Abstract

Humans live and spent their times in buildings. Determining the best configuration for their office or apartment (HVAC configuration, doors and windows positions, usage of appliances,...) is becoming subtle because low consumption buildings are becoming more and more sensitive to human behavior. Moreover, variable energy costs and energy availability issues increase the complexity of the energy management problem. In such complex situations, many scientific research and engineering works are ongoing with the aim of supporting occupants in their everyday life, but still, in most cases, there is a need for experts to design models for living zones to manage, which is time-consuming and very costly. This paper will continue in the stream to help occupants to understand their energy systems and the impact of their actions on the system, by providing causal explanations and presenting a path diagram for all actions and environmental changes and their consequences.

Keywords: Smart Buildings; efficient energy use; differential explanations; causality; multi-objective optimization; differential evolution; Pareto-optimality; ambient intelligence; user advice generation content...

1   Introduction

Considering the ever-growing energy demand and the depletion of non-renewable energy resources, it is important to limit the energy usage in buildings which constitute roughly about 40% of the global energy supply [1]. Thus, it is imperative to satisfy the demands of building occupants without increasing the present rate of energy consumption in buildings. Occupants, on the other hand,

1

being an integral part of the building system, can affect the indoor environmental condition through their actions. By intelligently utilizing these actions, positive effects can be brought upon the indoor environment.

Attempts have been done to meet the comfort demands of the occupants by improving building construction techniques and adding insulation to walls and ceilings. Building regulations also play an important role in the overall (both global and local) energy management. But all of this did generate a second effect presented in a major increase of the impact of user actions, obtaining positive impacts of occupant's actions in the energy consumption can help to manage their own comfort. It is therefore important to assist occupants with an optimal energy plan in order to explain that their expectations on comfort can be attained by themselves to some extent.

Thus, guiding the occupant's actions, like opening and closing doors and windows, for a significant period of time, can help to achieve better comfort in energy building at the same cost of energy consumption, if not minimizing it.

The approach used in this work is applied and tested in a real office, situated in Grenoble Institute of Technology, France, fitted with 27 sensors. To collect data like temperature, solar luminance, wind speed, humidity, moisture, CO_2 concentration, etc., and a daily presence of 4 researchers as shown in figure 1.

Also, physical models of the office are used. Those models are based on the physical context of outside environment and neighboring data and other variables. The indoor temperature and CO_2 concentration are responsible for thermal and air quality dissatisfaction of the occupants.

Depending on weather forecast, an optimal schedule of actions for desired criteria can be calculated using the physical models and by generating explanations, occupants can be implicated in the loop so they will understand the consequences of their actions and where the system recommendations are coming from, and how those actions are affecting their comfort criteria.

2   Problem Statement

The main objective of the paper is to propose solutions to assist occupants to better understand how they can modify their behavior and make better decisions with respect to their own comfort criteria. Due to the complexity of the building physics and unconscious routines, occupants face difficulties while trying to understand their energetic current situation and why they need to change their daily routines to obtain better comfort or reach a better compromise between comfort and cost. Generation of contextual explanation is therefore very important to involve the occupants by understanding how and why the system is recommending different actions, inhabitants will be able to reason and assess whether they will accept the recommended actions or not, and define how they will adapt their routine according to the best computed strategy.

The paper focuses on the generation of explanations about energy impact of user actions. Explanations occur in different ways [2] and for different reasons. One of the main motivation for having explanations is to be able to manage in a better way if similar events or scenarios arise in future [3]. Explanations usually rely on causal relationships. There are at least four kinds of causal explanations: common cause, common effect, linear causal chains, and causal homeostasis (cyclic causal relationships) [4]. According to [5], explanations
Figure 1: Map of the office with sensors

are ubiquitous, come in a variety of forms and formats, and are used for a variety of purposes. Still, the common feature about most explanations is their limitation. For most natural phenomena and many artificial ones, the full set of relations to be explained is complex and far beyond the grasp of any one individual. Explanations should rely on causal relationships i.e on an ordering in phenomena modeled by variables: the causes i.e. occupant actions (A) or contextual (C) phenomena, final effects (E) and intermediate effects (I). It is summarized in Fig. 1 for the studied office.

Arrows in the figure represent the cause-effect relation between these groups. More precisely, the different groups are:

1. Context group: it contains all the uncontrollable variables that the system needs to take into consideration like the outside temperature T_{out}, the temperatures in the neighbor zones T_{cor}, the number of occupants, etc.
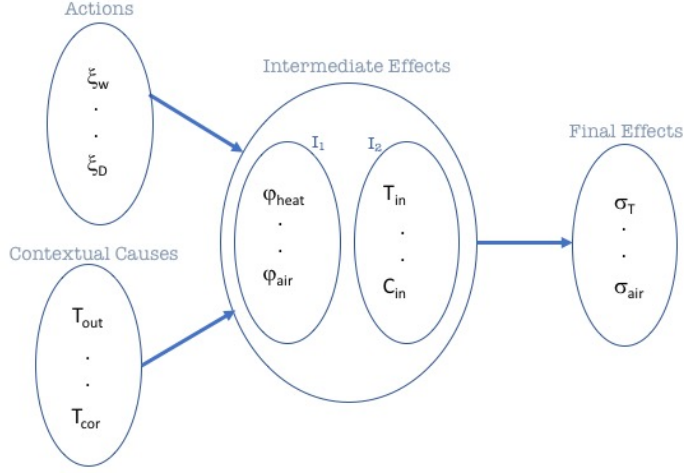

Figure 2: General schema of explanations

2. Action group: it contains all the different actions that the system can propose to the occupants to enhance their comfort levels (like opening the window ζ_w, and opening the door ζ_D).

3. Effect group: it contains the variables that will be directly experienced by the occupants like thermal dissatisfaction σ_T and air quality dissatisfaction σ_{air}.

4. Intermediate group: it contains different sub-groups and different levels for multiple intermediary variables. These variables are either measured like the indoor temperature T_{in} and the indoor CO_2 concentration C_{in} or estimated like the heat flow φ_{heat} and the air flow φ_{air}.

All of this can be reformulated as: $\mathcal{A}, \mathcal{C} \xrightarrow{\mathcal{I}} \mathcal{E}$ where:
$\mathcal{A}$ is the set of variables modeling occupant's actions,
$\mathcal{C}$ is the set of contextual variables,
$\mathcal{I}$ represents the intermediate variables, and
$\mathcal{E}$ represents the effect variables.

The effects resulting from the best actions according to some given criteria can be computed.

It is denoted by: $\mathcal{A}^*, \mathcal{C} \xrightarrow{I^*} \mathcal{E}^*$ where:
A^* is the optimal set of actions,
I^* represents the intermediate variables generated from optimal actions, and
E^* is the optimal effects that can be achieved.

To generate the explanations, a concept of the qualitative difference is defined by comparing the actual scenario $(\tilde{x})$ to the optimal one $(x^\star)$, which is given by:

$$
\begin{aligned}
\Pi_{v_{-3}, v_{-2}, v_{-1}, v_1, v_2, v_3}(x^\star - \tilde{x}) : \\
x^\star - \tilde{x} < v_{-3} &\to \text{very low} \\
v_{-3} \le x^\star - \tilde{x} < v_{-2} &\to \text{ low} \\
v_{-2} \le x^\star - \tilde{x} < v_{-1} &\to \text{slightly low} \\
v_{-1} \le x^\star - \tilde{x} < v_1 &\to \text{no change} \\
v_1 \le x^\star - \tilde{x} < v_2 &\to \text{slightly high} \\
v_2 \le x^\star - \tilde{x} < v_3 &\to \text{ high} \\
x^\star - \tilde{x} \ge v_3 &\to \text{very high}
\end{aligned}
\tag{1}
$$

This mapping is done to show the occupants the impact of their actions on the comfort criteria, and to convince them to change their behavior when it is far from their objectives.

3   Physical Knowledge Model

This section represents the physical models, showing its complexity and how the method proposed in this paper will profit from the models and facilitate their comprehension by occupants. Advanced energy management systems rely on one or more physical models. For example, the physical model for predicting the inside temperature for the office built by [6] is shown in figure 3 that represents a simplified physical for the same office which represents only one thermal zone. where :

Figure 3: The reference model of the physical model [6]

T_n, T_{in} and T_{out} represent respectively the temperatures of the adjacent corridor, the office and outdoor.

R_D and R_W represent respectively thermal resistances of the door and the window when are closed.

ζ_D and ζ_W represent the average of opening/closing in time T.

R_i and C_i represent respectively the resistance and the capacitance of walls.

ϕ_{in} represents the internal thermal gains: solar gains, gains of electric devices and gains due to occupancy.

The thermal physical model will be given in this formula :

$$T_{in} = \frac{R}{R_i}\tau + R(\frac{1}{R_{out}} + \frac{\zeta_W}{R_W})T_{out} + R(\frac{1}{R_n} + \frac{\zeta_D}{R_D})T_n \qquad (2)$$

with R_n, R_{out}, R_i and C_i being time-invariant.

Determination of the air quality is usually done by measuring the concentration of CO_2 in the air. The following air quality model has been used: C_{cor}, C_{in} and C_{out} represent respectively the CO_2 concentration of the corridor, the office and outdoor. V stands for the volume of the office and $n(t)$ for the number of occupants [7].

Then, it yields to:

$$\begin{aligned} V\frac{dC_{in}}{dt} = &- (Q_0(t)^{out} + Q_0(t)^{cor} + \zeta_W(t)Q_w \\ &+ \zeta_D(t)Q_D)C_{in} + (Q_0(t)^{out} \\ &+ \zeta_W(t)Q_W)C_{out} + (Q_0(t)^{cor} \\ &+ \zeta_D(t)Q_D)C_{cor} + S_{CO_2} \times n(t) \end{aligned} \qquad (3)$$

Further details of the physical model can be found in [6]. From Eq. (2) and (3), it is clearly noticeable that the desired criteria, thermal comfort and air quality, are dependent on many different phenomena from different zones and from different actions.

Another very important element in an energy management system is the optimizer [8].

The optimizer acquires the available data and the various models to compute the optimal scenario (set of actions) according to the chosen comfort criteria regarding the occupant's preferences. The details on the optimizer used for this paper is provided in [9].

Based only on these observations, it is very complex to correlate all these different data to understand why the energy management system is recommending some actions. If the user's behavior is not the same as the proposed optimal scenario, he will have to change his habits. To help him to change his habits, it is important to explain him what are the consequences of each of his non-optimal actions so that he can decide which one he will adapt his routine according to or not. Aiming for implicating the inhabitants, the proposed approach tries to benefit from the physical model then figures out how to extract useful information from different measured and calculated data, and represent them in a way that makes more meaning for the inhabitants.

4 Differential Explanations and the independence graph

To extract the knowledge from the physical models and render them comprehensible; this paper propose differential explanations as a solution for that. Differential explanations are constructed by analyzing the difference between two scenarios (for example a historical one and an optimal one calculated by the system) to assist occupants to realize the impact of their daily actions with the contextual variables on their desired criteria.

This comparison includes the set of possible actions, the intermediate variables, and the effects. The difference between the users' actions and optimal actions calculated by the energy management system form the basis for the explanations. With this, it is possible to generate an indicator for the impact of those actions on the desired objectives. It also evaluates the different criteria and represents them in form of causality chain or network to clarify them for occupants. This concept is presented in figure 4.

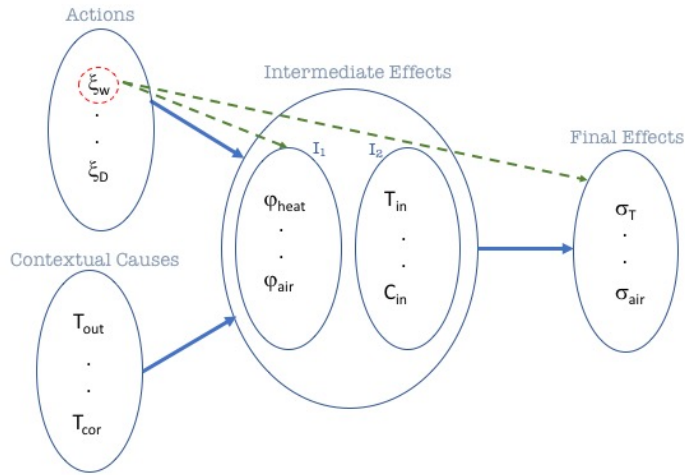

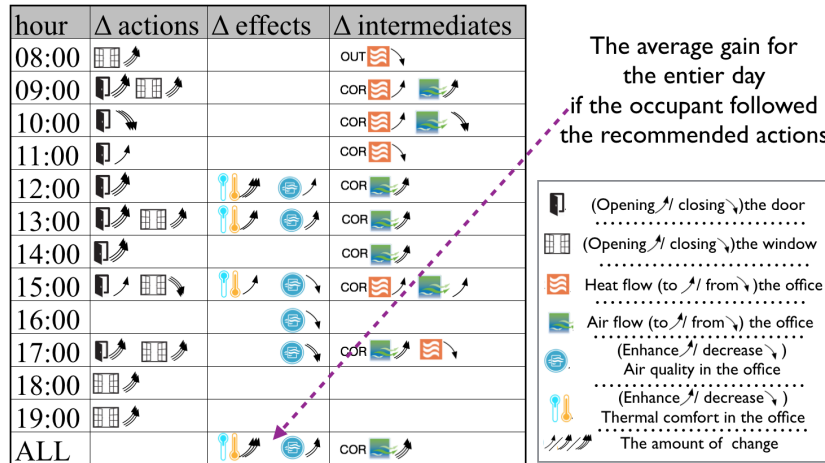

Figure 4: the principal

Figure 5: Differential Explanations

In figure. 4, differential explanations are illustrated in a table where the first column represents the distance to optimality for actions with what the occupant should have done according to the optimal plan, as shown in Eq. (4).

$$A_k^\star - \tilde{A}_k = \Delta A_k \tag{4}$$

where $A_k^\star$ represents the action (Fig. 2) calculated by the optimizer at time k (with a granularity of 1 hour) while $\tilde{A}_k$ represents a measured occupant's action at the same instant. The variable k can take any value in $\{\ 0,\ 23\ \}$. In this paper, $k = \{\ 8,\ 20\ \}$, $\forall k$, because it focuses on the time where occupants are present (daytime period). At 8am, for instance, the inhabitant should have opened the window more. At 4pm, the user behaves according to best scenario.

The second column presents the effects (Fig. 2), like in the thermal comfort and the air quality. This is given by Eq. (5).

$$E_k^\star - \tilde{E}_k = \Delta E_k \tag{5}$$

where $E_k^\star$ represents the calculated effect by system at instant k while $\tilde{E}_k$ represents the measured effect. The right-hand-side of Eq. (4) and (5) denotes the difference in actions of the occupants and its resulting difference in the effect at the k-th instant, respectively.

To better represent the causality in the explanations and extract the knowledge from the system, the intermediate variables are added in the third column of Fig. 4. Those variables are computed using the physical model to better represent the causal chain and by that more agreeably accepted by occupants.

The last row labeled ALL represents the overall gain or loss in the comfort criteria throughout the day. It's a small summary that gives the inhabitant an indicator of optimality for the entire day.

When computing this differential explanation, it is first necessary to transform quantitative variable values into qualitative ones that can be more easily understood by the occupants and allow to define qualitative distances. For instance, telling the occupant that closing the door at 2pm will cause a lot of decrease in the airflow and that he will obtain a significant decrease in the air quality level is easier to understand rather than telling that a difference in airflow of 30% will lead to a difference in CO_2 concentration of 400 ppm. The transformation from quantitative to qualitative is done by dividing the value domain of a variable into 7 sub-domains (3 positives, 3 negatives and 1 no-change levels). Those levels were chosen from the physical world according to their impact on the model and the occupant.

The levels for the variations in thermal dissatisfaction are given by:

$$\Pi^T_{-0.25,-0.15,-0.05,0.05,0.15,0.25}(\Delta\sigma_T^k(T_{in}))$$

The levels for the variations in air quality dissatisfaction are given by:

$$\Pi^{C_{CO_2}}_{-0.2,-0.1,-0.05,0.05,0.1,0.2}(\Delta\sigma_{air}^k(C_{in}))$$

The levels for the variations in the opening of the door and the window are given by (door or window opening means how long they have been opened in a one hour time period):

$$\Pi^{opening}_{-0.7,-0.5,-0.2,0.2,0.5,0.7}(\Delta\zeta_D)$$

$$\Pi^{opening}_{-0.7,-0.5,-0.2,0.2,0.5,0.7}(\Delta\zeta_w)$$

The arguments of each of these discretization functions is the difference of the measured quantity with the proposed optimal value of the quantity.

Except for the no-change level, where arrows are omitted, 1 to 3 arrows have been used to represent the associated sign of variation (arrows direction) and intensity (number of arrows). For instance, in Fig. 4, the window logo with three adjacent upward arrows means that the occupant should have opened the window for a much longer period of time during the corresponding time period.

As it can be seen, the differential explanations are much easier to understand as inhabitants don't need to figure the related variables and correlate between different actions, effects and intermediate variables. With differential explanation, it is thus easy for an occupant to identify the actions that needs to be modified, monitor the difference gained with respect to different criteria while at the same time use the intermediate variables as elements of understanding.

The differential explanation is providing a list of behavior modifications (opens the door for a longer period, for instance) with the associated impact. However, there are two limitations with such a description.

First, there is not a direct link between an action modification and its impact. Buildings have inertia i.e. energy dynamically stored in their structure. This inertia causes a delay and has a smoothing effect on different changes in the building preventing a rapid degradation or augmentations in temperature. Inertia is also present in the room volume for the CO_2 concentration. Thus, occupant actions might have a delayed impact.

Figure 6: Differential Explanations with Influences

In Fig. 6, closing the door at 10am does not have an immediate impact but it has a strong *influence* on the air quality at 12pm.

Second, all the proposed action modifications does not have the same importance: some of them have a limited influence and could be skipped if necessary (the inhabitant might not want for instance to interrupt his current activity to close the window). But some of them should be followed because of their high influence on the selected criteria (like the previous door example having a strong influence on the air quality).

Lets consider

$$\tilde{A} = \{\tilde{A}_{i,k}; \forall k\}$$
$$A^\star = \{A^\star_{i,k}; \forall k\}$$
(6)

where i stands for the different actions (window and door) and k for the time period. The influence of each action is determined by changing one action at a time like in Eq. (7). Starting from the calculated plan, we consider a new plan where all the actions are provided by the calculated plan except one which is replaced by the action that has been done by the inhabitant (the action that we want to calculate its influence).

$$A^\star_t = \{A^\star_k; \forall k \neq t\} \cup \left\{\tilde{A}_t\right\}$$
(7)

The physical model is then used to re-simulate the effects of the new plan.

$$\text{Physical model: } A^\star_t \implies E^\star_t$$
(8)

By comparing the optimal scenario with a scenario calculated by replacing one optimal action by the action that has been really done, it is possible to evaluate the impact of occupants behaviors that they may have on the comfort level and how it is preventing them from reaching their desired criteria level.

$$E^\star_t - E^\star_k = \Delta E$$
(9)

Within those equations, it is possible to generate cause-effect relations between actions and final effects, but the causality between the different levels of the intermediate variables and with final effects are unreachable because their changes can't be monitored with a physical model as experts try to simplify the model to the maximum.

In order to build a full cause-effect relation between variables, an expert knowledge needs to be represented to indicate the potential causality between variables and eliminates the impossible ones like in figure 7.

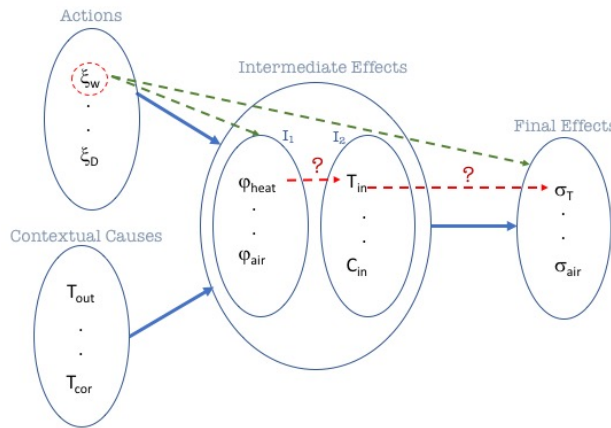

Figure 7: Missing Knowledge

By minimizing the number of variables to simplify the complicated calculations even when those variables probably hold a meaning for occupants. Reaching those variables is important to give occupants complete explanations.This can be achieved by injecting the expert knowledge in terms of rules representing the potential causality and the forbidden ones. This can be easily done because the expert has a very good knowledge about the nature of those variables.

Like presented in the figure 8, the expert will define the potential causality. So when the system detects a change in different variables in different layers at the same time. It will try to examine whether it can determine the variable from the first layer affecting the other variable in the second layer, and by this build the cause-effect relation between them.

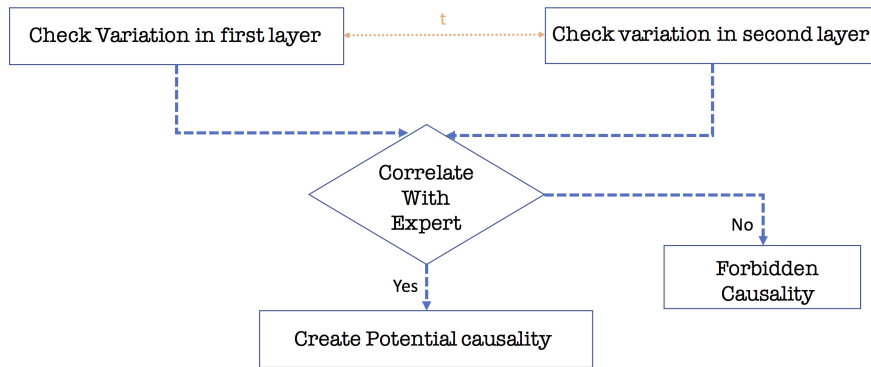

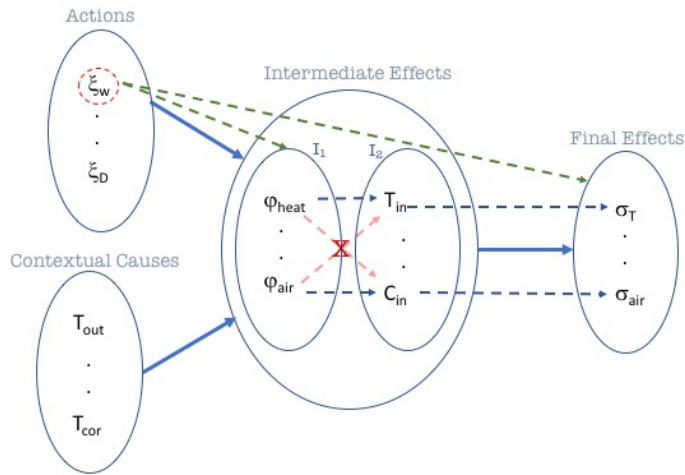

Figure 8: Adding Expert knowledge

Figure 9: Adding Expert knowledge

Thus, the proposed method allows the occupants to have an explanation based on the cause-effect relations of their actions and they may decide to change their routines, after learning from their historical actions.

11

Applying the same principle on the context variables , it is then possible to generate a full diagram like in the figure 10.

$$C_t^\star - C_k^\star = \Delta C \tag{10}$$

Within this the inhabitant would understand how much his actions are affecting the comfort criteria and evaluate this with the weight changing in the contextual variables.

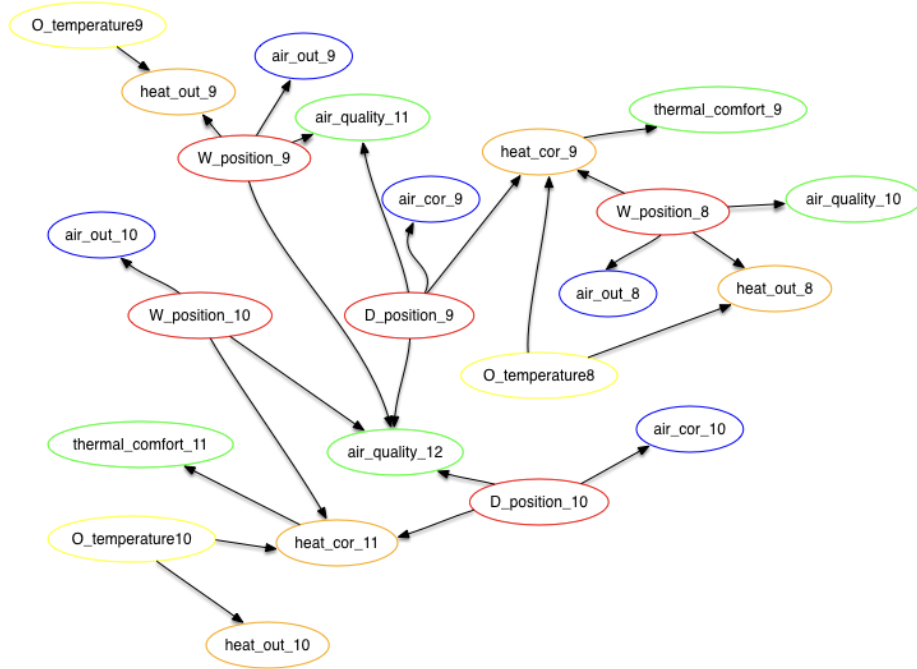

Figure 10: Part of the path diagram for one day

By developing the path diagram the occupant will be provided with a complete description of all factors that played a role in his day and he can inspect how did they evolved through the day. Allowing him to be explore where he is willing to enhance his routines and where not.

5 Text Generation

5.1 Objective

The differential explanations are provided to help inhabitants to better understand their habitats because they will easily understand the ecological impact of their behavior and how they can modify it to improve that impact. Still, reading complex graphic table may be a rather abstruse experience for the user. Therefore, to base on the inhabitant knowledge, such a table like in figure 4 is not easily understandable and occupants will favorite a statement in natural language rather than the table. The statement needs to be well written and also entirely automatically generated in a smart way to not repeat the same words

all the time. Thus, by making cooperation effort with occupants, it will be easier for them and they can more quickly adopt the right behaviors and enjoy the satisfaction that comes from understanding the effects and their behaviors.

5.2   Problem statement

Natural Language Generation (NLG) is an NLP sub-field concerned with the generation of texts from non-linguistic data [10]. Typical systems take a high-level representation of input data, select and structure the final information to convey (macro-planning), makes a lexical and syntactic transformation to this structured information (micro-planning) and to finally linearize it as text (surface generation). This classical pipeline as mainly be approached by expert and grammatical rules [11], statistical models [12] or machine learning [13] in application as diverse as complex medical data summarization [11], prose generation [12] or image captioning [13].

NLG is a dialogue system and Machine Translation (MT) system. Most recent stochastic MT systems perform NLG through shallow language models but MT systems using a high-level internal representation that presents deep general-purpose NLG module.

MT systems have to generate a target text that complies with the grammar rules of the target language, starting from a deep formal linguistic structure obtained from the linguistic analysis of a text in the source language. ARIANE-HELOISE was chosen to be used as MT system to be quickly able to generate the text form of the differential explanations.

5.3   system Ariane-Heloise

The Ariane-Heloise MT system [14] is the re-engineering of the widely known Ariane MT system [15]. It takes over all functionalities by improving or simplifying them. As well as its predecessor, it links together several transducers, which enable to transform the source text into a decorated tree to transform this tree into a linguistic tree structure to generate from that structure a target text. During the process, various linguistic operations are carried out: morphological and structural analysis, lexical transfer, syntactic and morphological generation. The decoration on each node of the decorated tree is a combination of values for a set of declared variables and allow for coding linguistic properties and relations.

5.4   GRA-FRA

A first model was developed in ARIANE-HELOISE for a feasibility demonstration: the GRA-FRA ("GRAphe vers texte en FRAnçais": graph to French text) model. It was specifically designed for generating messages from the tables containing differential explanations. It receives input text that is the linearized arbores-cent expression of the tables and it produces a French text. The 7 phases of contents processing are succinctly described below from a simple example. Phases 2-6 implement tree-to-tree transducers that transform the decorated tree by applying transformational grammars and consulting dictionaries (XA and LT).

hour	Δ action	Δ effect	Δ intermediates
17:00			COR OUT

Tableau(Hours(17(Actions(Door(Opening, Grad3),
Window(Opening, Grad3)), Effects(Airqual(minus, Grad1)),
Intermed(Airflow(to, COR, Grad2),
Heatflow(from, OUT, Grad1)))))

Figure 11: Table and its linearized expression

- MA, Morphological Analysis, implements a string-to-tree transducer in order to produce a decorated tree, the only data structure that can be manipulated by the Ariane-Heloise system. It also distinguishes between strings corresponding to "Concept-words" of the table and the elements of the tree structure (parentheses and commas).

- XA is an analysis dictionary that contains all the concepts used in tables with their description by means of variables values.

- SA1, Structural Analysis 1, produces the exact image of the table and its contents as a decorated tree.

- SA2, Structural Analysis 2, modifies the tree produced by SA1 to give it a syntagmatic linguistic expression, ready to be translated into French.

Figure 12: SA2

- LT, Lexical Transfer, translates the words of the table into French and sets the syntactic functions of words and phrases.

- SG, Syntactic Generation, calculates the surface syntactic structure of the sentences of the French target text and the morphological agreements in person, gender and number between the lexical constituents of the linguistic tree.

- MG, Morphological Generation, implements a tree-to-string transducer which first produces the correct forms of the words of the leaves of the linguistic tree and then outputs the final French text corresponding to the table contents.

Traduction

Dans le créneau horaire 17h-18h, si vous aviez laissé la porte et la fenêtre ouvertes beaucoup plus longtemps, la qualité de l'air aurait diminué un petit peu, il y aurait eu un courant d'air sensible vers le couloir et un flux thermique léger venant de l'extérieur ;

Figure 13: Output from Ariane-Heloise GRA-FRA GM phase

6 Conclusion

The main objective of this paper is to help the occupants to get a better understanding of their energy management system and their actions. This work discusses and presents why explanations are needed and why they are important for occupants apprehension of the energy management system and the impact of their actions. It presents the concept of differential explanations i.e. a type of cause-effect explanations and also presents the concept of the influence of the inhabitant's actions to clarify for him/her the long term effect of his/her actions. This study uses the multi-objective version of differential evolution (DEMO) for proposing optimal actions to the occupant based on his/her past actions. This is preliminary work dealing with thermal and air quality comfort criteria.

In future, this work will examine different methods to build and generate qualitative models to define causality between actions and their causal chain of impacts. This can be done by using causal physical models like bond graphs [16] and try to profit from the techniques of the causal graph to formalize the causal explanations like by using GARP3 [17] as a workbench for qualitative reasoning and modeling.

Another aspect to be explored is the optimal schedule obtained when other criteria such as humidity, consumption of energy, the price of electricity, etc. come into play. Besides having multiple criteria, the occupant may be biased towards certain criteria. Hence, the preference of the occupant plays a crucial role in decision making. Incorporating such user preferences is another open area of research. As the only machine learning tool used in this work is the optimization algorithm, the comparison of the performance of the proposed approach using other optimization algorithms is to be studied further.
