18666A, a compound known to block the fusion of the EBOV envelope with the endosomal membrane (Carette *et al.* 2011; Shoemaker *et al.* 2013)

MDEA, the main metabolite of amiodarone, reaches plasma concentrations close to those of the parent drug and contributes both to antiarrhythmic activity and toxicity (Quaglino *et al.* 2004; Ha *et al.* 2005; Piccoli *et al.* 2011). To investigate whether MDEA affects EBOV entry, Vero cells were incubated for 16 h with 2 or 10 μM amiodarone, 2 μM MDEA or with a combination of 2 μM amiodarone and 2 μM MDEA (a common condition in patients taking amiodarone chronically). Next, cells were infected with GP-pseudotyped virus (MOI of 0.1 FFU/cell), and 24 h later the infectivity was evaluated by cytofluorimetry. While amiodarone inhibits GP-pseudotyped virus infection more efficiently than MDEA, the combination of 2 μM amiodarone and 2 μM MDEA had a stronger inhibitory effect than the one achieved by treatment with each compound alone (Fig. 4a).

Figure 3. Amiodarone interferes with early steps of SUDV infection. Vero cells, treated with $10 \mu\text{M}$ amiodarone, were infected for 1 h with 0.05 FFU/cell of SUDV. After 24 h, infected cells were identified by staining with an antibody anti-SUDV Nucleoprotein (NP). No drug indicates no amiodarone treatment, (t -16) stands for 16 h treatment before infection, (t 1) indicates treatment during infection, (t 24) indicates a treatment of 24 h following infection and (t 21) indicates 21 h treatment starting 3 h after infection. Data (mean \pm SD, $N = 2$ experiments in duplicate) are percentages of NP-positive cells with respect to no drug, set as 100% (* = $P < 0.05$).

To further evaluate the effect of the amiodarone/MDEA combination on EBOV infection, we employed SUDV at the MOI of 0.05 FFU/cell. Twenty-four h later, viral entry was evaluated by indirect immunofluorescence, while progeny release was tested by viral titration at 48 h. U18666A and dronedarone were also included. In particular, dronedarone was used at a concentration of $0.3 \mu\text{M}$, which is found in patients chronically treated by the oral route. Results showed that amiodarone and MDEA in combination inhibited viral entry and progeny release and that their effect was stronger than the one due to dronedarone and U18666A (Fig. 4b and c). We conclude that amiodarone and MDEA, at concentrations of clinical significance, inhibit EBOV infection.

Amiodarone inhibits EBOV fusion with the endosomal membrane

Since our data demonstrate that amiodarone has an effect on the early phases of ebolavirus replication, we focused our attention on the key step of viral envelope/endosomal membrane fusion. Vero cells, treated for 16 h with $10 \mu\text{M}$ amiodarone, were incubated for 3 h with GP-pseudotyped virus or with the VSV-recombinant virus as a control (MOI of 20 FFU/cell). Next, cells were fixed and stained with an anti-VSV-M antibody (Carette et al. 2011). As shown in Fig. 5, untreated cells displayed a diffuse cytoplasmatic staining, with both GP-pseudotyped and VSV-recombinant viruses, indicating that the fusion of the viral envelope with the endosomal membrane occurred, allowing the release of VSV-M protein into the cytoplasm. By contrast, in the presence of amiodarone or U18666A, while in cells infected with VSV-recombinant virus a diffuse staining was observed, most of the cells infected by GP-pseudotyped virus displayed a punctate staining (Fig. 5). Similar results were also observed when cells were treated with amiodarone during the 3 h of viral incubation (data not shown).

Figure 4. Amiodarone and metabolite MDEA have additive antiviral activity. (a) Amiodarone and MDEA inhibit GP-dependent entry. Vero cells treated for 16 h with amiodarone or MDEA were infected for 2 h with GP-pseudotyped virus (MOI of 0.1 FFU/cell). Afterwards, cells were exposed to the same concentration of compounds for additional 24 h and then were evaluated by cytofluorimetry. Data (mean \pm SD, $N = 4$ experiments conducted in duplicate) are percentages of GFP-positive cells with respect to no drug, set as 100%. (b) Effect of amiodarone, MDEA and dronedarone on SUDV entry. Vero cells treated for 16 h with amiodarone, amiodarone + MDEA, dronedarone or U18666A were infected with SUDV for 1 h (MOI of 0.05 FFU/cell). Afterwards, cells were exposed to the same concentration of each compound for further 24 h, and viral entry was evaluated by immunostaining of SUDV Nucleoprotein with a specific antibody. (c) Evaluation of infectious viral particles release. Vero cells treated for 16 h with amiodarone, amiodarone + MDEA, dronedarone or U18666A were infected with SUDV as reported above. Then, cells were exposed for further 48 h to the same concentration of each compound. Next, viral particles released in the supernatants were titrated by infecting Vero cells and by counting SUDV Nucleoprotein-positive cells by fluorescence microscopy. Data in (b) and (c) (mean \pm SD, $N = 2$ experiments in duplicate) are percentages of no drug, set as 100% (* = $P < 0.05$).

Figure 5. Amiodarone blocks fusion of GP-pseudotyped virus with the endosomal membranes. Vero cells treated for 16 h with 10 μ M amiodarone or 20 μ M U18666A were infected for 3 h with GP-pseudotyped virus (upper panels) or VSV-recombinant virus (lower panels) (MOI of 20 FFU/cell). Three hours post-infection, the VSV-M protein was stained with 23H12 specific antibody (red). Nuclei were stained with DRAQ5TM (blue). Scale bar of confocal images: 25 μ m.

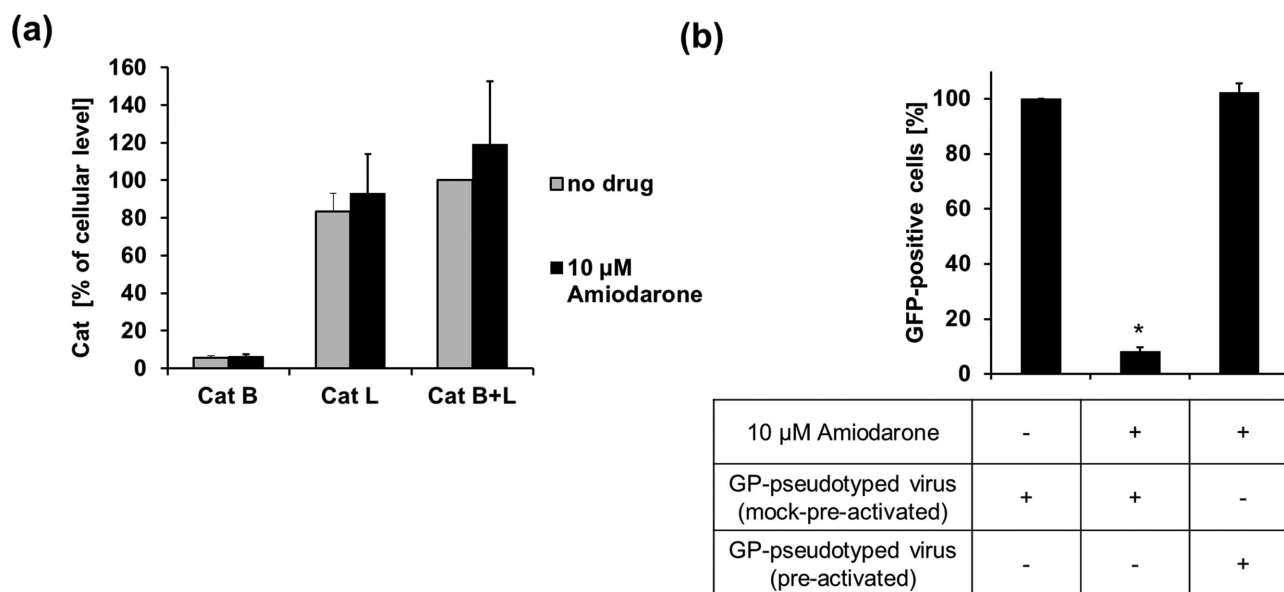

Figure 6. Amiodarone antiviral effect is rescued by *in vitro* proteolysis of GP. (a) Amiodarone does not affect the cell content of cathepsins B and L. Vero cells treated for 12 h with 10 μ M amiodarone were lysed and cathepsin activity was measured in the cell lysates. Data (mean \pm SD) are presented as percentages of Cat B + Cat L measured in the absence of drug (no drug). (b) *In vitro* proteolysis of GP rescues viral infectivity. Vero cells, treated for 16 h with 10 μ M amiodarone, were incubated for 2 h with GP-pseudotyped virus (MOI of 0.1 FFU/cell) treated for 1 h with either reaction buffer alone (mock pre-activated) or 0.2 mg ml⁻¹ thermolysin (pre-activated). Cells were then incubated for 24 h in plain medium (no drug) or with 10 μ M amiodarone, GFP-positive cells were estimated by cytofluorimetry. Data (mean \pm SD, N = 3 experiments in duplicate) are percentages of GFP-positive cells with respect to cells exposed to mock pre-activated virus in the absence of amiodarone, set as 100% (* = $P < 0.05$).

During viral entry, virion-associated GP is processed by cathepsins B and L into the 19 kDa fusogenic form (Martinez *et al.* 2013). Although amiodarone did not modify the total cell content of cathepsins B and L (Fig. 6a), incubation of GP-pseudotyped virus with thermolysin before infection, a treatment that allows the *in vitro* processing of the GP1 into the 19 kDa form, clearly rescued viral infectivity (Fig. 6b). Overall these data suggest that amiodarone affects GP-driven fusion.

Role of different structural groups of amiodarone on its antiviral activity

To clarify the structural basis of amiodarone ability to interfere with EBOV infection, we analysed the effect of amiodarone analogues (Fig. 1) on GP-pseudotyped virus infection. Analogues have already been tested for their toxicity and ability of inducing an NPC-like phenotype (Quaglino *et al.* 2004; Bigler *et al.* 2007; Pic-

coli *et al.* 2011). Vero cells were treated for 16 h with amiodarone or its analogues (at concentrations of clinical relevance, when applicable, or at the ones sufficient to induce an NPC-like phenotype without being toxic to cells) and then incubated for 2 h with GP-pseudotyped virus (MOI of 0.1 FFU/cell). Infected cells were maintained in medium containing the appropriate compound for additional 24 h, and GFP-positive cells were evaluated by cytofluorimetry. As shown in Fig. 7, the diethylamino- β -ethoxy lateral group, which is a determinant for accumulation into acidic organelles, is required for antiviral activity. Furthermore, it appears that, among the compounds bearing this group, the antiviral activity correlates with the ability of inducing an NPC-like phenotype (MeAmi > Amiodarone > PIPAM > MDEA) (Piccoli *et al.* 2011). In addition, a bulky benzofuran hydrophobic moiety is necessary for the antiviral activity, as D2, which has the diethylamino- β -ethoxy group but lacks a hydrophobic moiety, is inactive. Of note, the amiodarone metabolite didesethyl

Figure 7. Structural determinants of amiodarone antiviral activity. Vero cells were treated for 16 h with different compounds. Amiodarone, MDEA and dronedarone concentrations were close to maximum serum levels found in patients. The concentration of different analogues was the maximum achieved without cell toxicity. After 16 h of preincubation with amiodarone and its analogues, cells were infected for 2 h with GP-pseudotyped virus (MOI of 0.1 FFU/cell), and then exposed to the same concentration of each compound for additional 24 h. GFP-positive cells were then evaluated by cytofluorimetry. Data (mean \pm SD, $N = 4$ experiments in duplicate) are percentages of no drug set as 100% (* = $P < 0.05$).

amiodarone (DDEA), usually found in traces in serum, is devoid of antiviral activity.

Overall, the antiviral activity of amiodarone seems to correlate with motifs which lead to an expanded lysosome phenotype (Logan et al. 2014), namely the presence of an amine group, amphiphilicity, a bulky hydrophobic moiety and the ability to be incorporated into membranes (Mitterreiter et al. 2010). It also appears that subtle changes of the alkyl group of the diethylamino- β -ethoxy chain (as in the MeAmi compound) might increase amiodarone antiviral effect.

DISCUSSION

EVD is one of the most lethal transmissible infections. Although in the past this disease appeared sporadically, the increase of human incursions into endemic regions and the higher mobility have turned EBOV into a high-priority public threat. This is sadly confirmed by the biggest epidemic outbreak ever, currently occurring in the Western Africa (CDC 2014). The fast track access to treatment options for EVD is a key priority for the World Health Organization (WHO). With worst-ever outbreak of Ebola raging in West Africa, WHO concluded that it is ethical to use unproven drugs and vaccines to try to combat the disease. However, no medicines so far have been approved, for routine use in EVD.

Currently, despite the fact that different anti-EBOV compounds have been reported in the literature, their antiviral efficacy has been evaluated only *in vitro* and in animal models (Basu et al. 2011; Cote et al. 2011; Iversen et al. 2012; Johansen et al. 2013; Madrid et al. 2013; Shoemaker et al. 2013; Elshabrawy et al. 2014; Gehring et al. 2014; Oestereich et al. 2014; Picazo and Giordanetto 2014; Warren et al. 2014). Even though some of these compounds have been already approved for treatment of human diseases (Johansen et al. 2013; Shoemaker et al. 2013; Gehring et al. 2014), no clinical trials to evaluate their safety and efficacy in EVD have been completed so far. In this respect, the identification of commercially available drugs, already approved for the use in humans, and active against EBOV, might accelerate the organization of clinical trials and eventually clinical use.

Recently, Gehring et al. (2014) demonstrated that amiodarone and dronedarone, drugs approved for the treatment of cardiac

arrhythmias, inhibit filovirus infection. The aim of the present work was to further characterize the effect of amiodarone on EBOV infection. Interestingly, we found that amiodarone inhibits EBOV infection in a dose-dependent manner and at concentrations comparable to plasma levels found in intravenously treated patients. The IC_{50} of amiodarone calculated by employing a recombinant GP-pseudotyped VSV on Vero cells was 5.6 μ M. It has to be mentioned that a recent study (Gehring et al. 2014) reported an IC_{50} of amiodarone around 2.2 μ M, with a GP-pseudotyped lentivirus, and around 0.4 μ M with the ZEBOV. Taking into account the different viral/cellular systems employed, overall these data indicate that amiodarone efficiently inhibits EBOV infection. The antiviral potency varies with the timing of cell exposure to the drug. Inhibition is maximum when amiodarone pretreatment induces an NPC-like phenotype, but a partial inhibition is also appreciable when amiodarone is added during very early steps of infection, suggesting that the anti-EBOV properties might derive on one side from cell structural modifications associated with amiodarone accumulation, and on the other side from a direct effect of the drug on specific steps of the viral life cycle. In this respect, amiodarone could act by modifying lipid fluidity (Chatelain, Laruel and Gillard 1985), by increasing membrane-proximal pH (Mitterreiter et al. 2010), by competing for negatively charged groups on the surface or by affecting calcium channels, required for the maturation of the endosomes and/or viral entry (Kolter and Sandhoff 2010; Gehring et al. 2014). Interestingly, we found that amiodarone affects viral fusion, as it has been previously reported for the U18666A inhibitor (Carette et al. 2011). After viral internalization, GP cleavage proceeds through a 50 and a 20 kDa intermediate, ultimately generating the key 19 kDa core protein (Chandran et al. 2005; Schornberg et al. 2006; Dube et al. 2009; Hood et al. 2010; Miller et al. 2012). Interestingly, the artificial activation of GP by thermolysin treatment of viral particles before infection rescued the effect of amiodarone. It has been demonstrated that amiodarone can affect the stability of specific proteins, such as SP-A (Baritussio et al. 2001). Here we demonstrated that the cellular content of cathepsin B and L, required for the formation of the fusogenic form of GP, was not affected by drug treatment. However, we cannot exclude that amiodarone might influence the activity of these proteases, as it has been demonstrated for different

proteolytic enzymes (Mitterreiter et al. 2010; Piccoli et al. 2011). Furthermore, specific effects on steps subsequent to the EBOV entry/fusion, as demonstrated in the case of the SARS coronavirus and HCV (Stadler et al. 2008; Cheng et al. 2013), cannot be ruled out.

Importantly, we found that there is an additive effect between amiodarone and its pharmacologically active metabolite MDEA on GP-mediated entry into target cells. Furthermore, our results show that, at concentrations of clinical interest, amiodarone and amiodarone/MDEA combination are more effective than dronedarone and U18666A in reducing SUDV infection.

Finally, we found that the presence of a tertiary amine in the compound plays a key role in the antiviral effect, as demonstrated by the use here of different amiodarone derivatives and by the anti-filovirus activity of additional amphiphilic cations (Johansen et al. 2013; Shoemaker et al. 2013). Moreover, a hydrophobic moiety is also critical, perhaps regulating the interactions with membranes. Overall, these observations support the idea that the antiviral activity of amiodarone relies on its ability to interact with membranes, to accumulate into the acidic organelles (Logan et al. 2014) and to induce an NPC-like phenotype (Piccoli et al. 2011; Shoemaker et al. 2013; Gehring et al. 2014).

In conclusion, here we demonstrate that the anti-arrhythmic drug amiodarone specifically interferes with the early steps of EBOV life cycle, thus blocking viral replication. Overall, our data provide evidence that amiodarone deserves serious consideration for the treatment of EVD.

ACKNOWLEDGEMENTS

The authors are grateful to Michael Whitt, University of Tennessee, Memphis, USA, for providing the recombinant VSV, to Gary Nabel, Vaccine Research Center, NIH, Bethesda, USA, for providing the ZEBOV GP plasmid. We would also like to thank Enzo Di Iorio's Group, Department of Molecular Medicine, University of Padova, Padova, Italy, for help with confocal microscopy, Nadia Inglese, Department of Molecular Medicine, University of Padova, for technical assistance with recombinant virus working stocks production, and Daniela Bruttomesso, Department of Medicine, University of Padova, for continuous encouragement.

FUNDING

This work was supported by University of Padova grants (ex60% to CS, AC, AB and Progetti di Ateneo 2008 to AB), and Regione Veneto grants to CP and GP.

Conflict of interest. None declared.
