Title

Clinical, Physical and Radiographic Analyses of

Lumbar Degenerative Kyphosis and Spondylolisthesis Among Community-Based Cohort

1 [Structured Abstract]

2
3
4 2 **Purpose** To investigate longitudinal radiographic changes, and physical characteristics of
5
6
7 3 lumbar degenerative kyphosis (LDK) and spondylolisthesis (DS).

8
9
10 4 **Methods** Two-hundred eighty nine community-based female subjects were recruited from
11
12
13 5 population register and studied longitudinally for a mean 12.3 years. Upright entire spine
14
15
16 6 radiographs were used to evaluate spinopelvic parameters including lumbar lordosis (LL),
17
18
19 7 pelvic incidence (PI), and vertebral slip (% slip). Physical measurements included lumbar
20
21
22 8 range of motion (ROM), isometric trunk muscle strength, and photometric gait posture using
23
24
25 9 change in trunk inclination angle (dTIA).

26
27
28
29 10 **Results** Subjects' mean age (standard deviation; SD) was 56.9 (10.0) years at baseline and
30
31
32 11 68.5 (9.2) years at the final follow-up. Among 202 subjects who could perform instructed
33
34
35 12 physical measurements, DS, defined as more than 5% slip, was found in 50 subjects (24.8%),
36
37
38 13 and LDK, defined as LL of less than 1SD of mean value ($<24.4^\circ$), was found in 24 subjects
39
40
41 14 (11.9%). DS subjects showed significant weakness in trunk flexor strength (normal
42
43
44 15 $282.5\pm 73.0\text{N}$ vs. DS $245.5\pm 75.5\text{N}$, $p=0.0219$), and LDK subjects showed significant
45
46
47 16 differences in; trunk extensor strength (normal $493.4\pm 172.8\text{N}$ vs. LDK $386.3\pm 167.6\text{N}$,
48
49
50 17 $p=0.0066$), ROM, and dTIA (normal $3.5\pm 2.7^\circ$ vs. LDK $7.6\pm 4.8^\circ$, $p<0.0001$). PI was
51
52
53 18 significantly larger in DS and smaller in LDK than normal subjects (normal $53.8\pm 9.9^\circ$ vs. DS
54
55
56 19 $58.2\pm 10.6^\circ$, $p=0.0111$; normal vs. LDK $48.4\pm 9.2^\circ$, $p=0.0191$).

1 **Conclusions** Current study showed that DS was associated with reduced trunk flexor strength,
2
3
4 which might increase pelvic anteversion, and LDK was associated with reduced extensor
5
6
7 strength, ROM, and ambulatory kyphosis. Physical characteristics should be evaluated for
8
9
10 successful management of adult spinal deformity.

1 [Introduction]

2 Recent studies of adult spinal deformity (ASD), emphasizing the importance of
3 pelvic parameters and sagittal balance, prompted the understanding of normal spinopelvic
4 alignment, however, radiographic normative values are only one aspect of multifaceted
5 degenerative conditions[10]. We have been investigating etiology of ASD using
6 community-based cohorts, and Takemitsu et al. first reported comprehensive classification of
7 lumbar degenerative kyphosis (LDK) in 1988[17]. Their study indicated that LDK patients
8 showed severe histological atrophy in the back muscles and aggravated kyphosis during walk,
9 along with radiographic degenerative changes. LDK was predominantly found in female
10 farmers, and Takemitsu suggested overuse of back muscles, repeated minor injuries, and
11 increased compartmental pressure during prolonged bending posture as causative factors.

12 Degenerative spondylolisthesis (DS) is another common spinal deformity among
13 female population, and increased vertebral slope and sagittal facet morphology have been
14 reported radiographically. Recent studies indicated the importance of pelvic incidence (PI),
15 which showed positive correlation with lumbar lordosis and vertebral slope, and large PI was
16 reported as a risk factor of de novo DS after 12-year follow-up of female subjects without
17 baseline DS[1,3,4,6]. Contrary to LDK, physical characteristics among DS patients have not
18 been well-documented. One study by Sinaki et al. showed that trunk flexion exercise was
19 more favorable for reducing back pain than extension exercise among DS patients[16]. Their

1 1 study implicated the importance of trunk flexor muscle, however, subsequent studies could
2
3
4 2 not elucidate the relationship between DS and trunk muscle weakness. The purpose of this
5
6
7 3 study was to investigate radiographic, clinical, and physical characteristics of LDK and DS
8
9
10 4 among community-based female cohort.

1 [Methods]

2 This study was a part of our ongoing longitudinal cohort study, Asahikawa
3 observational study of Spinal Aging in Prospective cohort (the ASAP study), which has been
4 recruiting adult volunteers from population register since 1983, whose baseline demographic
5 data have been reported[1,7,8]. Follow-up study has been conducted since 1997 according to
6 following criteria; included if baseline age of 40 years or older, healthy enough to walk
7 independently to attend our program, available baseline and follow-up whole spine
8 radiographs, and submitted written informed consent; excluded if history of spinal arthrodesis
9 or joint replacement surgery, severe systemic or orthopaedic pathology requiring
10 hospitalization or repetitive medical consultation. A final total of 289 Japanese female
11 subjects were included and followed, and mean follow-up period was 12.3 (range 8-20) years.
12 Entire spine radiographs were taken at the entry and at the final follow-up in relaxed standing
13 posture with their arms supported and knees maximally extended. Digital image software was
14 used to measure standard sagittal spinopelvic parameters including thoracic kyphosis (TK;
15 between upper endplate of T4 and lower endplate of T12), lumbar lordosis (LL; between
16 upper endplate of L1 and S1), sagittal vertical axis (SVA; distance of plumb lines through C7
17 and S1 posterior edge), sacral slope (SS; between upper sacral endplate and horizontal
18 reference), pelvic tilt (PT; between the line through center of femoral head and midpoint of
19 sacral table, and vertical reference), PI (between the line through center of femoral head and

1 midpoint of sacral table, and the line perpendicular to sacral table), and percent slip (length of
2
3
4 2 vertebral displacement divided by the length of vertebral endplate below) of each lumbar
5
6
7 3 vertebra (Fig. 1). Measurements of spinopelvic parameters were in accordance with standard
8
9
10 4 methods used in recent studies of ASD[10,13,15]. Clinical and physical evaluations by spine
11
12
13 5 physicians and physical therapists were also conducted, and health-related quality of life
14
15
16 6 scores (HRQOL, using Roland-Morris disability questionnaire), lumbar range of motion
17
18
19 7 (ROM) evaluated by passive back extension (prone-press; distance of chin and floor at
20
21
22
23 8 maximum lumbar extension at push-up with thighs attached to the floor) and active back
24
25
26 9 extension test (BET; distance of sternal notch and floor at maximum active lumbar extension
27
28
29 10 with thighs attached to the floor) were recorded. Trunk flexor and extensor muscle strengths
30
31
32
33 11 were measured in a fixed sitting position using isometric dynamometer (GT350, OG Giken
34
35
36 12 Co., Japan). Each participant repeated the measurement at least three times and best scores
37
38
39 13 were used as flexor and extensor strength (Fig. 2). Gait posture was evaluated using
40
41
42 14 photometric technique; each participant was instructed to walk 6-meter walkway with surface
43
44
45 15 markers attached on C7 (or on prominent cervical spinous process) and on L4 (or on
46
47
48 16 intercrestal line). Digital camcorder was used to measure the change in trunk inclination angle
49
50
51
52 17 (dTIA), defined as the difference of angles subtended by the line through surface markers and
53
54
55 18 the vertical reference between walk and rest. Each participant repeated dTIA measurement at
56
57
58 19 least three-times and maximum difference was used. Most subjects showed increase in trunk
59
60
61
62
63
64
65

1 inclination angle at walk, and dTIA was defined as positive for forward inclination (Fig. 3).

2
3
4 2 Attending physician or physical therapist gave thorough explanation and demonstrations, if
5
6
7 3 needed, upon each physical measurement. Subjects with difficulty in performing repeated
8
9
10 4 physical measurements due to recent back pain, vertebral or non-vertebral fractures, clinical
11
12
13 5 frailty or other medical conditions were excluded, and included only for radiographic
14
15
16 6 measurements. Data of physical and clinical measurements were corrected at the latest visit,
17
18
19
20 7 and used as cross-sectional data. Statistical analysis was performed using the StatView
21
22
23 8 software (Abacus Concepts, Inc, Berkley, CA). Interclass comparison was done by analysis of
24
25
26 9 variance, and p-value of less than 0.05 was considered as significant difference. Institutional
27
28
29
30 10 review board approved the study, and written informed consent was mandatory for each
31
32
33 11 participant upon enrollment.

1 [Results]

2
3
4 2 Longitudinal changes (mean±SD) of anthropometric and radiographic measurements

5
6
7 3 of all 289 female subjects, from the age of 56.9±10.0 to 68.5±9.2 years, were as follows; body

8
9
10 4 height from 150.7±5.6cm to 149.3±6.3cm, body weight from 54.5±7.0kg to 55.7±8.6kg, TK

11
12
13 5 from 31.1±13.1° to 32.0±16.0°, LL from 43.8±14.3° to 39.6±15.2°, SVA from 22.0±31.5mm

14
15
16 6 to 30.9±42.8mm, SS from 34.0±10.4° to 30.6±12.7°, PT from 21.1±9.6° to 25.3±9.6°, and PI

17
18
19 7 from 55.9±10.7° to 56.1±11.3° (Table 1). After excluding 87 subjects with difficulty in

20
21
22 8 repeated physical measurements, physical measurements of eligible 202 subjects at the final

23
24
25 9 follow-up were as follows; isometric trunk flexor muscle strength 268.4±75.1N, isometric

26
27
28 10 trunk extensor muscle strength 455.3±174.1N, prone-press 26.3±6.5cm, BET 11.2±5.9cm,

29
30
31 11 and dTIA 4.4±3.7°. Using the final radiographic measurements, DS was defined as more than

32
33
34 12 5% of percent slip, according to our previous study [1]. LDK has been diagnosed both

35
36
37 13 radiographically and clinically, with aggravated kyphosis during walk. In the current study,

38
39
40 14 we adopted radiographic definition of LDK for screening purpose; LL of less than 1SD of

41
42
43 15 mean value (<24.4°). Among 202 subjects with full radiographic and physical evaluations,

44
45
46 16 DS was found in 50 subjects (24.8%), and LDK was found in 24 subjects (11.9%).

47
48
49 17 Physical, clinical, and radiographic parameters were compared among DS, LDK, and

50
51
52 18 normal subjects without DS or LDK (Fig.4). DS subjects showed significantly weaker trunk

53
54
55 19 flexor muscle strength than normal subjects (normal 282.5±73.0N vs. DS 245.5±75.5N,

1 p=0.0219; LDK 261.3±77.7N). LDK subjects, compared to normal subjects, showed
2 significant differences in; trunk extensor muscle strength (normal 493.4±172.8N vs. LDK
3 386.3±167.6N, p=0.0066; DS 448.7±170.9N), ROM (prone-press normal 27.2±6.0cm vs.
4 LDK 23.6±8.2cm, P=0.0146; DS 25.6±6.1cm / BET normal 12.0±5.5cm, LDK 5.4±5.3cm,
5 P<0.0001; DS 11.2±5.4cm), dTIA (normal 3.5±2.7° vs. LDK 7.6±4.8°, p<0.0001; DS
6 5.1±3.9°), HRQOL (normal 1.4±2.6 vs. LDK 5.2±6.0, p=0.0015; DS 1.2±2.8). PI was
7 significantly larger in DS and smaller in LDK than normal subjects (normal 53.8±9.9° vs. DS
8 58.2±10.6°, p=0.0111; normal vs. LDK 48.4±9.2°, p=0.0191)

1 [Discussions]

2
3
4 2 Current study showed that DS was associated with large PI and reduced trunk flexor
5
6
7 3 muscle strength by 13%, and LDK was associated with reduced extensor muscle strength by
8
9
10 4 22%, along with reduced ROM, increased trunk inclination during walk, and worse HRQOL.
11
12

13 5 In a prospective randomized study, Sinaki et al. divided 48 DS patients with back
14
15
16 6 pain into trunk flexion exercise group and trunk extension exercise group[16]. After 3 months,
17
18
19 7 the rate of back pain reduced to 27% in flexion exercise group and to 67% in extension
20
21
22 8 exercise group. The overall recovery rate after 3 years was 62% for the flexion group and 0%
23
24
25 9 for the extension group. Their study indicated the importance of trunk flexion exercise when
26
27
28 10 prescribing physical therapy for DS patients, however, magnitude of trunk flexor attenuation
29
30
31 11 with DS was not documented.
32
33
34

35 12 Sanderson et al. reported that history of pregnancy was related to increased incidence
36
37
38 13 of DS[14]. They reviewed medical record of 949 women, and those who had borne children
39
40
41 14 showed 28% incidence of DS compared to 16.7% among nullparous women with statistical
42
43
44 15 significance ($p=0.043$). Their retrospective study could not elucidate the mechanism of
45
46
47 16 muscle weakness and the development of DS, however, they proposed that weakened
48
49
50 17 abdominal muscle during pregnancy might be a causative factor, along with joint laxity, and
51
52
53 18 increased lumbar load equivalent to 22° of trunk inclination during pregnancy.
54
55
56

57 19 Current study could clarify statistically significant reduction of isometric trunk flexor
58
59
60

1 muscle strength by 13% with DS, using susceptible female subjects with comparable
2 background, and related mechanism should be that reduced trunk flexor strength reduced
3 pull-up force onto pelvic insertion, which might increase anteversion of pelvis and vertebral
4 slope (Fig. 5). Anatomically, subject with large PI exhibits large pelvic ROM. Reported
5 equation of $PI=SS+PT$ [15] showed that maximum value of SS depends on the magnitude of
6 PI, and subjects with large PI and weak flexor muscle are susceptible to increased SS and
7 vertebral slope, resulting in increased sheer stress and risk of vertebral slip. Female subjects
8 with large PI and reduced trunk flexor muscle should be recognized as a prominent risk of
9 developing DS, and trunk flexor exercise should be beneficial for this type of patients.

10 LDK was associated with small PI and reduced back extensor muscle strength and
11 aggravated kyphotic posture during walk, which substantiated previous study that LDK was
12 associated with back muscle attenuation and histological muscle fiber atrophy suggesting
13 'compartment syndrome' of back muscles, along with worsening kyphosis after distant walk
14 [17]. Ambulatory kyphosis with LDK, expressed as 2.2-fold increase in dTIA, proposed
15 limited relevance of static spinopelvic radiographs, and clinical and physical evaluation of
16 "dynamic kyphosis" during activities should be included for better management of senile
17 kyphotic deformity.

18 Contrary to DS, controversy exists about LDK and PI. Lee JH et al. reported that PI
19 was high up to 65.8° in Takemitsu type-1 LDK, characterized as flat back deformity[9]. Bae

1 JS et al. reported the number of LDK patients were 25.6% in low PI ($\leq 45^\circ$) and 29.6% in
2
3
4 high PI ($>60^\circ$), studying 172 symptomatic LDK patients[2]. Radiographic studies indicated
5
6
7 that small PI is usually associated with small LL, however, clinical studies by Le Huec or
8
9
10 others indicated that small LL with large PI, or 'mismatched' kyphosis, to be more difficult to
11
12
13 treat[11,12]. Aforementioned studies using symptomatic patients might include more number
14
15
16 of clinically problematic 'mismatched' kyphosis with large PI compared to studies using
17
18
19 community-based volunteers.
20
21
22

23 Limitations of this study included that this was an observational study and could not
24
25
26 elucidate the treatment regimen for each ASD condition, however, the characteristics of trunk
27
28
29 muscle attenuation implied that abdominal muscle exercise should be appropriate for DS
30
31
32 patients, and back muscle and ROM exercise should be appropriate for LDK. There has been
33
34
35 no gold standard for measuring trunk muscle strength, ROM, or gait posture, however, used
36
37
38 methods were in common clinical use especially among physical therapists, and provided
39
40
41 enough statistical significance using largest-ever number of study subjects for physical
42
43
44 evaluations with radiographic parameters. Currently ongoing studies include the assessment
45
46
47 of instructed exercise by physical therapists onto longitudinal changes in physical and
48
49
50 radiographic measurements, which should further clarify the impact of physical characteristics
51
52
53 upon ASD, and should provide answers to above-mentioned limitations.
54
55
56
57
58
59
60
61
62
63
64
65

1 [Conclusion]

2
3
4 2 Current study showed that DS was associated with large PI and reduced trunk flexor
5
6
7 3 muscle strength by 13%, supposedly leading to reduced capacity of maintaining pelvic
8
9
10 4 retroversion. LDK was associated with reduced extensor muscle strength by 22%, active
11
12
13 5 ROM by 55%, passive ROM by 13%, and increased ambulatory kyphosis by 117%. Physical
14
15
16 6 characteristics should be an important factor as well as radiographic parameters, and
17
18
19 7 distinctive radiographic, clinical and physical features should be considered for successful
20
21
22 8 management of ever-increasing adult spinal deformity.

2
3
4 2 Proposed relationship between trunk flexor muscle and DS. Reduced trunk flexor muscle
5
6
7 3 reduces pull-up force onto pelvic insertion, which might lead to increased anteversion of
8
9
10 4 pelvis and vertebral slope. Subjects with large PI anatomically have large pelvic range of
11
12
13 5 motion, thus increasing the risk of DS with reduced trunk flexor muscles. DS degenerative
