Abstract—In this study, a comparison between velocity fields for a plane wave 2-D vector flow imaging (VFI) method and a computational fluid dynamics (CFD) simulation is made. VFI estimates are obtained from the scan of a flow phantom, which mimics the complex flow conditions in the carotid artery. Furthermore, the precision of the VFI method is investigated under laminar and complex flow conditions *in vivo*. The carotid bifurcation of a healthy volunteer was scanned using both fast plane wave ultrasound and magnetic resonance imaging (MRI). The acquired MRI geometry of the bifurcation was used for fabricating an anthropomorphic flow phantom, which was also ultrasound scanned. The same geometry was used in a CFD simulation to calculate the velocity field. Results showed that similar flow patterns and vortices were estimated using CFD and VFI in the phantom. Velocity magnitudes were estimated with a mean difference within 15 %, however, it was 23 % in the external branch. For the *in vivo* scan, the precision in terms of mean standard deviation (SD) of estimates aligned to the cardiac cycle was highest in the center of the common carotid artery (SD 4.7° for angles) and lowest in the external branch and close to the vessel wall (SD 15.0° for angles).

I. INTRODUCTION

The combination of high-frame rate ultrasound imaging methods and 2-D vector flow imaging (VFI) [1]–[4] presents several advantages compared to conventional velocity imaging: Rapid blood flow patterns can be followed at hundreds or thousands of frames per second, the velocity estimates are angle-independent, and quantitative estimates are continuously available everywhere in the image. This enables visualization of complex blood flow patterns, e.g. the formation of vortices, which often form around bifurcations and valves. The VFI methods must provide precise and accurate velocity estimates for both laminar and complex flow when measured *in vivo*. However, when investigating the performance of a VFI method *in vivo*, two challenges arise: (i) independent methods such as spectral Doppler and magnetic resonance angiography (MRA) do not have sufficient spatial and temporal resolution to accurately capture complex flow patterns *in vivo*, which makes a comparison to VFI difficult; and (ii) data should be acquired for at least two to three heart beats to evaluate the precision in terms of repeatability of VFI estimates, but this generates

more transducer element data than most scanners can store.

In relation to (i), an alternative approach to investigate complex flow is to perform a realistic phantom study. Using an anthropomorphic geometry for the phantom fabrication, complex flow patterns may be measured in a realistic vessel geometry. The same geometry and boundary conditions can be used in a simulation of the velocity field using computational fluid dynamics (CFD). The CFD simulated velocities can then be compared to the VFI estimates obtained from the phantom. In relation to (ii), all element data can be stored in scans for up to 10 s by using the experimental scanner SARUS [5], which enables evaluation of the precision of the estimates from several heart beats.

The method for VFI in this paper was based on plane wave imaging and a combination of transverse oscillation (TO) and directional beamforming (DB), which was previously validated in simulations [6]. The objective of this paper was to investigate the accuracy and precision of the method under laminar and complex flow conditions in the carotid bifurcation of a healthy volunteer.

The accuracy of the method was investigated by comparing ultrasound VFI estimates obtained from an anthropomorphic phantom measurement to a CFD simulated velocity field derived from the same geometry. The precision was investigated *in vivo* by calculating the repeatability of the VFI estimates at several estimation points in the bifurcation.

II. METHODS

A 27 year old healthy volunteer participated after informed consent, and the study was approved by the National Committee on Biomedical Research Ethics (Protocol No. H-1-2014-fsp-072). An *in vivo* VFI scan was conducted during a session in the morning, and an MRI scan was performed in the evening.

A. *In vivo* VFI scan

A plane wave VFI scan was performed using a linear array transducer (BK 8L2, BK Ultrasound, Herlev, Denmark), which was connected to the SARUS scanner [5]. The carotid bulb was

scanned with the best possible view of the bifurcation, and a duplex sequence consisting of flow and B-mode emissions was employed (4.1 MHz center frequency, 10 kHz PRF, plane waves at -15° , 0° , 15°) [6]. Element RF data were acquired for a total of 10 s. Echo-canceling of beamformed data was performed using an energy-based filter with a manual threshold [7].

A two-step procedure was employed for velocity estimation: First, the TO method was used to estimate an initial flow angle θ , which was calculated from the axial and lateral velocities v_z and v_x , respectively. Second, three DB lines were focused around θ at each estimation point to find a refined angle $\hat{\theta}$ using the largest normalized cross-correlation estimate [6]. The velocity magnitude was estimated along the direction $\hat{\theta}$ using a cross-correlation estimator.

B. MRI scan

A 1.5 T whole body scanner (Magnetom Avanto, Siemens, Erlangen, Germany) was used with a head and a neck matrix coil. The carotid artery was MRI scanned to acquire anatomical images of the common carotid artery (CCA) and carotid bifurcation. The repetition time of the sequence was 42 ms, echo-time 3 ms, pixel resolution 1.1 x 1.1 mm, and slice thickness 5 mm. The anatomical images were used to create a 3-D geometry representing the carotid artery of the volunteer. A CFD model and a flow phantom were produced from the 3-D geometry as described in the following sections.

C. Flow phantom fabrication and scan

An anthropomorphic flow phantom matching the flow domain of the original scanned vessel was fabricated using stereolithography [8]. After 3-D printing of the vessel core, it was fixated in a container and cast in polyvinyl alcohol (PVC) cryogel to obtain a tissue-mimicking surrounding medium. The elastic properties of the cast material were controlled by varying the number of freeze-thaw cycles. After completion of three cycles, the core was removed manually to obtain the wall-less phantom.

A flow system (CompuFlow 1000, Shelley Medical Imaging Technologies, Toronto, Canada) was connected to the phantom and circulated a blood-mimicking fluid, which had a viscosity of $4.1 \cdot 10^{-3}$ Pa·s and a density of 1030 kg/m³. The CompuFlow system was set to generate a standard carotid artery waveform. The transducer was placed on the phantom to scan the bifurcation. The SARUS scanner was used for data acquisition with the same sequence and parameters as for the *in vivo* scan.

D. CFD model

The flow simulation in the CFD model was governed by solving the Navier-Stokes equations. The properties of the emulated fluid matched those of the blood-mimicking fluid used for the phantom study. It was assumed that the fluid was Newtonian, entrance effects were discarded, the vessel was rigid, and the flow had reached a steady state of pulsation.

The inlet condition was constructed using the Womersley-Evans model [9], [10]. In details, the individual components of the mean spatial velocity curve, which was obtained from the measured plane wave VFI data at a point in the CCA, were found by Fourier decomposition. Thereafter, superposition of the first ten harmonics provided a smooth spatial velocity variation. This result was then used to reconstruct the velocity profile in both time and space using the Womersley-Evans model. An outlet pressure of 0 Pa was set for the two exit branches, while a no-slip condition with $\vec{v} = 0$ m/s was set at the walls of the flow domain. The CFD simulation was carried out in Comsol Multiphysics (v5.2a, Comsol AB, Stockholm, Sweden).

E. Evaluation

Prior to the comparison between the flow field of the CFD simulation and the phantom VFI scan, the geometries were aligned. Rotation and translation of the geometries were performed manually after visual inspection. A quantitative comparison of velocities acquired from CFD and VFI were made at selected planes in the bifurcation. Furthermore, the vorticity was calculated using the rotational frequency:

$$\omega = \nabla \times \vec{v} = \left(\frac{\partial v_z}{\partial x} - \frac{\partial v_x}{\partial z} \right), \quad (1)$$

where ∇ is the nabla operator. The mean rotational frequency was calculated for an area covering a (part of a) vortex.

For the precision study, a medical doctor evaluated the *in vivo* scan by selecting evaluation points in the center of the CCA, close to the vessel wall of CCA, in the internal carotid artery (ICA), and in the external (ECA). An automatic procedure calculated the mean cardiac period and coherently aligned the velocity magnitude and angle estimates according to the cardiac period. The standard deviation $\sigma(t)$ at time t was calculated among the aligned estimates. The mean standard deviation (SD) was

$$SD = \sqrt{\frac{1}{N_f} \sum_{t=1}^{N_f} \sigma(t)^2}, \quad (2)$$

where N_f is the number of frames encompassing a cardiac cycle. The mean SD of velocity magnitude estimates, (2) was calculated relative to the peak velocity magnitude v_0 .

III. RESULTS

A. Comparison between phantom VFI and CFD simulation

A frame from the comparison between CFD simulation and the VFI scan is shown in Fig. 1. The frame is within systolic deceleration (0.32 s) and shows similar flow patterns for CFD and VFI. Both the CFD and VFI showed a large vortex or recirculation zone, which extended from the ICA into the CCA. There were small differences in the extend of the recirculation zone and velocity magnitudes, but similar flow patterns were provided. The jet of streamlined forward flow found close to the inner vessel wall of the ICA in the CFD image was also measured using VFI. A small vortex in

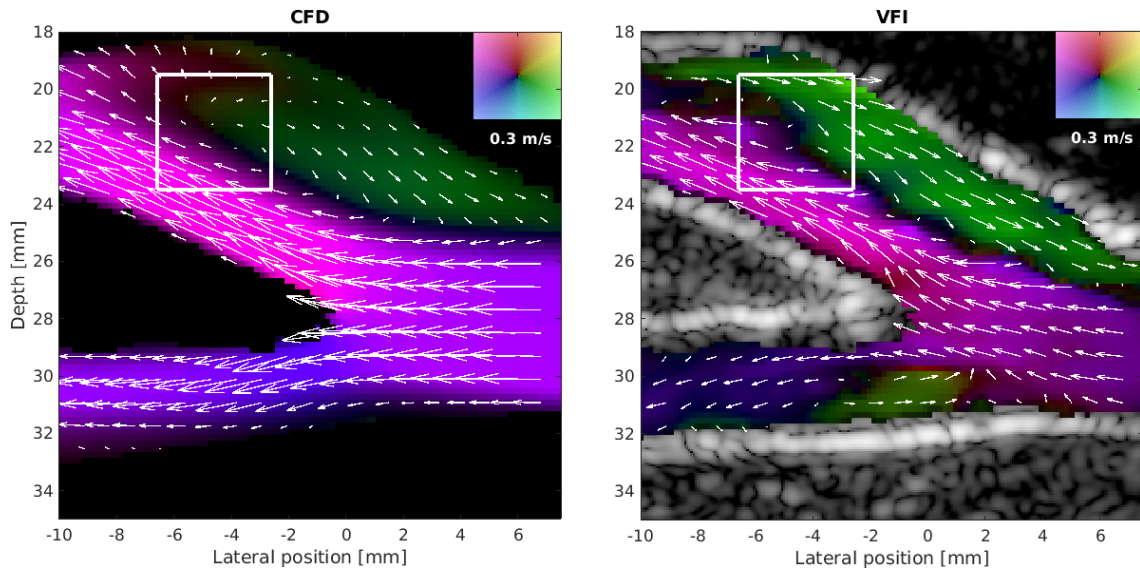

Fig. 1. Velocity estimates from CFD simulation (left image) and VFI scan of phantom (right image). The frame is within the systolic deceleration ($t = 0.32$ s). The vorticity within the white box covering a part of the recirculation zone is shown in Fig. 3.

Fig. 2. Comparison of velocity magnitude profiles at selected locations in the CCA (left column), ICA (middle column), and ECA (right column). Sampling was performed at $t = 0.16$ s (top row), $t = 0.32$ s (bottom row). Red profiles indicate CFD estimates and black VFI estimates.

the ECA was measured using VFI as indicated by the green area in the lower branch in Fig. 1 (right). However, this vortex was not visible in the CFD.

A more quantitative comparison between CFD and VFI is shown in Fig. 2, where the velocity magnitude profiles at selected locations in the CCA, ICA, and ECA are shown at peak systole ($t = 0.16$ s) and systolic deceleration ($t = 0.32$ s).

The mean difference between CFD and VFI was of -1.4% for the velocity profile in the CCA at peak systole, while it was 23.6% for the ECA. During systolic deceleration (Fig. 2 bottom row), lower velocities were estimated in both the CCA and ECA (mean difference was -12.3% and -13.3% ,

respectively), when using VFI compared to CFD. However, the velocity magnitudes of the backflow in the ICA from -5 mm to 0 mm were larger for VFI, which is also shown in Fig. 1.

The rotation of flow in the recirculation zone inside the white box in Fig. 1 was quantified by calculating the mean rotational frequency as a function of time, and the result is shown in Fig. 3. The two peaks of the rotational frequency for VFI at 0.14 s and 0.3 s revealed that a vortex or recirculation evolved at two time instances, while a single recirculation built up after 0.15 s in the CFD simulation and lasted until 0.3 s. For the remaining cardiac period (from 0.3 s to 0.84 s) there is a good agreement between CFD and VFI for the rotational

frequency.

B. Precision *in vivo*

The precision of velocity magnitude and angle estimates was calculated for evaluation points in the center of the CCA, close to the vessel wall of the CCA, in the ICA, and the ECA. The points are indicated on the VFI frame shown in Fig. 4. The highest precision was obtained in the center of the CCA (3.0 % for velocities and 4.7° for angles) and in the ICA (5.5 % and 6.5°), where the highest velocities were estimated and flow was mainly unidirectional. Slightly lower precisions were obtained in the ECA (5.1 % and 13.3°) and close to the vessel wall of the CCA (7.3 % and 15.0°). Lower velocities and a larger variation in the angles were found for these evaluation points.

The rotational frequency was calculated for the vortex indicated by the white square in Fig. 4 and for all frames during the 10 s scan. After alignment of estimates to the cardiac cycle, the mean SD of the rotational frequency was calculated to 6.2 %. This indicated a high cardiac cycle-to-cycle repeatability of the velocity estimates and flow patterns in a zone covering the vortex.

IV. DISCUSSION AND CONCLUSION

A comparison between flow in a carotid bifurcation phantom using VFI and simulated CFD velocities was made. Similar flow patterns were obtained, and the mean difference between VFI and CFD was within 23 % for velocities. However, the alignment of the transducer scan plane in the phantom and the CFD geometry was not perfect, and the assumptions of rigid walls and inlet and outlet boundary conditions may represent limitations in the CFD model.

The study showed that the precision *in vivo* was highest in the center of the common carotid artery and lowest in the external branch (standard deviation for angles 4.7° and 15.0°). This indicated that quantitative velocity estimates could be obtained in the carotid artery of the healthy volunteer.
