Abstract We consider the cubic defocusing nonlinear Schrödinger equation on the two dimensional torus. We exhibit smooth solutions for which the support of the conserved energy moves to higher Fourier modes. This behavior is quantified by the growth of higher Sobolev norms: given any $\delta \ll 1$, $K \gg 1$, $s > 1$, we construct smooth initial data u_0 with $\|u_0\|_{H^s} < \delta$, so that the corresponding time evolution u satisfies $\|u(T)\|_{H^s} > K$ at some time T . This growth occurs despite the Hamiltonian's bound on $\|u(t)\|_{\dot{H}^1}$ and despite the conservation of the quantity $\|u(t)\|_{L^2}$.

The proof contains two arguments which may be of interest beyond the particular result described above. The first is a construction of the solution's frequency support that simplifies the system of ODE's describing each Fourier mode's evolution. The second is a construction of solutions to these simpler systems of ODE's which begin near one invariant manifold and ricochet from arbitrarily small neighborhoods of an arbitrarily large number of other invariant manifolds. The techniques used here are related to but are distinct from those traditionally used to prove Arnold Diffusion in perturbations of Hamiltonian systems.

1 Introduction

We consider the periodic defocusing cubic nonlinear Schrödinger (NLS) equation

$$\begin{cases} -i\partial_t u + \Delta u = |u|^2 u, \\ u(0, x) := u_0(x), \end{cases} \tag{1.1}$$

where $u(t, x)$ is a complex valued function with the spatial variable x lying in the torus $\mathbb{T}^2 := \mathbb{R}^2 / (2\pi\mathbb{Z})^2$. Equations such as (1.1) arise as models in various physical settings, including the description of the envelope of a general dispersive wave in a weakly nonlinear medium, and more specifically in some models of surface water waves. (See e.g. the survey in [75], Chap. 1.)

We shall always take the initial data $u_0(x)$ to be smooth. Recall (see e.g. [29, 77]) that smooth solutions to (1.1) exhibit both conservation of the Hamiltonian,

$$\begin{aligned} E[u](t) &:= \int_{\mathbb{T}^2} \frac{1}{2} |\nabla u|^2 + \frac{1}{4} |u|^4 dx(t) \\ &= E[u](0), \end{aligned} \tag{1.2}$$

and conservation of mass, or $L^2(\mathbb{T}^2)$ norm,

$$\int_{\mathbb{T}^2} |u|^2 dx(t) = \int_{\mathbb{T}^2} |u|^2 dx(0), \tag{1.3}$$

for all $t > 0$. The local-in-time well-posedness result of Bourgain [13] for data $u_0 \in H^s(\mathbb{T}^2)$, $s > 0$, together with these conservation laws, immediately gives the existence of a global smooth solution to (1.1) from smooth initial data.

We are interested in whether there exist solutions of (1.1) which initially oscillate only on scales comparable to the spatial period and eventually oscillate on arbitrarily short spatial scales. One can quantify such motion in terms of the growth in time of higher Sobolev norms $\|u(t)\|_{H^s(\mathbb{T}^2)}$, $s > 1$, defined using the Fourier transform by,

$$\|u(t)\|_{H^s(\mathbb{T}^2)} := \|u(t, \cdot)\|_{H^s(\mathbb{T}^2)} := \left(\sum_{n \in \mathbb{Z}^2} \langle n \rangle^s |\hat{u}(t, n)| \right)^{\frac{1}{2}} \tag{1.4}$$

where $\langle n \rangle := (1 + |n|^2)^{\frac{1}{2}}$ and,¹

$$\hat{u}(t, n) := \int_{\mathbb{T}^2} u(t, x) e^{-in \cdot x} dx.$$

For example, together (1.2) and (1.3) give a uniform bound

$$\|u(t)\|_{H^1(\mathbb{T}^2)} = \left(\sum_{n \in \mathbb{Z}^2} \langle n \rangle^2 |\hat{u}(t, n)|^2 \right)^{\frac{1}{2}} \leq C \quad (1.5)$$

on the solution's H^1 norm. Hence, for fixed $s > 1$, $\|u(t)\|_{H^s(\mathbb{T}^2)}$ could grow in time if the terms contributing substantially to the sum on the left hand side of (1.5) correspond, loosely speaking, to ever higher $|n|$. From this point of view then, we are interested in whether the energy of a solution to (1.1) can be carried by higher and higher Fourier modes.

The one space-dimensional analog of (1.1) is completely integrable [82], and the higher conservation laws in that case imply $\|u(t)\|_{H^s(\mathbb{T}^1)} \leq C(\|u(0)\|_{H^s(\mathbb{T}^1)})$, $s \geq 1$ for all $t > 0$. It is unknown (see e.g. [25]) whether unbounded growth in H^s , $s > 1$, is possible in dimensions 2 and higher, let alone whether such growth is generic. The main result of this paper is the construction of solutions to (1.1) with arbitrarily large growth in higher Sobolev norms,

Theorem 1.1 *Let $1 < s$, $K \gg 1$, and $0 < \delta \ll 1$ be given parameters. Then there exists a global smooth solution $u(t, x)$ to (1.1) and a time $T > 0$ with*

$$\|u(0)\|_{H^s} \leq \delta$$

and

$$\|u(T)\|_{H^s} \geq K.$$

Note that, in view of (1.2), (1.3), the growth constructed here must involve both movement of energy to higher frequencies, and movement of mass to lower frequencies. (The mass associated to the higher and higher frequency energy must be decreasing by energy conservation. This must be balanced, by mass conservation, by more and more mass at low frequencies.) Recall again that any smooth data in (1.1) evolves globally in time. While finite and infinite time blowup results are known for focusing analogs of (1.1) (e.g. [18, 20, 52,

¹In what follows, we omit the factors of 2π arising in definitions of the Fourier transform and its inverse, as these play no role in our analysis.

65, 69]), the mechanism responsible for the H^s norm growth in Theorem 1.1 is distinct from these blowup dynamics.

Using the conservation laws (1.2), (1.3) and the Sobolev embedding theorem, we observe that, for $s = 1$, we have a stability property near zero,

$$\left(\limsup_{|t| \rightarrow \infty} \left[\sup_{\|u_0\|_{H^1} \leq \delta} \|u(t)\|_{H^1} \right] \right) \leq C\delta.$$

Theorem 1.1 implies a different behavior in the range $s > 1$. Since δ may be chosen to be arbitrarily small and K may be chosen arbitrarily large in Theorem 1.1, we observe the following:

Corollary 1.1 (H^s instability of zero solution) *The global-in-time solution map taking the initial data u_0 to the associated solution u of (1.1) is strongly unstable in H^s near zero for all $s > 1$:*

$$\inf_{\delta > 0} \left(\limsup_{|t| \rightarrow \infty} \left[\sup_{\|u_0\|_{H^s} \leq \delta} \|u(t)\|_{H^s} \right] \right) = \infty. \tag{1.6}$$

It does not follow from (1.6), nor directly from Theorem 1.1, that there exists initial data $u_0 \in H^s$ for some $s > 1$ which evolves globally in time and satisfies $\limsup_{|t| \rightarrow \infty} \|u(t)\|_{H^s} = \infty$. As remarked above, this remains an interesting open question [25]. In the Appendix, we do prove that (1.1) has no nontrivial solutions which scatter—i.e. which approach a solution to the linear equation at time $t = \infty$. Note that Theorem 1.1 and Corollary 1.1 also hold true for higher dimensional generalizations of (1.1) by considering solutions which are only dependent upon two of the spatial coordinates.

Theorem 1.1 is motivated by a diverse body of literature. We mention first foundational work which extended results for close to integrable Hamiltonian systems in finite dimensions to the context of partial differential equations in one space dimension. Especially relevant to the question addressed here are the early papers on periodic solutions to nonlinear PDE (see e.g. Rabinowitz [72], and the survey in Brezis [28]), the earliest KAM-type results for PDE (see e.g. those of Kuksin [59, 60], Wayne [79], Craig-Wayne [35, 36], and Kuksin-Pöschel [61], see also the surveys [34, 80]), and the Nekhoroshev type estimates of Bambusi [3] (see also related work of Pöschel [71]). There are many related results, extending the analysis too to higher dimensional partial differential equations, see e.g. the works of Bambusi [3], Grebert [47], Eliasson-Kuksin [45], Bourgain [23], and references therein. We briefly review now some results particularly related to Theorem 1.1, including upper bounds on the possible growth of Sobolev norms for (1.1), lower bounds for related models, and extensive work on the so-called *weak-turbulence theory* of related wave models.

A straightforward iteration argument based on the local theory [13] shows that high Sobolev norms of solutions of (1.1) can grow no faster than exponential-in-time. Bourgain used refinements [19] of the Strichartz inequality to prove polynomial-in-time upper bounds [16] on Sobolev norm growth. These results were sharpened, using a normal forms reduction, in [17]. (See also [31, 74].)

Previous examples of growth in the higher Sobolev norms of solutions to (1.1) are, to the best of our knowledge, found only in the work of Kuksin [55] (see also related work in [54, 56–58]), where the following small dispersion nonlinear Schrödinger equation is considered,²

$$-i\partial_t w + \delta\Delta w = |w|^2 w \quad (1.7)$$

with odd, periodic boundary conditions, where δ is taken to be a small parameter. Kuksin shows, among other results and in various formulations, that smooth norms of solutions of (1.7) evolving from relatively generic data with unit L^2 norm eventually grow larger than a negative power of δ . This result can be compared with Theorem 1.1 as follows. Suppose w is a solution of (1.7). The rescaled function $u_\delta(t, x) = \delta^{-\frac{1}{2}} w(\delta^{-1}t, x)$ satisfies the PDE (1.1), the same equation as (1.7) with $\delta = 1$. Note that $\|D_x^s u_\delta(0, \cdot)\|_{L^2} = \delta^{-\frac{1}{2}} \|D_x^s w(0, \cdot)\|_{L_x^2}$. Hence, in the context of (1.1), the above described result in [55] addresses growth of solutions emerging from a relatively generic class of sufficiently large initial data, where the size of the data depends on the amount of growth desired. In contrast, Theorem 1.1 concerns growth from specially selected small, or order one, data³ and its proof involves a strong interplay between the equation's dispersion and nonlinearity.

In contrast to the question for the nonlinear problem (1.1), there are several results on the growth of Sobolev norms in linear Schrödinger equations with potentials,

$$-i\partial_t v + \Delta v + V(t, x)v = 0, \quad x \in \mathbb{T}^2. \quad (1.8)$$

For example, for V smooth in space, and random in time (resp. smooth and periodic in x and t), Bourgain proved that generic data grows polynomially [26] (resp. logarithmically [21]) in time.

²In these papers, Kuksin considers a variety of deterministic and random nonlinear Schrödinger equations in addition to (1.7). In [57] the analog of (1.7) for the second order wave equation is considered. Note too that we write (1.7) with the sign convention on the time variable as in (1.1), rather than the convention used in [55], but this makes no substantial difference in describing the results.

³Theorem 1.1 is stated for the case $\delta \ll 1$. However as we hope is clear from the discussion in Sect. 2.6 below, the construction allows any choice of $\delta > 0$.

Bourgain has constructed [14, 15] Hamiltonian PDEs with solutions with divergent high Sobolev norms. These constructions are based on perturbation arguments off linear equations with spectrally defined Laplacian and also involve somewhat artificial⁴ choices of nonlinearities. In [16], solutions with divergent Sobolev norms are constructed for a wave equation with a natural cubic nonlinearity but still involving a spectrally defined Laplacian.

Bourgain has also shown [22, 24] that there is an abundance of time quasi-periodic solutions of (1.1).

As mentioned at the outset, the growth of higher Sobolev norms is just one way to quantify the diffusion of energy to higher and higher modes—also called a forward cascade, or a direct cascade. Further motivation for Theorem 1.1, and indeed for much of the work cited above, is the literature of analysis, physics, numerics, heuristics and conjectures regarding this phenomenon in related wave models. For example, since the early 1960's a so-called *weak turbulence theory* (alternatively *wave turbulence theory*) has been developed which gives a statistical description of a robust forward cascade in various “weakly interacting” dispersive wave models, mainly based on the analysis of associated kinetic equations for the evolution of the Fourier modes [7, 8, 48, 62, 81]. There are a great many subsequent works both within and outside the framework of weak turbulence theory which address the passage of energy to higher modes in dispersive wave models. We are not prepared to give here a representative survey, but see [41, 44, 53, 63, 68] and references therein for examples.

In broadest outline, the proof of Theorem 1.1 proceeds by first viewing (1.1) as an infinite dimensional system of O.D.E.'s in $\{a_n(t)\}_{n \in \mathbb{Z}^2}$, where $a_n(t)$ is closely related to the Fourier mode $\hat{u}(t, n)$ of the solution. We identify a related system, which we call the *resonant system*, that we use as an approximation to the full system.⁵ The goal then will be to build a solution $\{r_n(t)\}_{n \in \mathbb{Z}^2}$ to the resonant system which grows in time. This is accomplished by choosing the initial data $\{r_n(0)\}_{n \in \mathbb{Z}^2}$ to be supported on a certain frequency set $\Lambda \subset \mathbb{Z}^2$ in such a way that the resonant system of O.D.E.'s collapses to an even simpler, finite dimensional system that we call *the Toy Model System*, and whose solution we denote by $b(t) \equiv \{b_1(t), b_2(t), \dots, b_N(t)\}$. Each variable $b_i(t)$ will represent how a certain subset of the $\{r_n(t)\}_{n \in \mathbb{Z}^2}$ evolves in time. There are two independent but related ingredients which complete the proof of the main Theorem. First, we show the existence of the frequency set Λ , which is defined in terms of the desired Sobolev norm growth and

⁴See Remark 2 on p. 303 of [16] for further discussion.

⁵The reduction here is very much related to normal forms (see e.g. [4, 6, 61, 73] and the surveys [5, 47]). A difference is that the nonresonant terms are removed here using perturbation theory directly, rather than by first transforming the Hamiltonian and then using perturbation theory to handle the resulting higher order terms.

according to a wish-list of geometric and combinatorial properties aimed at simplifying the resonant system. Second, we show that the Toy Model System exhibits unstable orbits that travel from an arbitrarily small neighborhood of one invariant manifold to near a distant invariant manifold. It is this instability which is ultimately responsible for the support of the solution's energy moving to higher frequencies. Instabilities like this have been remarked on at least as far back as [70], but have been studied with increasing interest since the paper of Arnold [2]. Our construction has similarities with previous work on so-called "Arnold Diffusion"⁶ and more general instabilities in Hamiltonian systems (see e.g. [1, 2, 9–12, 27, 30, 32, 33, 37–40, 42, 43, 46, 50, 51, 64, 66, 67, 78]). At the same time, however, the instability we observe in the toy model differs in some respects from the original phenomenon observed by Arnold. Our analysis of the instability seems to be different than arguments presently in the literature and might be of independent interest. More specifically, it may be possible to prove the instability by "softer" methods that do not require as many quantitative estimates as the arguments in this paper, although the presence of secular modes in the dynamics may complicate such a task. While such a soft proof would be simpler, we believe that the approach here is also of interest, as it provides a rather precise description of the orbits.

The paper is organized as follows. Section 2 provides a more detailed overview of the argument, giving the proof of Theorem 1.1 modulo some intermediate claims. Section 3 contains a proof that the Toy Model System exhibits the unstable orbits described above. Section 4 constructs the frequency set Λ . Finally, we prove as a postscript in Sect. 4 that no nontrivial solutions to (1.1) scatter to linear solutions.

2 Overview and proof of main theorem

2.1 Preliminary reductions: NLS as an infinite system of ODE's

Equation (1.1) has gauge freedom: upon writing

$$v(t, x) = e^{iGt} u(t, x), \quad G \in \mathbb{R} \text{ (constant)}, \quad (2.1)$$

the NLS equation (1.1) becomes the following equation for v ,

$$(-i\partial_t + \Delta)v = (G + |v|^2)v \quad (2.2)$$

with the same initial data. (We will soon choose the constant G to achieve a cancellation.)

⁶There are several different definitions of "Arnold Diffusion" (see e.g. the remarks in the introduction of the survey by Delshams, Gidea, and de la Llave in [33]).

We make the *Fourier Ansatz*, motivated by the explicit solution of the linear problem associated to *NLS*. For solutions of the *NLS_G* equation (2.2), we write

$$v(t, x) = \sum_{n \in \mathbb{Z}^2} a_n(t) e^{i(n \cdot x + |n|^2 t)}. \tag{2.3}$$

We consider in this paper only smooth solutions, so the series on the right of (2.3) is absolutely summable. Substituting (2.3) into (1.1) and equating Fourier coefficients for both sides gives the following infinite system of equations for $a_n(t)$,

$$-i \partial_t a_n = G a_n + \sum_{\substack{n_1, n_2, n_3 \in \mathbb{Z}^2 \\ n_1 - n_2 + n_3 = n}} a_{n_1} \overline{a_{n_2}} a_{n_3} e^{i \omega_4 t}, \tag{2.4}$$

where

$$\omega_4 = |n_1|^2 - |n_2|^2 + |n_3|^2 - |n|^2. \tag{2.5}$$

Certain terms on the right hand side of (2.4) can be removed by correctly choosing the gauge parameter G . We describe this cancellation this now. Split the sum on the right hand side of (2.4) into the following terms,

$$\begin{aligned} \sum_{\substack{n_1, n_2, n_3 \in \mathbb{Z}^2 \\ n_1 - n_2 + n_3 = n}} &= \sum_{\substack{n_1, n_2, n_3 \in \mathbb{Z}^2 \\ n_1 - n_2 + n_3 = n \\ n_1, n_3 \neq n}} + \sum_{\substack{n_1, n_2, n_3 \in \mathbb{Z}^2 \\ n_1 - n_2 + n_3 = n \\ n_1 = n}} + \sum_{\substack{n_1, n_2, n_3 \in \mathbb{Z}^2 \\ n_1 - n_2 + n_3 = n \\ n_3 = n}} - \sum_{\substack{n_1, n_2, n_3 \in \mathbb{Z}^2 \\ n_1 - n_2 + n_3 = n \\ n_3 = n_1 = n}} \\ &:= \text{Term I} + \text{Term II} + \text{Term III} + \text{Term IV}. \end{aligned} \tag{2.6}$$

Term IV here is not a sum at all, but rather $-a_n(t) |a_n(t)|^2$. Terms II and III are single sums which by Plancherel’s theorem and (1.3) total,

$$\begin{aligned} 2a_n(t) \cdot \sum_{m \in \mathbb{Z}^2} |a_m(t)|^2 &= 2a_n(t) \cdot \|u(t)\|_{L^2(\mathbb{T}^2)}^2 \\ &= 2a_n(t) M^2, \end{aligned}$$

where we’ve written $M := \|u(t)\|_{L^2(\mathbb{T}^2)}$. We can cancel this with the first term on the right side of (2.4) by choosing $G = -2M$ in (2.1). Equation (2.4) takes then the following useful form, which we denote *FNLS*,

$$-i \partial_t a_n = -a_n |a_n|^2 + \sum_{n_1, n_2, n_3 \in \Gamma(n)} a_{n_1} \overline{a_{n_2}} a_{n_3} e^{i \omega_4 t}, \tag{2.7}$$

where

$$\Gamma(n) = \{(n_1, n_2, n_3) \in (\mathbb{Z}^2)^3 : n_1 - n_2 + n_3 = n, n_1 \neq n, n_3 \neq n\}. \tag{2.8}$$

Note that at each time u is easily recoverable from v , and both functions have identical Sobolev norms.

One can easily show that \mathcal{FNLS} is locally well-posed in $l^1(\mathbb{Z}^2)$, and for completeness we sketch the argument here. Define the trilinear operator

$$\mathcal{N}(t) : l^1(\mathbb{Z}^2) \times l^1(\mathbb{Z}^2) \times l^1(\mathbb{Z}^2) \mapsto l^1(\mathbb{Z}^2)$$

by

$$(\mathcal{N}(t)(a, b, c))_n = -a_n \overline{b_n} c_n + \sum_{n_1, n_2, n_3 \in \Gamma(n)} a_{n_1} \overline{b_{n_2}} c_{n_3} e^{i\omega_4 t}. \tag{2.9}$$

With this notation, we can reexpress \mathcal{FNLS} as $-i \partial_t a_n = (\mathcal{N}(t)(a, a, a))_n$.

Lemma 2.1

$$\|(\mathcal{N}(t)(a, b, c))_n\|_{l^1(\mathbb{Z}^2)} \lesssim \|a\|_{l^1(\mathbb{Z}^2)} \|b\|_{l^1(\mathbb{Z}^2)} \|c\|_{l^1(\mathbb{Z}^2)}. \tag{2.10}$$

Proof The l^1 norm of the first term in (2.9) is bounded by $\|a\|_{l^\infty} \|b\|_{L^\infty} \|c\|_{l^1}$, which is bounded as claimed. For the second term, take absolute values inside the $\sum_{n_1, n_2, n_3 \in \Gamma(n)}$ and then replace the n_3 sum by the n sum using the $\Gamma(n)$ defining relation to observe the bound (2.10). \square

Remark 2.1 From Lemma 2.1 and standard Picard iteration arguments one obtains local well-posedness in $l^1(\mathbb{Z}^2)$. The local well-posedness result is valid on $[0, T]$ with

$$T \sim \|a(0)\|_{l^1(\mathbb{Z}^2)}^{-2}.$$

Equation $-i \partial_t a = \mathcal{N}(t)(a, a, a)$ behaves roughly like the ODE $\partial_t a = a^3$ for the purposes of local existence theory.

2.2 Resonant and finite dimensional truncations of \mathcal{FNLS}

We define the *set of all resonant non-self interactions* $\Gamma_{res}(n) \subset \Gamma(n)$ by

$$\Gamma_{res}(n) = \{(n_1, n_2, n_3) \in \Gamma(n) : \omega_4 = |n_1|^2 - |n_2|^2 + |n_3|^2 - |n|^2 = 0\}. \tag{2.11}$$

Note that $(n_1, n_2, n_3) \in \Gamma_{res}(n)$ precisely when (n_1, n_2, n_3, n) form four corners of a nondegenerate rectangle with n_2 and n opposing each other, and similarly for n_1 and n_3 . One way to justify this claim is to first note the following symmetry: the two conditions (2.8), (2.11) defining $\Gamma_{res}(n)$ imply directly that $(n_1, n_2, n_3) \in \Gamma_{res}(n)$ if and only if $(n_1 - n_0, n_2 - n_0, n_3 - n_0) \in \Gamma_{res}(n - n_0)$ for any $n_0 \in \mathbb{Z}^2$. Choosing $n_0 = n$, it suffices to prove the above geometric interpretation for $\Gamma_{res}(n)$ in the case $n = 0$, and this follows immediately from the law of cosines.

Heuristically, the resonant interactions dominate in (2.7) because they do not contain the $e^{i\omega_4 t}$ factor that oscillates in time. We approximate solutions of (2.7) by simply discarding the nonresonant interactions—and we make this approximation rigorous with Lemma 2.3 below. For now, we simply define the *resonant truncation* $R\mathcal{FNLS}$ of \mathcal{FNLS} by,

$$-i\partial_t r_n = -r_n|r_n|^2 + \sum_{(n_1, n_2, n_3) \in \Gamma_{res}(n)} r_{n_1} \overline{r_{n_2}} r_{n_3}. \tag{2.12}$$

Even after making the resonant approximation, we still have an infinite ODE to work with— n can range freely over \mathbb{Z}^2 . Our strategy is to choose initial data for which the system simplifies in several ways.

Suppose we have some finite set of frequencies Λ that satisfies the following two properties:

- (Property I_Λ : Initial data) The initial data $r_n(0)$ is entirely supported in Λ (i.e. $r_n(0) = 0$ whenever $n \notin \Lambda$).
- (Property II_Λ : Closure) Whenever (n_1, n_2, n_3, n_4) is a rectangle in \mathbb{Z}^2 such that three of the corners lie in Λ , then the fourth corner must necessarily lie in Λ . In terms of previously defined notation, this can be expressed as follows,

$$(n_1, n_2, n_3) \in \Gamma_{res}(n), n_1, n_2, n_3 \in \Lambda \implies n \in \Lambda. \tag{2.13}$$

Then one can show that $r_n(t)$ stays supported in Λ for all time. Intuitively, this is because the non-linearity in (2.12) cannot excite any modes outside of Λ if one only starts with modes inside Λ .

For completeness, we include here the short argument that condition (2.13) guarantees a finite dimensional model if the finite set Λ contains the support of the initial data $r(0) = \{r_n(0)\}_{n \in \mathbb{Z}^2}$ for (2.12).

Lemma 2.2 *If Λ is a finite set satisfying Property I_Λ , Property II_Λ above, and $r(0) \mapsto r(t)$ solves $R\mathcal{FNLS}$ (2.12) on $[0, T]$ then for all $t \in [0, T]$ $\text{spt}[r(t)] \subset \Lambda$.*

Proof Define,

$$B(t) := \sum_{n \notin \Lambda} |r_n(t)|^2.$$

Thus $B(0) = 0$, and from the closure property and the boundedness⁷ of $r_n(t)$ we get the differential inequality

$$|B'(t)| \leq C|B(t)|.$$

Thus, by the Gronwall estimate, $B(t) = 0$ for all t . Hence, none of the modes outside of Λ are excited. \square

Our strategy thus far is to choose initial data for (1.1) with Fourier support in such a set Λ —so that the resonant system (2.12) reduces to a finite dimensional system. We now place more conditions on the set Λ and on the initial data which bring about further simplifications.

We demand that for some positive integer N (to be specified later), the set Λ splits into N disjoint *generations* $\Lambda = \Lambda_1 \cup \dots \cup \Lambda_N$ which satisfy the properties we specify below, after first introducing necessary terminology. Define a *nuclear family* to be a rectangle (n_1, n_2, n_3, n_4) where the frequencies n_1, n_3 (known as the “parents”) live in a generation Λ_j , and the frequencies n_2, n_4 (known as the “children”) live in the next generation Λ_{j+1} . Note that if (n_1, n_2, n_3, n_4) is a nuclear family, then so is (n_1, n_4, n_3, n_2) , (n_3, n_2, n_1, n_4) , and (n_3, n_4, n_1, n_2) ; we shall call these the *trivial permutations* of the nuclear family. We require the following properties (in addition to the initial data and closure hypotheses described above):

- (Property III $_{\Lambda}$: Existence and uniqueness of spouse and children) For any $1 \leq j < N$ and any $n_1 \in \Lambda_j$ there exists a unique nuclear family (n_1, n_2, n_3, n_4) (up to trivial permutations) such that n_1 is a parent of this family. In particular each $n_1 \in \Lambda_j$ has a unique spouse $n_3 \in \Lambda_j$ and has two unique children $n_2, n_4 \in \Lambda_{j+1}$ (up to permutation).
- (Property IV $_{\Lambda}$: Existence and uniqueness of sibling and parents) For any $1 \leq j < N$ and any $n_2 \in \Lambda_{j+1}$ there exists a unique nuclear family (n_1, n_2, n_3, n_4) (up to trivial permutations) such that n_2 is a child of this family. In particular each $n_2 \in \Lambda_{j+1}$ has a unique sibling $n_4 \in \Lambda_{j+1}$ and two unique parents $n_1, n_3 \in \Lambda_j$ (up to permutation).
- (Property V $_{\Lambda}$: Nondegeneracy) The sibling of a frequency n is never equal to its spouse.
- (Property VI $_{\Lambda}$: Faithfulness) Apart from the nuclear families, Λ contains no other rectangles. (Indeed, from the Closure hypothesis, it does not even contain any right-angled triangles which are not coming from a nuclear family.)

Despite the genealogical analogies, we will not assign a gender to any individual frequency (one could do so, but it is somewhat artificial); these are

⁷The argument sketched previously for local well-posedness in l^1 of (2.7) carries over to (2.12) without change.

asexual families. Since every pair of parents in one generation corresponds to exactly one pair of children in the next, a simple counting argument now shows that each generation must have exactly the same number of frequencies.

At present it is not at all clear that such a Λ even exists for any given N . But assuming this for the moment, we can simplify (2.12). It now becomes

$$\begin{aligned}
 -i\partial_t r_n(t) = & -|r_n(t)|^2 r_n(t) + 2r_{n_{\text{child}-1}}(t)r_{n_{\text{child}-2}}(t)\overline{r_{n_{\text{spouse}}}(t)} \\
 & + 2r_{n_{\text{parent}-1}}(t)r_{n_{\text{parent}-2}}(t)\overline{r_{n_{\text{sibling}}}(t)}
 \end{aligned} \tag{2.14}$$

where for each $n \in \Lambda_j$, $n_{\text{spouse}} \in \Lambda_j$ is its spouse, $n_{\text{child}-1}, n_{\text{child}-2} \in \Lambda_{j+1}$ are its two children, $n_{\text{sibling}} \in \Lambda_j$ is its sibling, and $n_{\text{parent}-1}, n_{\text{parent}-2} \in \Lambda_{j-1}$ are its parents. If n is in the last generation Λ_N then we omit the term involving spouse and children; if n is in the first generation Λ_1 we omit the term involving siblings and parents. The factor “2” arises from the trivial permutations of nuclear families.

We now simplify this ODE by making yet another assumption, this time again involving the initial data:

- (Property VII $_{\Lambda}$: Intragenerational equality) The function $n \mapsto r_n(0)$ is constant on each generation Λ_j . Thus $1 \leq j \leq N$ and $n, n' \in \Lambda_j$ imply $r_n(0) = r_{n'}(0)$.

It is easy to verify by another Gronwall argument that if one has intragenerational equality at time 0 then one has intragenerational equality at all later times. This is basically because the frequencies from each generation interact with that generation and with its adjacent generations in exactly the same way (regardless of what the combinatorics of sibling, spouse, children, and parents are). Thus we may collapse the function $n \mapsto r_n(t)$, which is currently a function on $\Lambda = \Lambda_1 \cup \dots \cup \Lambda_N$, to the function $j \mapsto b_j(t)$ on $\{1, \dots, N\}$, where $b_j(t) := r_n(t)$ whenever $n \in \Lambda_j$. Thus we describe the evolution by using a single complex scalar for each generation. The ODE (2.14) now collapses to the following system that we call the *Toy Model System*

$$-i\partial_t b_j(t) = -|b_j(t)|^2 b_j(t) + 2b_{j-1}(t)^2 \overline{b_j(t)} + 2b_{j+1}(t)^2 \overline{b_j(t)}, \tag{2.15}$$

with the convention⁸ that $b_0(t) = b_{N+1}(t) = 0$.

There are three main ingredients in the proof of Theorem 1.1. The first ingredient is the construction of the finite set Λ of frequencies. The second

⁸We show rigorously later that the support of $b(t)$ is constant in time—so that b_0, b_{N+1} will vanish as a consequence of our choice of initial data. In other words, $b_0(t)$ and $b_{N+1}(t)$ remain zero for all time because of the dynamics induced by the resonant system, and not by a possibly artificial convention introduced alongside these new variables.

ingredient is the proof that the Toy Model System described above exhibits a particular instability: we show that there exist solutions of the Toy Model which thread through small neighborhoods of an arbitrary number of distinct invariant tori. More specifically, we show that we have a “multi-hop” solution to this ODE in which the mass is initially concentrated at b_3 but eventually ends up at b_{N-2} . In terms of the resonant system (2.12), this instability corresponds to the growth of higher Sobolev norms. The third ingredient is an Approximation Lemma which gives conditions under which solutions of \mathcal{RFNLS} (2.12), and hence solutions corresponding to the Toy Model System, approximate an actual solution of the original NLS equation. When the conditions of this Approximation Lemma are satisfied, it is enough to construct a solution evolving according to the Toy Model which exhibits the desired growth in H^s . A scaling argument shows that these conditions can indeed be satisfied, and glues the three ingredients together to complete the proof. We now detail the claims of the three ingredients and prove Theorem 1.1 modulo these intermediate claims.

2.3 First ingredient: the frequency set Λ

The approximation to (2.7) that we ultimately study is the time evolution of very particular data under the equation with the nonresonant part of the nonlinearity removed. The very particular initial data $u(0)$ that we construct has Fourier support on a set $\Lambda \subset \mathbb{Z}^2$ which satisfies one more important condition in addition to those described above.

The construction of this frequency set Λ is carried out in detail in Sect. 4. Here we record the precise claim we make about the set.

Proposition 2.1 (First Ingredient: the frequency set Λ) *Given parameters $\delta \ll 1$, $K \gg 1$, we can find an $N \gg 1$ and a set of frequencies $\Lambda \subset \mathbb{Z}^2$ with,*

$$\Lambda = \Lambda_1 \cup \Lambda_2 \cup \cdots \cup \Lambda_N \quad \text{disjoint union}$$

which satisfies Property II_Λ —Property VI_Λ ⁹ and also,

$$\frac{\sum_{n \in \Lambda_N} |n|^{2s}}{\sum_{n \in \Lambda_1} |n|^{2s}} \gtrsim \frac{K^2}{\delta^2}. \quad (2.16)$$

In addition, given any $\mathcal{R} \gg C(K, \delta)$, we can ensure that Λ consists of $N \cdot 2^{N-1}$ disjoint frequencies n satisfying $|n| \geq \mathcal{R}$.

⁹Note that Property I_Λ , Property VII_Λ will be easily satisfied when we choose our initial data.

We will use the term *generations* to describe the sets Λ_j that make up Λ . The *norm explosion* condition (2.16) describes how in a sense, generation Λ_N has moved very far away from the frequency origin compared to generation Λ_1 . We will use the term *inner radius* to denote the parameter \mathcal{R} which we are free to choose as large as we wish. The norm explosion property (2.16) is ultimately responsible, as the name suggests, for the quantity $\|u(t)\|_{H^s(\mathbb{T}^2)}$ growing by a factor of $\frac{K}{\delta}$. The inner radius parameter \mathcal{R} plays the role of a scalar which multiplies the frequencies that populate Λ , and will be chosen large enough to ensure $\|u(0)\|_{H^s(\mathbb{T}^2)}$ starts with size δ , and not something much smaller. The argument is detailed in Sect. 2.6 below.

2.4 Second ingredient: instability in the toy model

The second main component of the proof is, in comparison with the first one, considerably more difficult to prove. Our claim is that we can construct initial data for the Toy Model System (2.15) so that at time zero, $b(0)$ is concentrated in its third component b_3 and this concentration then propagates from b_3 to b_4 , then to b_5 etc. until at some later time the solution is concentrated at¹⁰ b_{N-2} . We will measure the extent to which the solution is concentrated with a parameter ϵ . More precisely,

Proposition 2.2 (Second ingredient: instability in the toy model) *Given $N > 1, \epsilon \ll 1$, there is initial data $b(0) = (b_1(0), b_2(0), \dots, b_N(0)) \in \mathbb{C}^N$ for (2.15) and there is a time $T = T(N, \epsilon)$ so that*

$$\begin{aligned} |b_3(0)| &\geq 1 - \epsilon, & |b_j(0)| &\leq \epsilon, & j &\neq 3, \\ |b_{N-2}(T)| &\geq 1 - \epsilon, & |b_j(T)| &\leq \epsilon, & j &\neq N - 2. \end{aligned}$$

In addition, the corresponding solution satisfies $\|b(t)\|_{l^\infty} \sim 1$ for all $0 \leq t \leq T$.

This proposition will be recast in a slightly different language in Sect. 3 as Theorem 3.1.

2.5 Third ingredient: the approximation lemma

This ingredient concerns the extent to which we can approximate the system of ODE's corresponding to the full NLS equation (2.7) by other systems of ODE's. The approximate system we will ultimately study is that coming from

¹⁰One could in fact construct solutions that diffuse all the way from b_1 to b_N by a simple modification of the argument, but to avoid some (very minor) technical issues we shall only go from b_3 to b_{N-2} .

removing the non-resonant part of the Fourier transform of the equation's cubic nonlinearity (i.e. (2.12)). Here we write the approximation lemma in a more general form.

Lemma 2.3 (Third ingredient: approximation lemma) *Let $0 < \sigma < 1$ be an absolute constant (all implicit constants in this lemma may depend on σ). Let $B \gg 1$, and let $T \ll B^2 \log B$. Let*

$$g(t) := \{g_n(t)\}_{n \in \mathbb{Z}^2}$$

be a solution to the equation

$$-i \partial_t g(t) = (\mathcal{N}(t)(g(t), g(t), g(t))) + \mathcal{E}(t) \quad (2.17)$$

for times $0 \leq t \leq T$, where $\mathcal{N}(t)$ is defined in (2.9), (2.5) and where the initial data $g(0)$ is compactly supported. Assume also that the solution $g(t)$ and the error term $\mathcal{E}(t)$ obey the bounds of the form

$$\|g(t)\|_{l^1(\mathbb{Z}^2)} \lesssim B^{-1}, \quad (2.18)$$

$$\left\| \int_0^t \mathcal{E}(s) ds \right\|_{l^1(\mathbb{Z}^2)} \lesssim B^{-1-\sigma} \quad (2.19)$$

for all $0 \leq t \leq T$.

We conclude that if $a(t)$ denotes the solution to $\mathcal{F}NLS$ (2.7) with initial data $a(0) = g(0)$, then we have

$$\|a(t) - g(t)\|_{l^1(\mathbb{Z}^2)} \lesssim B^{-1-\sigma/2} \quad (2.20)$$

for all $0 \leq t \leq T$.

Proof First note that since $a(0) = g(0)$ is assumed to be compactly supported, the solution $a(t)$ to (2.7) exists globally in time, is smooth with respect to time, and is in $l^1(\mathbb{Z}^2)$ in space.

Write

$$F(t) := -i \int_0^t \mathcal{E}(s) ds, \quad \text{and} \quad d(t) := g(t) + F(t).$$

Observe that

$$-i d_t = \mathcal{N}(d - F, d - F, d - F),$$

where we have suppressed the explicit t dependence for brevity. Observe that $g = O_{l^1}(B^{-1})$ and $F = O_{l^1}(B^{-1-\sigma})$, where we use $O_{l^1}(X)$ to denote any

quantity with an $l^1(\mathbb{Z}^2)$ norm of $O(X)$. In particular we have $d = O_{l^1}(B^{-1})$. By trilinearity and (2.10) we thus have

$$-id_t = \mathcal{N}(d, d, d) + O_{l^1}(B^{-3-\sigma}).$$

Now write $a := d + e$. Then we have

$$-i(d + e)_t = \mathcal{N}(d + e, d + e, d + e),$$

which when subtracted from the previous equation gives (after more trilinearity and (2.10))

$$ie_t = O_{l^1}(B^{-3-\sigma}) + O_{l^1}(B^{-2}\|e\|_1) + O_{l^1}(\|e\|_1^3),$$

and so by the differential form of Minkowski’s inequality, we have

$$\partial_t \|e\|_1 \lesssim B^{-3-\sigma} + B^{-2}\|e\|_1 + \|e\|_1^3.$$

If we assume temporarily (i.e. as a bootstrap assumption) that $\|e\|_1 = O(B^{-1})$ for all $t \in [0, T]$, then one can absorb the third term on the right-hand side in the second. Gronwall’s inequality then gives

$$\|e\|_1 \leq B^{-1-\sigma} \exp(CB^{-2}t)$$

for all $t \in [0, T]$. Since we have $T \ll B^2 \log B$, we thus have $\|e\|_1 \ll B^{-1-\sigma/2}$, and so we can remove the a priori hypothesis $\|e\|_1 = O(B^{-1})$ by continuity arguments, and conclude the proof. \square

Lemma 2.3 gives us an approximation on a time interval of approximate length $B^2 \log B$, a factor $\log B$ larger than the interval $[0, B^2]$ for which the solution is controlled by a straightforward local-in-time argument. The exponent $\sigma/2$ can be in fact replaced by any exponent between 0 and σ , but we choose $\sigma/2$ for concreteness.

2.6 The scaling argument and the proof of Theorem 1.1

Finally we present the relatively simple scaling argument that glues the three main components together to get Theorem 1.1.

Given δ, K , construct Λ as in Proposition 2.1. (This is done in Sect. 4 below.) Note that we are free to specify \mathcal{R} (which measures the inner radius of the frequencies involved in Λ) as large as we wish and this will be done shortly, with $\mathcal{R} = \mathcal{R}(\delta, K)$.

With the number $N = N(\delta, K)$ from the construction of Λ (recall N represents the number of generations in the set of frequencies), and a number $\epsilon = \epsilon(K, \delta)$ which we will specify shortly, we construct a traveling wave

solution $b(t)$ to the toy model concentrated at scale ϵ according to Proposition 2.2 above. This proposition also gives us a time $T_0 = T_0(K, \delta)$ at which the wave has traversed the N generations of frequencies. Note that the toy model has the following scaling,

$$b^{(\lambda)}(t) := \lambda^{-1} b\left(\frac{t}{\lambda^2}\right).$$

We choose the initial data for (1.1) by setting

$$a_n(0) = b_j^{(\lambda)}(0) \quad \text{for all } n \in \Lambda_j, \quad (2.21)$$

and $a_n(t) = 0$ when $n \notin \Lambda$. We specify first the scaling parameter λ and then the parameter \mathcal{R} according to the following considerations which we detail below after presenting them now in only the roughest form. The parameter λ is chosen large enough to ensure the Approximation Lemma 2.3 applies, with c_n the solution of the resonant system of O.D.E.'s (2.12) also evolving from the data (2.21), over the time interval $[0, \lambda^2 T_0]$ —which is the time the rescaled solution $b^{(\lambda)}$ takes to travel through all the generations in Λ . In other words, we want to apply the Approximation Lemma 2.3 with a parameter B chosen large enough so that,

$$B^2 \log B \gg \lambda^2 T_0. \quad (2.22)$$

With λ and B so chosen, we will be able to prove that $\|u(t)\|_{H^s(\mathbb{T}^2)}$ grows by a factor of $\frac{K}{\delta}$ on $[0, \lambda^2 T_0]$. We finally choose \mathcal{R} to ensure this quantity starts at size approximately δ , rather than a much smaller scale.

We detail now these general remarks. The aim is to apply Lemma 2.3 with $g(t) = \{g_n(t)\}_{n \in \mathbb{Z}^2}$ defined by,

$$g_n(t) = b_j^{(\lambda)}(t),$$

for $n \in \Lambda_j$, and $g_n(t) = 0$ when $n \notin \Lambda$. Hence, we set $\mathcal{E}(t)$ to be the non-resonant part of the nonlinearity on the right hand side of (2.7). That is,

$$\mathcal{E}(t) := - \sum_{[\Gamma(n) \setminus \Gamma_{res}(n)] \cap \Lambda^3} g_{n_1} \overline{g_{n_2}} g_{n_3} e^{i\omega_4 t} \quad (2.23)$$

where ω_4 is as in (2.5). (We include the set Λ in the description of the sum above to emphasize once more that the frequency support of $g(t)$ is always in this set.) We choose $B = C(N)\lambda$ and then show that for large enough λ the required conditions (2.18) and (2.19) hold true. Observe that (2.22) holds true with this choice for large enough λ . Note first that simply by considering its

support, the fact that $|\Lambda| = C(N)$, and the fact that $\|b(t)\|_{l^\infty} \sim 1$, we can be sure that, $\|b(t)\|_{l^1(\mathbb{Z})} \sim C(N)$ and therefore

$$\|b^{(\lambda)}(t)\|_{l^1(\mathbb{Z})}, \|g(t)\|_{l^1(\mathbb{Z}^2)} \leq \lambda^{-1}C(N). \tag{2.24}$$

Thus, (2.18) holds with the choice $B = C(N)\lambda$. For the second condition (2.19), we claim

$$\left\| \int_0^t \mathcal{E}(s) ds \right\|_{l^1} \lesssim C(N)(\lambda^{-3} + \lambda^{-5}T). \tag{2.25}$$

Note that this is sufficient with our choices $B = \lambda \cdot C(N)$ and $T = \lambda^2 T_0$. It remains only to show (2.25), but this follows quickly from an integration by parts argument as in the van der Corput lemma (see e.g. Chap. VIII in [76]). For convenience we carry out the argument explicitly: since ω_4 does not vanish in the set $\Gamma(n) \setminus \Gamma_{res}(n)$, we can replace $e^{i\omega_4 s}$ by $\frac{d}{ds} [\frac{e^{i\omega_4 s}}{i\omega_4}]$ and then integrate by parts. Three terms arise: the boundary terms at $s = 0, T$ and the integral term involving $\frac{d}{ds} [g_{n_1}(s)\overline{g_{n_2}}(s)g_{n_3}(s)]$. For the boundary terms, we use (2.24) to obtain an upper bound of $C(N)\lambda^{-3}$. For the integral term, the s derivative falls on one of the g factors. We replace this differentiated term using the equation to get an expression that is 5-linear in g and bounded by $C(N)\lambda^{-5}T$.

Once λ has been chosen as above, we choose \mathcal{R} sufficiently large so that the initial data $g(0) = a(0)$ has the right size:

$$\left(\sum_{n \in \Lambda} |g_n(0)|^2 |n|^{2s} \right)^{\frac{1}{2}} \sim \delta. \tag{2.26}$$

This is possible since the quantity on the left scales like λ^{-1} in λ , and \mathcal{R}^s in the parameter \mathcal{R} . (The issue here is that our choice of frequencies Λ only gives us a large factor (that is, $\frac{K}{\delta}$) by which the Sobolev norm of the solution will grow. If our data is much smaller than δ in size, the solution’s Sobolev norm will not grow to be larger than K .)

It remains to show that we can guarantee,

$$\left(\sum_{n \in \mathbb{Z}^2} |a_n(\lambda^2 T_0)|^2 |n|^{2s} \right)^{\frac{1}{2}} \geq K, \tag{2.27}$$

where $a(t)$ is the evolution of the data $c(0)$ under the full system (2.7). We do this by first establishing,

$$\left(\sum_{n \in \Lambda} |g_n(\lambda^2 T_0)|^2 |n|^{2s} \right)^{\frac{1}{2}} \gtrsim K, \tag{2.28}$$

and second that,

$$\sum_{n \in \Lambda} |g_n(\lambda^2 T_0) - a_n(\lambda^2 T_0)|^2 |n|^{2s} \lesssim 1. \quad (2.29)$$

As for (2.28), consider the ratio of this norm of the resonant evolution at time $\lambda^2 T_0$ to the same norm at time 0,

$$\begin{aligned} Q &:= \frac{\sum_{n \in \mathbb{Z}^2} |g_n(\lambda^2 T_0)|^2 |n|^{2s}}{\sum_{n \in \mathbb{Z}^2} |g_n(0)|^2 |n|^{2s}} \\ &= \frac{\sum_{i=1}^N \sum_{n \in \Lambda_i} |b_i^{(\lambda)}(\lambda^2 T_0)|^2 |n|^{2s}}{\sum_{i=1}^N \sum_{n \in \Lambda_i} |b_i^{(\lambda)}(0)|^2 |n|^{2s}}, \end{aligned}$$

since $g_n := 0$ when $n \notin \Lambda$. We use now the notation $S_j := \sum_{n \in \Lambda_j} |n|^{2s}$,

$$\begin{aligned} Q &= \frac{\sum_{i=1}^N |b_i^{(\lambda)}(\lambda^2 T_0)|^2 S_i}{\sum_{i=1}^N |b_i^{(\lambda)}(0)|^2 S_i} \\ &\gtrsim \frac{S_{N-2}(1-\epsilon)}{\epsilon S_1 + \epsilon S_2 + (1-\epsilon)S_3 + \epsilon S_4 + \cdots + \epsilon S_N} \\ &= \frac{S_{N-2}(1-\epsilon)}{S_{N-2} \cdot [\epsilon \frac{S_1}{S_{N-2}} + \epsilon \frac{S_2}{S_{N-2}} + (1-\epsilon) \frac{S_3}{S_{N-2}} + \epsilon \frac{S_4}{S_{N-2}} + \cdots + \epsilon + \epsilon \frac{S_{N-1}}{S_{N-2}} + \epsilon \frac{S_N}{S_{N-2}}]} \\ &= \frac{(1-\epsilon)}{(1-\epsilon) \frac{S_3}{S_{N-2}} + O(\epsilon)} \\ &\gtrsim \frac{K^2}{\delta^2}, \end{aligned}$$

where the last inequality is ensured by Proposition 2.1 and by choosing $\epsilon \lesssim C(N, K, \delta)$ sufficiently small.

As for the second inequality (2.29), using Approximation Lemma 2.3 we obtain that

$$\sum_{n \in \Lambda} |g_n(\lambda^2 T_0) - a_n(\lambda^2 T_0)|^2 |n|^{2s} \lesssim \lambda^{-2-2\sigma} \sum_{n \in \Lambda} |n|^{2s} \leq \frac{1}{2}, \quad (2.30)$$

by possibly increasing λ and \mathcal{R} , maintaining¹¹ (2.26). Together, the inequalities (2.30), (2.20) give us immediately (2.29).

¹¹If we set $C \gg 1$ some constant and scale λ and \mathcal{R} by C and $C^{\frac{1}{s}}$, respectively, then the right hand side of the first inequality in (2.30) scales as $C^{-2\sigma}$, while the left hand side of (2.26) remains unchanged.

3 Instability in the toy model

In this section we prove Proposition 2.2 above, which claims a particular sort of instability for the system which we call the Toy Model System,

$$\partial_t b_j = -i|b_j|^2 b_j + 2i\bar{b}_j(b_{j-1}^2 + b_{j+1}^2). \tag{3.1}$$

This system was derived in the discussion preceding equation (2.15) above. We write $b(t)$ for the vector $(b_j)_{j \in \mathbb{Z}}$ and begin with some general remarks about the system (3.1).

Note that (3.1) is globally well-posed in $l^2(\mathbb{Z})$. To see local well-posedness, observe that the system is of the form $\partial_t b = T(b, \bar{b}, b)$ where $T : l^2 \times l^2 \times l^2 \rightarrow l^2$ is a trilinear form which is bounded on l^2 . Local well-posedness then follows from the Picard existence theorem. The time of existence obtained by the Picard theorem depends on the l^2 norm of b , but one quickly observes that this quantity is conserved. Indeed, we have

$$\begin{aligned} \partial_t |b_j|^2 &= 2 \operatorname{Re} \bar{b}_j \partial_t b_j \\ &= 4 \operatorname{Re} i \left[\bar{b}_j^2 b_{j-1}^2 + \bar{b}_j^2 b_{j+1}^2 \right] \\ &= 4 \operatorname{Im} (b_j^2 \bar{b}_{j-1}^2 - b_{j+1}^2 \bar{b}_j^2) \end{aligned} \tag{3.2}$$

and hence by telescoping series we obtain the mass conservation law $\partial_t \sum_j |b_j|^2 = 0$. Note that all these formal computations are justified if b is in l^2 , thanks to the inclusion $l^2(\mathbb{Z}) \subset l^4(\mathbb{Z})$.

Though our analysis won't use it explicitly, we note next that (3.1) also enjoys the conservation of the Hamiltonian

$$H(b) := \sum_j \frac{1}{4} |b_j|^4 - \operatorname{Re} (\bar{b}_j^2 b_{j-1}^2).$$

Indeed, if one rewrites $H(b)$ algebraically in terms of b and \bar{b} as

$$H(b) = \sum_j \frac{1}{4} b_j^2 \bar{b}_j^2 - \frac{1}{2} \bar{b}_j^2 b_{j-1}^2 - \frac{1}{2} b_j^2 \bar{b}_{j-1}^2$$

then we see from (3.1) that

$$\partial_t b = -2i \frac{\partial H}{\partial \bar{b}}; \quad \partial_t \bar{b} = 2i \frac{\partial H}{\partial b},$$

and thus

$$\partial_t H(b) = \partial_t b \cdot \frac{\partial H}{\partial b} + \partial_t \bar{b} \cdot \frac{\partial H}{\partial \bar{b}} = 0.$$

Again, it is easily verified that these formal computations can be justified in $l^2(\mathbb{Z})$.

The system (3.1) enjoys a number of symmetries. Firstly, there is phase invariance

$$b_j(t) \leftarrow e^{i\theta} b_j(t)$$

for any angle θ ; this symmetry corresponds to the l^2 conservation. There is also scaling symmetry

$$b_j(t) \leftarrow \lambda b(\lambda^2 t)$$

for any $\lambda > 0$, time translation symmetry

$$b_j(t) \leftarrow b_j(t - \tau)$$

for any $\tau \in \mathbb{R}$ (corresponding to Hamiltonian conservation, of course), and space translation symmetry

$$b_j(t) \leftarrow b_{j-j_0}(t)$$

for any $j_0 \in \mathbb{Z}$. Finally, there is time reversal symmetry

$$b_j(t) \leftarrow \overline{b_j}(-t)$$

and space reflection symmetry

$$b_j(t) \leftarrow b_{-j}(t).$$

There is also a sign symmetry

$$b_j(t) \leftarrow \epsilon_j b_j(t)$$

where for each j , $\epsilon_j = \pm 1$ is an arbitrary sign.

Next we show that the infinite system (3.1) evolving from l^2 data reduces to a finite system if the data is supported on only a finite number of modes b_i . Indeed (3.2) gives the crude differential inequality

$$\begin{aligned} \partial_t |b_j|^2 &= 2 \operatorname{Re}(\overline{b_j} \partial_t b_j) \\ &= 4 \operatorname{Re}(i \overline{b_j}^2 (b_{j-1}^2 + b_{j+1}^2)) \\ &\leq 4 |b_j|^2 \end{aligned}$$

for any $j \in \mathbb{Z}$. From Gronwall's inequality we conclude first that if b is an $l^2(\mathbb{Z})$ solution to (3.1), then the support of b is nonincreasing in time, i.e. if $b(t_0)$ is supported on $I \subseteq \mathbb{Z}$ at some time $t_0 \in \mathbb{R}$, then $b(t)$ is supported in I

for all time. The time reversal symmetry allows us to conclude that in fact the support of b is constant in time.

In particular, if I is finite, then (3.1) collapses to a finite-dimensional ODE, which is obtained from (3.1) by setting $b_j = 0$ for all $j \notin I$.

We conclude our general remarks here on the dynamics of (3.1) by observing how this evolution, and the assumptions on Λ that went into its derivation, account for the necessary balance in mass at high and low frequencies dictated by the conservation laws (1.2) and (1.3). As discussed immediately following Theorem 1.1, this balance—i.e. the presence of both a forward and inverse cascade of mass—is an important complication to constructing any solutions to (1.1) that carry energy at higher and higher frequencies. Recall that the Toy Model comes from imposing a host of assumptions on the initial data for the resonant truncation system (2.12), which also has conserved mass, energy, and momentum. Under the assumptions that led to the Toy Model System, the conserved mass becomes essentially¹²

$$\sum_j |b_j(t)|^2, \tag{3.3}$$

the conserved momentum essentially becomes

$$\sum_j |b_j(t)|^2 \left(\sum_{n \in \Lambda_j} n \right), \tag{3.4}$$

and the conserved energy now becomes

$$\begin{aligned} & \frac{1}{2} \sum_j |b_j(t)|^2 \left(\sum_{n \in \Lambda_j} |n|^2 \right) + \frac{1}{2} \left[\sum_j |b_j(t)|^2 |\Lambda_j| \right]^2 - \frac{1}{4} \sum_j |b_j(t)|^4 |\Lambda_j| \\ & + \sum_j \operatorname{Re} b_j(t)^2 \overline{b_{j+1}(t)}^2. \end{aligned} \tag{3.5}$$

It looks like these three quantities are quite different. However, one observes the identities

$$\sum_{n \in \Lambda_j} n = \sum_{n \in \Lambda_{j+1}} n$$

and

$$\sum_{n \in \Lambda_j} |n|^2 = \sum_{n \in \Lambda_{j+1}} |n|^2$$

¹²We are systematically ignoring a harmless multiplicative constant.

for all $1 \leq j < N$. This simply reflects the fact that in any nuclear family (n_1, n_2, n_3, n_4) , one has $n_1 + n_3 = n_2 + n_4$ and $|n_1|^2 + |n_3|^2 = |n_2|^2 + |n_4|^2$. Thus the conservation of momentum follows trivially from the conservation of mass, and the conservation of energy is now equivalent to the conservation of the Hamiltonian $H(b)$ introduced earlier.

We turn now to the more specific, unstable behavior in (3.1) which we aim to demonstrate. Let $N \geq 1$ be a fixed integer and let $\Sigma \subset \mathbb{C}^N$ be the unit-mass sphere

$$\Sigma := \{x \in \mathbb{C}^N : |x|^2 = 1\}.$$

Assigning initial data $b(t_0)$ with $b_j(t_0) = 0$ for $j \leq 0, j > N$, (3.1) generates a group $S(t) : \Sigma \rightarrow \Sigma$ of smooth flows on the smooth $2N - 1$ -dimensional compact manifold Σ , defined by $S(t)b(t_0) := b(t + t_0)$. We shall refer to elements x of Σ as *points*.

Define the circles $\mathbb{T}_1, \dots, \mathbb{T}_N$ by

$$\mathbb{T}_j := \{(b_1, \dots, b_N) \in \Sigma : |b_j| = 1; b_k = 0 \text{ for all } k \neq j\}$$

then it is easy to see from the above arguments that the flows $S(t)$ leave each of the circles \mathbb{T}_j invariant: $S(t)\mathbb{T}_j = \mathbb{T}_j$. Indeed for each j we have the following explicit oscillator solutions to (3.1) that traverse the circle \mathbb{T}_j :

$$b_j(t) := e^{-i(t+\theta)}; \quad b_k(t) := 0 \quad \text{for all } k \neq j. \quad (3.6)$$

Here θ is an arbitrary phase.

The main result in this section is that there are orbits connecting arbitrarily small neighborhoods of any two of these circles, for instance between the third¹³ circle \mathbb{T}_3 and the third-to-last circle \mathbb{T}_{N-2} .

Theorem 3.1 (Instability for (3.1)) *Let $N \geq 6$. Given any $\varepsilon > 0$, there exists a point x_3 within ε of \mathbb{T}_3 (using the usual metric on Σ), a point x_{N-2} within ε of \mathbb{T}_{N-2} , and a time¹⁴ $t \geq 0$ such that $S(t)x_3 = x_{N-2}$.*

To state this result more informally, there exist solutions to (3.1) of total mass 1 which are arbitrarily concentrated at the mode $j = 3$ at some time, and then arbitrarily concentrated at the mode $j = N - 2$ at a later time.

¹³As mentioned previously, one could in fact construct an orbit travelling all the way from \mathbb{T}_1 to \mathbb{T}_N by a simple modification of the argument, but to avoid some (very minor) notational issues near the endpoints we shall only go from \mathbb{T}_3 to \mathbb{T}_{N-2} .

¹⁴We shall only flow forwards in time here. However, the time reversal symmetry $b_j(t) \mapsto \overline{b_j(-t)}$ (or the spatial reflection symmetry $b_j(t) \mapsto b_{N+1-j}(t)$) allows one to obtain analogues of all these results when one evolves backwards in time. Of course, when doing so, the stable and unstable modes that we describe below shall exchange roles.

Fig. 1 Explicit oscillator solution around \mathbb{T}_1 and the slider solution from \mathbb{T}_1 to \mathbb{T}_2

To motivate the theorem let us first observe that when $N = 2$ we can easily demonstrate an orbit connecting \mathbb{T}_1 to \mathbb{T}_2 . Indeed in this case we have the explicit “slider” solution

$$b_1(t) := \frac{e^{-it}\omega}{\sqrt{1 + e^{2\sqrt{3}t}}}; \quad b_2(t) := \frac{e^{-it}\omega^2}{\sqrt{1 + e^{-2\sqrt{3}t}}} \tag{3.7}$$

where $\omega := e^{2\pi i/3}$ is a cube root of unity. This solution approaches \mathbb{T}_1 exponentially fast as $t \rightarrow -\infty$, and approaches \mathbb{T}_2 exponentially fast as $t \rightarrow +\infty$. One can translate this solution in the j parameter, and obtain solutions that “slide” from \mathbb{T}_j to \mathbb{T}_{j+1} (or back from \mathbb{T}_{j+1} to \mathbb{T}_j , if we reverse time or apply a spatial reflection). This for instance validates the $N = 6$ case of Theorem 3.1. Intuitively, the proof of Theorem 3.1 for higher N should then proceed by concatenating these slider solutions. Of course, this does not work directly, because each solution requires an infinite amount of time to connect one circle to the next, but it turns out that a suitably perturbed or “fuzzy” version of these slider solutions can in fact be glued together.

3.1 General notation

We shall use the usual $O()$ notation, but allow the constants in that notation to depend on N . Hence $X = O(Y)$ denotes $X \leq CY$ for some constant C that depends on N , but is otherwise universal. We use $X \lesssim Y$ as a synonym for $X = O(Y)$.

We will also use *schematic notation*, so that an expression such as $\mathcal{O}(fgh)$ will mean some linear combination of quantities which resemble fgh up to the presence of constants and complex conjugation of the terms. Thus for instance $3f\bar{g}h + 2fgh - ifgh$ qualifies to be of the form $\mathcal{O}(fgh)$, and $|b|^2b$ qualifies to be of the form $\mathcal{O}(b^3)$. We will extend this notation to the case when f, g, h are vector-valued, and allow the linear combination to depend on N . Thus for instance if $c = (c_1, \dots, c_N)$ then $\sum_{j=1}^{N-1} c_j \overline{c_{j+1}}$ would qualify to be of the form $\mathcal{O}(c^2)$.

3.2 Abstract overview of argument

Off the expressway, over the river, off the billboard, through the window, off the wall, nothin' but net. Michael Jordan [49]

To prove Theorem 3.1, one has to engineer initial conditions near \mathbb{T}_3 that can “hit” the target \mathbb{T}_{N-2} (or more precisely a small neighborhood of \mathbb{T}_{N-2}) after some long period of time. This is difficult to do directly. Instead, what we shall do is create a number of intermediate “targets” between \mathbb{T}_3 and \mathbb{T}_{N-2} , and show that in a certain sense one can hit any point on each target (to some specified accuracy) by some point on the previous target (allowing for some specified uncertainty in one’s “aim”). These intermediate trajectories can then be chained together to achieve the original goal. The basic difficulty here comes from the fact that we are working with flows in high dimensions, so there are many secular modes which have the ability to knock a candidate orbit not only away from the stable manifold T_j , but also away from its immediate target (for example, the next \mathbb{T}_j in the chain). The only way to prevent such an occurrence is to keep the secular modes reasonably small (e.g. exponentially small) in size. However, the only way to keep these secular modes small is to keep all other modes small as well, and so we’re led to the large menu of estimates that this section of the paper considers. To describe the strategy more precisely, it is useful to set up some abstract notation.

Definition 3.1 (Targets) A *target* is a triple (M, d, R) , where M is a subset of Σ , d is a semi-metric¹⁵ on Σ , and $R > 0$ is a radius. We say that a point $x \in \Sigma$ is *within* a target (M, d, R) if we have $d(x, y) < R$ for some $y \in M$. Given two points $x, y \in \Sigma$, we say that x *hits* y , and write $x \mapsto y$, if we have $y = S(t)x$ for some $t \geq 0$. Given an initial target (M_1, d_1, R_1) and a final target (M_2, d_2, R_2) , we say that (M_1, d_1, R_1) *can cover* (M_2, d_2, R_2) , and write $(M_1, d_1, R_1) \rightarrow (M_2, d_2, R_2)$, if for every $x_2 \in M_2$ there exists an $x_1 \in M_1$, such that for any point $y_1 \in \Sigma$ with $d(x_1, y_1) < R_1$ there exists a point $y_2 \in \Sigma$ with $d_2(x_2, y_2) < R_2$ such that y_1 hits y_2 .

Remark 3.1 One could eliminate the radius parameter R here by replacing each target (M, d, R) with the equivalent target $(M, d/R, 1)$, but this seems to make the concept slightly less intuitive (it is like replacing all metric balls $B_d(x, R)$ with unit balls $B_{d/R}(x, 1)$ in a renormalized metric).

¹⁵A semi-metric is the same as a metric, except that $d(x, y)$ is allowed to degenerate to zero even when $x \neq y$. The reason we need to deal with semi-metrics is because of the phase symmetry $x \mapsto e^{i\theta}x$ on Σ ; one could quotient this out and then deal with nondegenerate metrics if desired.

Fig. 2 $M_1 \rightarrow M_2$. The shaded disk of radius r_1 around x_1 flows out to the shaded area near M_2 inside a disk of radius r_2 around x_2

Remark 3.2 The notion of covering may seem somewhat complicated (involving no less than five quantifiers!), but it can be summarized as follows. The assertion $(M_1, d_1, R_1) \rightarrow (M_2, d_2, R_2)$ is a guarantee that one can hit any point in the final target M_2 that one desires—within an accuracy of R_2 in the d_2 metric—by “aiming” at some well-chosen point in the initial target M_1 and then evolving by the flow, even if one’s “aim” is a little uncertain (by an uncertainty of R_1 in the d_1 metric). Thus the concept of covering is simultaneously a notion of surjectivity (that the flowout of M_1 contains M_2 in some approximate sense) and a notion of stability (that small perturbations of the initial state lead to small perturbations in the final state). See also Fig. 2.

Informally, one can think of a target (M, d, R) as a “fuzzy” set $\{x + O_d(R) : x \in M\}$, where $O_d(R)$ represents some “uncertainty” of extent R as measured in the semi-metric d . Thus, for instance, if we were working in \mathbb{R}^2 with the usual metric d , and M was a rectangle $\{(x_1, x_2) : |x_1| \leq r_1, |x_2| \leq r_2\}$ then one might describe the target (M, d, R) somewhat schematically as

$$\{(O(r_1) + O(R), O(r_2) + O(R))\}$$

where the first term in each coordinate represents the parameters of the set (basically, they describe the points that one can “aim” at), and the second term in each coordinate represents the uncertainty of the set (this describes the inevitable error that causes the actual location of the solution to deviate from the point that one intended to hit). This schematic notation may be somewhat confusing and we shall reserve it for informal discussions only.

One of the most important features of the covering concept for us is its transitivity.

Lemma 3.1 (Transitivity) *If $(M_1, d_1, R_1), (M_2, d_2, R_2), (M_3, d_3, R_3)$ are targets such that $(M_1, d_1, R_1) \rightarrow (M_2, d_2, R_2)$ and $(M_2, d_2, R_2) \rightarrow (M_3, d_3, R_3)$, then $(M_1, d_1, R_1) \rightarrow (M_3, d_3, R_3)$.*

Proof Let x_3 be any point in M_3 . Since $(M_2, d_2, R_2) \rightarrow (M_3, d_3, R_3)$, we can find $x_2 \in M_2$ such that for every y_2 with $d_2(x_2, y_2) < R_2$, there exists y_3 with $d_3(x_3, y_3) < R_3$ such that $y_2 \mapsto y_3$. Since $(M_1, d_1, R_1) \rightarrow (M_2, d_2, R_2)$, we can find an $x_1 \in M_1$ such that for every y_1 with $d_1(x_1, y_1) < R_1$, we

Fig. 3 $M_1 \rightarrow M_2$,
 $M_2 \rightarrow M_3$ imply $M_1 \rightarrow M_3$.
 The shaded disk of radius r_1 centered x_1 flows out onto the double shaded portion of the disk of radius r_2 centered at x_2 . The disk of radius r_2 centered at x_2 maps into the disk of radius r_3 near M_3

can find y_2 with $d_2(x_2, y_2) < R_2$ such that $y_1 \mapsto y_2$. Putting these two together, we thus see that for every y_1 with $d_1(x_1, y_1) < R_1$, we can find y_3 with $d_2(x_3, y_3) < R_3$ such that $y_1 \mapsto y_2 \mapsto y_3$, which by the group properties of the flow imply that $y_1 \mapsto y_3$, and the claim follows. \square

The reader is invited to see how the transitivity of the covering relation follows intuitively from the interpretation of the concept given in Remark 3.2. See also Fig. 3.

We can now outline the idea of the proof. For each $j = 3, \dots, N - 2$, we will define three targets which lie fairly close to \mathbb{T}_j , namely

- An incoming target (M_j^-, d_j^-, R_j^-) (located near the stable manifold of \mathbb{T}_j),
- A ricochet target (M_j^0, d_j^0, R_j^0) (located very near \mathbb{T}_j itself), and
- An outgoing target (M_j^+, d_j^+, R_j^+) (located near the unstable manifold of \mathbb{T}_j).

We will then prove the covering relations

$$(M_j^-, d_j^-, R_j^-) \rightarrow (M_j^0, d_j^0, R_j^0) \quad \text{for all } 3 < j \leq N - 2, \tag{3.8}$$

$$(M_j^0, d_j^0, R_j^0) \rightarrow (M_j^+, d_j^+, R_j^+) \quad \text{for all } 3 \leq j < N - 2, \tag{3.9}$$

$$(M_j^+, d_j^+, R_j^+) \rightarrow (M_{j+1}^-, d_{j+1}^-, R_{j+1}^-) \quad \text{for all } 3 \leq j < N - 2 \tag{3.10}$$

which by many applications of Lemma 3.1 implies covering relation

$$(M_3^0, d_3^0, R_3^0) \rightarrow (M_{N-2}^0, d_{N-2}^0, R_{N-2}^0). \tag{3.11}$$

As we shall construct (M_3^0, d_3^0, R_3^0) to be close to \mathbb{T}_3 and $(M_{N-2}^0, d_{N-2}^0, R_{N-2}^0)$ to be close to \mathbb{T}_{N-2} , Theorem 3.1 will follow very quickly¹⁶ from (3.11).

¹⁶Readers familiar with the original paper of Arnold [2] will see strong parallels here; the notion of one set “obstructing” another in that paper is analogous to the notion of “covering” here, the targets (M_j^-, d_j^-, R_j^-) are analogous to “incoming whiskers” for the torus \mathbb{T}_j , and the targets (M_j^+, d_j^+, R_j^+) are “outgoing whiskers”. Unfortunately, it seems that we cannot

Our exposition is structured as follows. In Sect. 3.4, we shall define the targets (M_j^-, d_j^-, R_j^-) , (M_j^0, d_j^0, R_j^0) , (M_j^+, d_j^+, R_j^+) , after construction of some useful local coordinates near each circle \mathbb{T}_j in Sect. 3.3, and then in Sect. 3.5 see why (3.11) implies Theorem 3.1. In Sect. 3.6, we establish the incoming covering estimate (3.8), and in Sect. 3.8 we establish the (very similar) outgoing covering estimate. Finally in Sect. 3.10 we establish the (comparatively easy) transitory covering estimate (3.10) and hence (3.11).

3.3 Local coordinates near \mathbb{T}_j

Fix $3 \leq j \leq N - 2$. In this section we shall devise a useful local coordinate system around the circle \mathbb{T}_j that will clarify the dynamics near that circle, and will motivate the choice of targets (M_j^-, d_j^-, R_j^-) , (M_j^0, d_j^0, R_j^0) , (M_j^+, d_j^+, R_j^+) involved.

We will assume here that $b_j \neq 0$; as mentioned in the introduction, this constraint is preserved by the flow. We shall refer to the b_j mode as the *primary mode*, the mode b_{j-1} as the *trailing secondary mode*, the mode b_{j+1} as the *leading secondary mode*, the modes b_1, \dots, b_{j-2} as the *trailing peripheral modes*, and the modes b_{j+2}, \dots, b_N as the *leading peripheral modes*. In the vicinity of the circle \mathbb{T}_j , it is the primary mode that will have by far the most mass and will thus dominate the evolution. From (3.1) we see that the secondary modes will be linearly forced by the primary mode. The peripheral modes will only be influenced by the primary mode indirectly (via its influence on the secondary modes) and their evolution will essentially be trivial. At this stage there is a symmetry between the leading and trailing modes, but later on we shall break this symmetry when trying to construct a solution that evolves from the 3 mode to the $N - 3$ mode (requiring one to be far more careful with the leading modes than the trailing ones).

Bearing in mind the phase rotation symmetry $x \mapsto xe^{i\theta}$ we shall select the ansatz

$$b_j = r e^{i\theta}; \quad b_k = c_k e^{i\theta} \quad \text{for } k \neq j \tag{3.12}$$

where r, θ are real and the c_k are allowed to be complex (again we assume $b_j \neq 0$). In other words, we are conjugating the secondary and peripheral modes by the phase of the primary mode. Substituting these equations into (3.1) gives

$$\begin{aligned} \partial_t c_{j\pm 1} + i c_{j\pm 1} \partial_t \theta &= -i |c_{j\pm 1}|^2 c_{j\pm 1} + 2ir^2 \overline{c_{j\pm 1}} + 2i c_{j\pm 2}^2 \overline{c_{j\pm 1}} \\ \text{for } \pm 1 &= +1, -1, \end{aligned} \tag{3.13}$$

use the machinery from [2] directly, mainly because our invariant manifolds have too small a dimension and so do not have the strong “transversality” properties required in [2]. This requires a certain “thickening” of these sets using the above machinery of covering of targets.

$$\partial_t \theta = -r^2 + 2 \operatorname{Re}(c_{j-1}^2 + c_{j+1}^2), \quad (3.14)$$

$$\partial_t c_k + i c_k \partial_t \theta = -i |c_k|^2 c_k + 2i \overline{c_k} (c_{k-1}^2 + c_{k+1}^2) \quad \text{for } |j - k| \geq 2. \quad (3.15)$$

We have not stated the equation for r (the magnitude of the primary mode) explicitly, since on Σ one can recover r from the other coordinates by the conservation of mass which gives the formula

$$r^2 = 1 - \sum_{k \neq j} |c_k|^2. \quad (3.16)$$

In particular we have the crude estimates

$$r^2 = 1 - \mathcal{O}(c^2); \quad \partial_t \theta = -1 + \mathcal{O}(c^2)$$

where we use *schematic notation*, thus $\mathcal{O}(c^2)$ denotes any quadratic combination of the c_k and their conjugates. We can substitute this into (3.15) to obtain an equation for the evolution of the peripheral modes

$$\partial_t c_k = i c_k + \mathcal{O}(c_k c^2). \quad (3.17)$$

Now we turn to the secondary modes (3.13). Fix a sign \pm . From (3.16), (3.14) we have

$$\begin{aligned} r^2 &= 1 - |c_{j\pm 1}|^2 - \mathcal{O}(c_{\neq j\pm 1}^2); \\ \partial_t \theta &= -1 + |c_{j\pm 1}|^2 + 2 \operatorname{Re}(c_{j\pm 1}^2) + \mathcal{O}(c_{\neq j\pm 1}^2) \end{aligned}$$

where we write $c_{\neq j+1} := (c_1, \dots, c_{j-1}, c_{j+2}, \dots, c_N)$ and $c_{\neq j-1} := (c_1, \dots, c_{j-2}, c_{j+1}, \dots, c_N)$. Substituting this into (3.13) we have

$$\begin{aligned} \partial_t c_{j\pm 1} &= i c_{j\pm 1} + 2i \overline{c_{j\pm 1}} - 2i |c_{j\pm 1}|^2 c_{j\pm 1} - 2i \operatorname{Re}(c_{j\pm 1}^2) c_{j\pm 1} \\ &\quad - 2i |c_{j\pm 1}|^2 \overline{c_{j\pm 1}} + \mathcal{O}(c_{j\pm 1} c_{\neq j\pm 1}^2). \end{aligned}$$

It is then natural to diagonalize the linear component of this equation by introducing the coordinates

$$c_{j\pm 1} = \omega c_{j\pm 1}^- + \omega^2 c_{j\pm 1}^+, \quad (3.18)$$

where as in (3.7) $\omega := e^{2\pi i/3}$. One then computes

$$i c_{j\pm 1} + 2i \overline{c_{j\pm 1}} = -\sqrt{3} \omega c_{j\pm 1}^- + \sqrt{3} \omega^2 c_{j\pm 1}^+$$

and

$$\operatorname{Re}(c_{j\pm 1}^2) = -\frac{1}{2} |c_{j\pm 1}|^2 + \mathcal{O}(c_{j\pm 1}^- c_{j\pm 1}^+)$$

and thus

$$\begin{aligned} \partial_t c_{j\pm 1} &= (1 - |c_{j\pm 1}|^2)(-\sqrt{3}\omega c_{j\pm 1}^- + \sqrt{3}\omega^2 c_{j\pm 1}^+) + \mathcal{O}(c_{j\pm 1}^- c_{j\pm 1}^+) \\ &\quad + \mathcal{O}(c_{j\pm 1} c_{\neq j\pm 1}^2). \end{aligned} \tag{3.19}$$

Taking components, we conclude

Proposition 3.1 (Local coordinates near \mathbb{T}_j) *Let $3 \leq j \leq N - 2$, and let $b(t)$ be a solution to (3.1) with $b_j(t) \neq 0$. Define the coordinates r, θ (primary mode), $c_{j\pm 1}^-, c_{j\pm 1}^+$ (secondary modes), and $c_* := (c_1, \dots, c_{j-2}, c_{j+2}, \dots, c_N)$ (peripheral modes) by (3.12), (3.18). Then we have the system of equations*

$$\partial_t c_{j\pm 1}^- = -\sqrt{3}c_{j\pm 1}^- + \mathcal{O}(c^2 c_{j\pm 1}^-) + \mathcal{O}(c_{j\pm 1}^+ c_{\neq j\pm 1}^2), \tag{3.20}$$

$$\partial_t c_{j\pm 1}^+ = \sqrt{3}c_{j\pm 1}^+ + \mathcal{O}(c^2 c_{j\pm 1}^+) + \mathcal{O}(c_{j\pm 1}^- c_{\neq j\pm 1}^2), \tag{3.21}$$

$$\partial_t c_* = ic_* + \mathcal{O}(c^2 c_*). \tag{3.22}$$

Also, the constraint $b_j(t) \neq 0$ is equivalent (via (3.16)) to the condition

$$|c| < 1. \tag{3.23}$$

Remark 3.3 Note the total disappearance of the primary mode coordinates r, θ . From a symplectic geometry viewpoint, we have effectively taken the *symplectic quotient* of the state space with respect to the rotation symmetry $x \mapsto e^{i\theta} x$. The elimination of these (very large) coordinates is conducive to analyzing the evolution of the (much smaller) secondary and peripheral modes accurately.

When one is near the torus \mathbb{T}_j (which in these coordinates is just the origin $c = 0$), we expect the cubic terms $\mathcal{O}(c^3)$ in the above proposition to be negligible. From (3.20), (3.21), (3.22) we conclude in this regime that the two real-valued modes $c_{j\pm 1}^-$ are linearly stable, the two real-valued modes $c_{j\pm 1}^+$ are linearly unstable (growing like $e^{\sqrt{3}t}$), and the remaining modes c_* are oscillatory (behaving like e^{it}). Observe also that most of the nonlinear interaction on these modes resembles a diagonal linear potential of magnitude $\mathcal{O}(c^2)$, indicating that the coupling between these modes is relatively weak (especially when $\mathcal{O}(c^2)$ is small); however there are some troublesome interactions arising from the final terms in the right-hand sides of (3.20), (3.21) that allow the stable modes to influence the unstable modes and vice versa (via coupling with other modes). This causes a certain amount of mixing in the evolution which will require some care to handle, and is directly responsible for the rather inelegant appearance of polynomial factors of T (in addition to the more natural exponential factors) in the analysis of later sections.

For the purpose of obtaining upper bounds for the magnitude of the various modes, the following useful lemma captures the stable nature of the $c_{j\pm 1}^-$, the unstable nature of the $c_{j\pm 1}^+$, and the oscillatory nature of the c_* , provided that the solution stays close to the circle \mathbb{T}_j (which corresponds in these coordinates to $c = 0$) in a certain L^2 sense.

Lemma 3.2 (Upper bounds) *Suppose that $[0, t]$ is a time interval on which we have the smallness condition*

$$\int_0^t |c(s)|^2 ds \lesssim 1. \quad (3.24)$$

Then we have the estimates

$$|c_{j\pm 1}^-(t)| \lesssim e^{-\sqrt{3}t} |c_{j\pm 1}^-(0)| + \int_0^t e^{-\sqrt{3}(t-s)} |c_{j\pm 1}^+(s)| |c_{\neq j\pm 1}^2(s)| ds, \quad (3.25)$$

$$|c_{j\pm 1}^+(t)| \lesssim e^{\sqrt{3}t} |c_{j\pm 1}^+(0)| + \int_0^t e^{\sqrt{3}(t-s)} |c_{j\pm 1}^-(s)| |c_{\neq j\pm 1}^2(s)|^2 ds, \quad (3.26)$$

$$|c_{j\pm 1}(t)| \lesssim e^{\sqrt{3}t} |c_{j\pm 1}(0)|, \quad (3.27)$$

$$|c_*(t)| \lesssim |c_*(0)|. \quad (3.28)$$

Proof We take absolute values in (3.20), (3.21), (3.22) and obtain the differential inequalities¹⁷

$$\begin{aligned} \partial_t |e^{\sqrt{3}t} c_{j\pm 1}^-| &\lesssim |c|^2 |e^{\sqrt{3}t} c_{j\pm 1}^-| + e^{\sqrt{3}t} |c_{j\pm 1}^+| |c_{\neq j\pm 1}|^2, \\ \partial_t |e^{-\sqrt{3}t} c_{j\pm 1}^+| &\lesssim |c|^2 |e^{-\sqrt{3}t} c_{j\pm 1}^+| + e^{-\sqrt{3}t} |c_{j\pm 1}^-| |c_{\neq j\pm 1}|^2, \\ \partial_t |c_*| &\lesssim |c|^2 |c_*|. \end{aligned}$$

The claims (3.25), (3.26), (3.28) now follow from Gronwall's inequality. To obtain (3.27), we take absolute values of (3.20), (3.21) and sum to obtain

$$\partial_t (|c_{j\pm 1}^-| + |c_{j\pm 1}^+|) \leq (\sqrt{3} + O(|c|^2)) (|c_{j\pm 1}^-| + |c_{j\pm 1}^+|)$$

and the claim now follows from Gronwall's inequality again. \square

¹⁷As the quantity being differentiated is only Lipschitz rather than smooth, these inequalities should be interpreted in the appropriate weak sense.

Remark 3.4 The slider solution (3.7), using the $j = 1$ coordinates, is simply $c_2^-(t) = 0, c_2^+(t) = (1 + e^{-2\sqrt{3}t})^{-1/2}$, thus escaping away from \mathbb{T}_1 using the unstable component of the 2-mode. Viewed instead in the $j = 2$ coordinates, it becomes $c_1^-(t) = (1 + e^{2\sqrt{3}t})^{-1/2}, c_1^+(t) = 0$, thus collapsing into \mathbb{T}_2 using the stable component of the 1-mode. We shall use this solution to transition from (M_j^+, d_j^+, R_j^+) to $(M_{j+1}^-, d_{j+1}^-, R_{j+1}^-)$.

3.4 Construction of the targets

Always be nice to people on the way up, because you'll meet the same people on the way down. (Wilson Mizner)

We now are ready to construct the targets $(M_j^-, d_j^-, R_j^-), (M_j^0, d_j^0, R_j^0), (M_j^+, d_j^+, R_j^+)$. As it turns out, these sets will lie close to \mathbb{T}_j (and thus away from the coordinate singularity at $b_j = 0$), and will therefore be represented using the modes $c_{j+1}^\pm, c_{j-1}^\pm, c_*$ from Proposition 3.1. (The modes r, θ are also present but will have no impact on our computations.) Broadly speaking, these targets will demand a lot of control on the leading modes (in order to set up future “ricochets” off of subsequent tori $\mathbb{T}_{j+1}, \mathbb{T}_{j+2}$, etc.) but will be rather relaxed about the trailing modes (as they will become small and stay small for the remainder of the evolution).

We need a number of parameters. First, we need for technical reasons an increasing set of exponents

$$1 \ll A_3^0 \ll A_3^+ \ll A_4^- \ll \dots \ll A_{N-2}^- \ll A_{N-2}^0.$$

For sake of concreteness, we will take these to be consecutive powers of 10 (thus $A_3^0 = 10, A_3^+ = 10^2$, and so forth up to $A_{N-2}^0 = 10^{3N-14}$).

Next, we shall need a small parameter

$$0 < \sigma \ll 1$$

depending on N and the exponents A (actually one could take $\sigma = 1/100$ quite safely). This basically measures the distance to \mathbb{T}_j at which the local coordinates become effective, and the linear terms in Proposition 3.1 dominate the cubic terms.

For technical reasons, we shall need a set of scale parameters

$$1 \ll r_{N-2}^0 \ll r_{N-2}^- \ll r_{N-3}^+ \ll \dots \ll r_3^+ \ll r_3^0$$

where each parameter is assumed to be sufficiently large depending on the preceding parameters and on σ and the A 's; these parameters represent a

certain shrinking of each target from the previous one (in order to guarantee that each target can be covered by the previous).

Finally, we need a very large time parameter

$$T \gg 1$$

that we shall assume to be as large as necessary depending on all the previous parameters (in particular, we will obtain exponential gains in T that will handle all losses arising from the A , σ , r parameters).

For each $3 \leq j \leq N - 2$, we also need the concatenated coordinates

$$\begin{aligned} c_{\leq j-2} &:= (c_1, \dots, c_{j-2}) \in \mathbb{C}^{j-2} && \text{(trailing peripheral modes),} \\ c_{\leq j-1} &:= (c_1, \dots, c_{j-1}) \in \mathbb{C}^{j-1} && \text{(trailing modes),} \\ c_{\geq j+1} &:= (c_{j+1}, \dots, c_N) \in \mathbb{C}^{N-j} && \text{(leading modes),} \\ c_{\geq j+2} &:= (c_{j+2}, \dots, c_N) \in \mathbb{C}^{N-j-1} && \text{(leading peripheral modes).} \end{aligned}$$

Very roughly, the targets (M_j^-, d_j^-, R_j^-) , (M_j^0, d_j^0, R_j^0) , (M_j^+, d_j^+, R_j^+) can be defined in terms of the modes c by Table 1. Thus for instance, the $c_{\geq j+2}$ mode of (M_j^-, d_j^-, R_j^-) ranges over arbitrary values of magnitude $O(r_j^- e^{-2\sqrt{3}T})$, plus an unavoidable uncertainty of magnitude $O(T^{A_j^-} e^{-3\sqrt{3}T})$. As one advances from (M_j^-, d_j^-, R_j^-) , to (M_j^0, d_j^0, R_j^0) , to (M_j^+, d_j^+, R_j^+) , to $(M_{j+1}^-, d_{j+1}^-, R_{j+1}^-)$, and so forth, the uncertainty will increase by a polynomial factor in T (this will be where the A exponents come in), while the size of the manifolds M will shrink somewhat (this will be where the r parameters come in).

It will take time T to flow from (M_j^-, d_j^-, R_j^-) to (M_j^0, d_j^0, R_j^0) , and time T from (M_j^0, d_j^0, R_j^0) to (M_j^+, d_j^+, R_j^+) . (On the other hand, we will be able to flow from (M_j^+, d_j^+, R_j^+) to $(M_{j+1}^-, d_{j+1}^-, R_{j+1}^-)$ in time $O(\log \frac{1}{\sigma})$.) The reader may wish to verify that this is broadly consistent with Table 1, using the heuristics from the previous section that the stable modes $c_{j\pm 1}^-$ should decay by a factor of $e^{-\sqrt{3}T}$ over this time, the unstable modes $c_{j\pm 1}^+$ should grow by the same factor of $e^{\sqrt{3}T}$, and the remaining modes $c_{\leq j-2}$, $c_{\geq j-2}$ should simply oscillate.

We now give more precise definitions of these objects.

The incoming target (M_j^-, d_j^-, R_j^-) We define the *incoming target* (M_j^-, d_j^-, R_j^-) by setting M_j^- to be the set of all points whose coordinates obey the relations

$$c_{\leq j-2}, c_{j-1}^+ = 0,$$

Table 1 The targets (M_j^-, d_j^-, R_j^-) , (M_j^0, d_j^0, R_j^0) , (M_j^+, d_j^+, R_j^+) . It is the factors of $e^{-\sqrt{3}T}$ which are the most important feature here; the polynomial powers of T in the uncertainties, and the scales r in the main terms, are technical corrections which should be ignored at a first reading, and σ should be thought of as a small constant (independent of T or the r). Note that the outgoing target (M_j^+, d_j^+, R_j^+) resembles a shifted version of the incoming target (M_j^-, d_j^-, R_j^-) ; this will be important in Sect. 3.10

Mode	(M_j^-, d_j^-, R_j^-)	(M_j^0, d_j^0, R_j^0)	(M_j^+, d_j^+, R_j^+)
$c_{\leq j-2}$	$0 + O(T^{A_j^-} e^{-2\sqrt{3}T})$	$0 + O(T^{A_j^0} e^{-2\sqrt{3}T})$	$0 + O(T^{A_j^+} e^{-2\sqrt{3}T})$
c_{j-1}^-	$\sigma + O(T^{A_j^-} e^{-\sqrt{3}T})$	$0 + O(T^{A_j^0} e^{-\sqrt{3}T})$	$0 + O(T^{A_j^+} e^{-2\sqrt{3}T})$
c_{j-1}^+	$0 + O(T^{A_j^-} e^{-4\sqrt{3}T})$	$0 + O(T^{A_j^0} e^{-3\sqrt{3}T})$	$0 + O(T^{A_j^+} e^{-2\sqrt{3}T})$
c_{j+1}^-	$O(r_j^- e^{-2\sqrt{3}T})$ $+ O(T^{A_j^-} e^{-3\sqrt{3}T})$	$0 + O(T^{A_j^0} e^{-3\sqrt{3}T})$	$0 + O(T^{A_j^+} e^{-4\sqrt{3}T})$
c_{j+1}^+	$O(r_j^- e^{-2\sqrt{3}T})$ $+ O(T^{A_j^-} e^{-3\sqrt{3}T})$	$O(\sigma e^{-\sqrt{3}T})$ $+ O(T^{A_j^0} e^{-2\sqrt{3}T})$	$\sigma + O(T^{A_j^+} e^{-\sqrt{3}T})$
$c_{\geq j+2}$	$O(r_j^- e^{-2\sqrt{3}T})$ $+ O(T^{A_j^-} e^{-3\sqrt{3}T})$	$O(r_j^0 e^{-2\sqrt{3}T})$ $+ O(T^{A_j^0} e^{-3\sqrt{3}T})$	$O(r_j^+ e^{-2\sqrt{3}T})$ $+ O(T^{A_j^+} e^{-3\sqrt{3}T})$
θ	uncontrolled	uncontrolled	uncontrolled

$$c_{j-1}^- = \sigma,$$

$$|c_{\geq j+1}| \leq r_j^- e^{-2\sqrt{3}T}$$

with uncertainty $R_j^- := T^{A_j^-}$ and with semimetric $d_j^-(x, \tilde{x})$ defined by

$$d_j^-(x, \tilde{x}) := e^{2\sqrt{3}T} |c_{\leq j-2} - \tilde{c}_{\leq j-2}|$$

$$+ e^{\sqrt{3}T} |c_{j-1}^- - \tilde{c}_{j-1}^-| + e^{4\sqrt{3}T} |c_{j-1}^+ - \tilde{c}_{j-1}^+|$$

$$+ e^{3\sqrt{3}T} |c_{\geq j+1} - \tilde{c}_{\geq j+1}|$$

where \tilde{c} of course denotes the coordinates of \tilde{x} . This metric is not defined on the set $b_j = 0$ (where the local coordinates break down), but this is not of importance to us because the metric is well defined for all points within (M_j^-, d_j^-, R_j^-) , since T is so large. (If one wished, extend d_j^- in some arbitrary fashion to be defined on the remaining portions of Σ , but this will have no impact on the argument.)

Fig. 4 An illustration of a configuration of modes within the incoming target (M_j^-, d_j^-, R_j^-) . The illustration ignores the tiny polynomial corrections. The diagonal lines highlight the vertical scale compression between the tiny exponential scales and the scale of $\sigma \sim \frac{1}{100}$

Informally, the incoming target has a significant presence (of size roughly σ) on the trailing stable mode, but is small elsewhere, except of course at the primary mode.

The ricochet target (M_j^0, d_j^0, R_j^0) We define the *ricochet target* (M_j^0, d_j^0, R_j^0) by setting M_j^0 to be the set of all points whose coordinates obey the relations

$$\begin{aligned} c_{\leq j-1}, c_{j+1}^- &= 0, \\ |c_{j+1}^+| &\leq r_j^0 e^{-\sqrt{3}T}, \\ |c_{\geq j+2}| &\leq r_j^0 e^{-2\sqrt{3}T} \end{aligned}$$

with uncertainty $R_j^0 := T^{A_j^0}$ and with semimetric $d_j^0(x, \tilde{x})$ defined by

$$\begin{aligned} d_j^0(x, \tilde{x}) &:= e^{2\sqrt{3}T} |c_{\leq j-2} - \tilde{c}_{\leq j-2}| + e^{\sqrt{3}T} |c_{j-1}^- - \tilde{c}_{j-1}^-| \\ &\quad + e^{3\sqrt{3}T} |c_{j-1}^+ - \tilde{c}_{j-1}^+| \\ &\quad + e^{3\sqrt{3}T} |c_{j+1}^- - \tilde{c}_{j+1}^-| + e^{2\sqrt{3}T} |c_{j+1}^+ - \tilde{c}_{j+1}^+| \\ &\quad + e^{3\sqrt{3}T} |c_{\geq j+2} - \tilde{c}_{\geq j+2}|. \end{aligned}$$

Informally, the ricochet target is small everywhere outside of the primary mode, but has its largest presence at the trailing stable mode and the leading unstable mode, with the latter just having overtaken the former.

Fig. 5 An illustration of a configuration of modes within the ricochet target (M_j^0, d_j^0, R_j^0) . Note that all the modes displayed here are extremely small relative to $\sigma \sim \frac{1}{100}$

The outgoing target (M_j^+, d_j^+, R_j^+) We define the outgoing target (M_j^+, d_j^+, R_j^+) by setting M_j^+ to be the set of all points whose coordinates obey the relations

$$\begin{aligned} c_{\leq j-1} &= c_{j+1}^- = 0, \\ c_{j+1}^+ &= \sigma, \\ |c_{\geq j+2}| &\leq r_j^+ e^{-2\sqrt{3}T} \end{aligned}$$

with uncertainty $R_j^+ = T^{A_j^+}$ and with semimetric $d_j^+(x, \tilde{x})$ defined by

$$\begin{aligned} d_j^+(x, \tilde{x}) &:= e^{2\sqrt{3}T} |c_{\leq j-1} - \tilde{c}_{\leq j-1}| + e^{4\sqrt{3}T} |c_{j+1}^- - \tilde{c}_{j+1}^-| \\ &\quad + e^{\sqrt{3}T} |c_{j+1}^+ - \tilde{c}_{j+1}^+| + e^{3\sqrt{3}T} |c_{\geq j+2} - \tilde{c}_{\geq j+2}|. \end{aligned}$$

Informally, the outgoing target has a significant presence (of size σ) on the leading unstable mode and is small at all other secondary and peripheral modes.

3.5 Proof of Theorem 3.1 assuming (3.11)

From (3.11), we see that there is at least one solution $b(t)$ to (3.1) which starts within the ricochet target (M_3^0, d_3^0, R_3^0) at some time t_0 and ends up within the ricochet target $(M_{N-2}^0, d_{N-2}^0, R_{N-2}^0)$ at some later time $t_1 > t_0$. But from the definition of these targets, we thus see that $b(t_0)$ lies within a distance $O(r_3^0 e^{-\sqrt{3}T})$ of \mathbb{T}_3 , while $b(t_1)$ lies within a distance $O(r_{N-2}^0 e^{-\sqrt{3}T})$ of \mathbb{T}_{N-2} . The claim follows.

Fig. 6 An illustration of a configuration of modes within the outgoing target (M_j^+, d_j^+, R_j^+)

It now remains to show the covering relationships (3.8), (3.9), (3.10). That is the purpose of the next three sections; the main tool shall be repeated and careful applications of Gronwall-type inequalities.

3.6 Flowing from the incoming target to the ricochet target

Fix $3 \leq j \leq N - 2$. In this section we show that (M_j^-, d_j^-, R_j^-) covers (M_j^0, d_j^0, R_j^0) ; this is the lengthiest and most delicate part of the argument. We shall be able to flow from (M_j^-, d_j^-, R_j^-) to (M_j^0, d_j^0, R_j^0) for time exactly T . To do this we will of course need good control on the evolution of a solution starting within (M_j^-, d_j^-, R_j^-) for this length of time. The full evolution is summarized in Table 2, but to establish this behavior we shall need to proceed in stages. Firstly, we need upper bounds on the flow; then we bootstrap these upper bounds to more precise asymptotics; then we use these asymptotics to hit arbitrary locations on the final target (M_j^0, d_j^0, R_j^0) starting from a well-chosen location on the initial target (M_j^-, d_j^-, R_j^-) . This basic strategy will also be employed in the next two sections, though the technical details are slightly different in each case.

We begin with some basic upper bounds on the flow.

Proposition 3.2 (Upper bounds, inbound leg) *Let $b(t)$ be a solution to (3.1) such that $b(0)$ is within (M_j^-, d_j^-, R_j^-) . Let $c(t)$ denote the coordinates of $b(t)$ as in Proposition 3.1. Then we have the bounds*

$$|c_*(t)| = O(T^{A_j^-} e^{-2\sqrt{3}T}),$$

$$|c_{j-1}^-(t)| = O(\sigma e^{-\sqrt{3}t}),$$

Table 2 The evolution of a solution which is within the incoming target (M_j^-, d_j^-, R_j^-) at time $t = 0$. The $a_{\geq 2}, a_j^+, a_j^-$ are explicit numbers defined below in (3.34), (3.42). The function $g(t)$ and the transfer matrices $G_{j+1}(t), G_{\geq j+2}(t)$ are explicit objects (depending only on σ) that will be defined below. The configuration of the modes in the incoming target at $t = 0$ is illustrated in Fig. 4. Upon arrival at $t = T$, the modes have adjusted and appear as in Fig. 5

Mode	$t = 0$	$0 < t < T$	$t = T$
$c_{\leq j-2}$	$O(T^{A_j^-} e^{-2\sqrt{3}T})$	$O(T^{A_j^-} e^{-2\sqrt{3}T})$	$O(T^{A_j^-} e^{-2\sqrt{3}T})$
c_{j-1}^-	$\sigma + O(e^{-\sqrt{3}T})$	$g(t) + O(e^{-\sqrt{3}T})$	$O(e^{-\sqrt{3}T})$
c_{j-1}^+	$O(T^{A_j^-} e^{-4\sqrt{3}T})$	$O(T^{2A_j^-+1} e^{-4\sqrt{3}T} e^{\sqrt{3}t})$	$O(T^{2A_j^-+1} e^{-3\sqrt{3}T})$
c_{j+1}^-	$e^{-2\sqrt{3}T} a_{j+1}^- + O(T^{A_j^-} e^{-3\sqrt{3}T})$	$O(T^{A_j^-} e^{-2\sqrt{3}T} e^{-\sqrt{3}t})$	$O(T^{A_j^-} e^{-3\sqrt{3}T})$
c_{j+1}^+	$e^{-2\sqrt{3}T} a_{j+1}^+ + O(T^{A_j^-} e^{-3\sqrt{3}T})$	$e^{-2\sqrt{3}T} e^{\sqrt{3}t} G_{j+1}^+(t) a_{j+1}^+ + O(T^{A_j^-+2} e^{-3\sqrt{3}T} e^{\sqrt{3}t})$	$e^{-\sqrt{3}T} G_{j+1}^+(T) a_{j+1}^+ + O(T^{A_j^-+2} e^{-2\sqrt{3}T})$
$c_{\geq j+2}$	$e^{-2\sqrt{3}T} a_{\geq j+2} + O(T^{A_j^-} e^{-3\sqrt{3}T})$	$e^{-2\sqrt{3}T} G_{\geq j+2}(t) a_{\geq j+2} + O(T^{A_j^-} e^{-3\sqrt{3}T})$	$e^{-2\sqrt{3}T} G_{\geq j+2}(T) a_{\geq j+2} + O(T^{A_j^-} e^{-3\sqrt{3}T})$

$$|c_{j-1}^+(t)| = O(T^{2A_j^-+1} e^{-4\sqrt{3}T} e^{\sqrt{3}t}),$$

$$|c_{j+1}^-(t)| = O(r_j^- (1+t) e^{-2\sqrt{3}T} e^{-\sqrt{3}t}),$$

$$|c_{j+1}^+(t)| = O(r_j^- e^{-2\sqrt{3}T} e^{\sqrt{3}t})$$

for $0 \leq t \leq T$.

Proof From the hypothesis that $b(0)$ is within (M_j^-, d_j^-, R_j^-) , we easily verify that the bounds hold at time $t = 0$. To establish the bounds for later times, we can use the continuity method. Let C_0 be a large constant (depending only on N) to be chosen later, and suppose that $0 \leq T' \leq T$ is a time for which the bounds

$$|c_*(t)| = O(C_0 T^{A_j^-} e^{-2\sqrt{3}T}),$$

$$|c_{j-1}^-(t)| = O(C_0 \sigma e^{-\sqrt{3}t}),$$

$$|c_{j-1}^+(t)| = O(C_0 T^{2A_j^-+1} e^{-4\sqrt{3}T} e^{\sqrt{3}t}),$$

$$|c_{j+1}^-(t)| = O(C_0 r_j^- (1+t) e^{-2\sqrt{3}T} e^{-\sqrt{3}t}),$$

$$|c_{j+1}^+(t)| = O(C_0 r_j^- e^{-2\sqrt{3}T} e^{\sqrt{3}t})$$

are known to hold for all $0 \leq t \leq T'$. We will then prove the same bounds without the C_0 factor for the same range of times t , implying that the set of times T' for which the above statements hold is both open and closed; since that set contains 0, it must then also contain T and we are done.

Our main tool shall of course be Lemma 3.2. From our bootstrap hypotheses (and the largeness of T) we can control the total magnitude of the modes:

$$|c(t)| \lesssim C_0 \sigma e^{-\sqrt{3}t} + C_0 r_j^- e^{-2\sqrt{3}T} e^{\sqrt{3}t} \quad (3.29)$$

for all $0 \leq t \leq T'$ (the trailing stable mode is almost always dominant, except near time T where the leading unstable mode begins to compete) and hence (3.24) will hold for all $0 \leq t \leq T'$ (assuming σ is small depending on C_0). From (3.28) we thus have

$$|c_*(t)| \lesssim |c_*(0)| \lesssim T^{A_j^-} e^{-2\sqrt{3}T} \quad (3.30)$$

for all $0 \leq t \leq T'$, which is the desired bound on the peripheral modes $c_*(t)$. Similarly from (3.27) we have

$$|c_{j+1}(t)| \lesssim e^{\sqrt{3}t} |c_{j+1}(0)| \lesssim r_j^- e^{-2\sqrt{3}T} e^{\sqrt{3}t} \quad (3.31)$$

which gives the desired bound on the leading unstable mode c_{j+1}^+ . From (3.30), (3.31) we have

$$|c_{\neq j-1}(t)| \lesssim e^{-2\sqrt{3}T} (T^{A_j^-} + r_j^- e^{\sqrt{3}t}) \quad (3.32)$$

and hence from (3.25) we have

$$\begin{aligned} |c_{j-1}^-(t)| &\lesssim e^{-\sqrt{3}t} |c_{j-1}^-(0)| \\ &+ \int_0^t e^{-\sqrt{3}(t-s)} |c_{j-1}^+(s)| e^{-4\sqrt{3}T} (T^{A_j^-} + r_j^- e^{\sqrt{3}s})^2 ds. \end{aligned}$$

Since $c_{j-1}^-(0) = O(\sigma)$ and $c_{j-1}^+(s) = O(C_0 T^{2A_j^-+1} e^{-4\sqrt{3}T} e^{\sqrt{3}s})$, we conclude (using the largeness of T) that

$$|c_{j-1}(t)^-| = O(\sigma e^{-\sqrt{3}t}) \quad (3.33)$$

which is the desired bound on the trailing stable mode. This and (3.30) imply that

$$|c_{\neq j+1}(t)| \lesssim \sigma e^{-\sqrt{3}t}$$

and then from (3.25) we have

$$|c_{j+1}^-(t)| \lesssim e^{-\sqrt{3}t} |c_{j+1}^-(0)| + \int_0^t e^{-\sqrt{3}(t-s)} |c_{j+1}^+(s)| \sigma^2 e^{-2\sqrt{3}s} ds.$$

Using (3.31) to estimate $|c_{j+1}^+(s)|$, together with the initial bound $|c_{j+1}^-(0)| = O(r_j^- e^{-2\sqrt{3}T})$ we obtain

$$|c_{j+1}^-(t)| \lesssim r_j^- (1+t) e^{-\sqrt{3}t} e^{-2\sqrt{3}T}$$

which is the desired bound on the leading stable mode. Finally, from (3.26) and (3.32) we have

$$|c_{j-1}^+(t)| \lesssim e^{\sqrt{3}t} |c_{j-1}^+(0)| + \int_0^t e^{\sqrt{3}(t-s)} |c_{j-1}^-(s)| e^{-4\sqrt{3}T} (T^{A_j^-} + r_j^- e^{\sqrt{3}s})^2 ds$$

and thus from (3.33) and the initial bound $|c_{j-1}^+(0)| = O(T^{A_j^-} e^{-4\sqrt{3}T})$ we have

$$|c_{j-1}^+(t)| \lesssim T^{2A_j^-+1} e^{-4\sqrt{3}T} e^{\sqrt{3}t}$$

which is the desired bound on the trailing unstable mode. □

For the rest of this section, the time variable t is assumed to lie in the range $0 \leq t \leq T$. Let us make some more precise hypotheses on the initial data, namely

$$\begin{aligned} c_{j+1}^-(0) &= e^{-2\sqrt{3}T} a_{j+1}^- + O(T^{A_j^-} e^{-3\sqrt{3}T}), \\ c_{j+1}^+(0) &= e^{-2\sqrt{3}T} a_{j+1}^+ + O(T^{A_j^-} e^{-3\sqrt{3}T}), \\ c_{\geq j+2}(0) &= e^{-2\sqrt{3}T} a_{\geq j+2} + O(T^{A_j^-} e^{-3\sqrt{3}T}) \end{aligned} \tag{3.34}$$

for some data $a_{j+1}^\pm \in \mathbb{R}$, $a_{\geq j+2} \in \mathbb{C}^{N-j-1}$ of magnitude at most $r_j^-/2$ which we shall choose later. In order to reach the turnaround set (M_j^0, d_j^0, R_j^0) , we will need slightly more precise bounds on the leading modes (and also the stable trailing mode, which is dominant) as follows.

Improved control on $c_{j-1}^-(t)$ We first give a better bound on the trailing stable mode $c_{j-1}^-(t)$, which is the largest of all the modes (other than the primary one, of course). Observe from Proposition 3.2 that any cubic term $\mathcal{O}(c^3)$ splits as the sum of a main term of the form $\mathcal{O}((c_{j-1}^-)^3)$, plus an error

of size at most $O(T^{A_j^-} e^{-2\sqrt{3}T})$ (say). Thus we may rewrite (3.20) somewhat crudely as

$$\partial_t c_{j-1}^- = -\sqrt{3}c_{j-1}^- + \mathcal{O}((c_{j-1}^-)^3) + O(T^{A_j^-} e^{-2\sqrt{3}T})$$

for some explicit cubic expression $\mathcal{O}((c_{j-1}^-)^3)$ of c_{j-1}^- . Now let g be the solution¹⁸ to the corresponding exact (scalar) equation

$$\partial_t g = -\sqrt{3}g + \mathcal{O}(g^3)$$

with the same initial data $g(0) = \sigma$. Because σ is small, it is easy to establish the decay bound

$$g(t) = O(\sigma e^{-\sqrt{3}t}) \tag{3.35}$$

(e.g. by the continuity method). Writing $c_{j-1}^- = g + E_{j-1}^-$, the error function $E_{j-1}^-(t)$ thus obeys the difference equation

$$\partial_t E_{j-1}^- = -\sqrt{3}E_{j-1}^- + O(\sigma^2 e^{-2\sqrt{3}t} |E_{j-1}^-|) + O(|E_{j-1}^-|^3) + O(T^{A_j^-} e^{-2\sqrt{3}T})$$

with initial data $E_{j-1}^-(0) = 0$. From this equation it is an easy matter (e.g. by the continuity method) to establish the bound

$$E_{j-1}^-(t) = O(T^{A_j^-+1} e^{-2\sqrt{3}T})$$

for all $0 \leq t \leq T$. In other words we have the estimate

$$c_{j-1}^-(t) = g(t) + O(T^{A_j^-+1} e^{-2\sqrt{3}T}). \tag{3.36}$$

This and Proposition 3.2 allow us to refine our bound for c^2 and for $c_{\neq j+1}^2$:

$$\mathcal{O}(c^2) = \mathcal{O}(g^2) + O(T^{A_j^-+1} e^{-2\sqrt{3}T}) \tag{3.37}$$

and

$$\mathcal{O}(c_{\neq j+1}^2) = \mathcal{O}(g^2) + O(T^{A_j^-+1} e^{-2\sqrt{3}T} e^{-\sqrt{3}t}). \tag{3.38}$$

¹⁸This function g can in fact be computed explicitly, in fact it is essentially the function appearing in Remark 3.4, up to a translation in time. However, we will not need to know the exact formula for it here; the only relevant features for us is that g depends only on σ (and possibly N) and obeys the bound (3.35).

Improved control on $c_{\geq j+2}$ Now we control the leading peripheral modes. Inserting (3.37) into (3.17) we see that

$$\partial_t c_{\geq j+2} = i c_{\geq j+2} + \mathcal{O}(c_{\geq j+2} g^2) + \mathcal{O}(T^{A_j^-+1} e^{-2\sqrt{3}T} |c_{\geq j+2}|).$$

We approximate this by the corresponding linear equation

$$\partial_t u = i u + \mathcal{O}(u g^2)$$

where $u(t) \in \mathbb{C}^{N-j-1}$. This equation has a fundamental solution $G_{\geq 2}(t) : \mathbb{C}^{N-j-1} \rightarrow \mathbb{C}^{N-j-1}$ for all $t \geq 0$, thus $G_{\geq 2}(t)u(0) = u(t)$. (Again, this solution could be described explicitly since g is itself explicit, but we will not need to do so here). From (3.35) we have

$$\int_0^T g^2(t) dt = \mathcal{O}(1), \tag{3.39}$$

and so an easy application of Gronwall’s inequality shows that

$$|G_{\geq 2}(t)|, |G_{\geq 2}(t)^{-1}| = \mathcal{O}(1). \tag{3.40}$$

Since $c_{\geq j+2}(0) = e^{-2\sqrt{3}T} a_{\geq j+2} + \mathcal{O}(T^{A_j^-} e^{-3\sqrt{3}T})$, we are motivated to use the ansatz

$$c_{\geq j+2} = e^{-2\sqrt{3}T} G_{\geq 2}(t) a_{\geq j+2} + E_{\geq j+2}.$$

The error $E_{\geq j+2}$ then solves the equation

$$\partial_t E_{\geq j+2} = i E_{\geq j+2} + \mathcal{O}(E_{\geq j+2} g^2) + \mathcal{O}(T^{A_j^-+1} e^{-2\sqrt{3}T} |c_{\geq j+2}|)$$

with initial data $E_{\geq j+2}(0) = \mathcal{O}(T^{A_j^-} e^{-3\sqrt{3}T})$. Applying the bound on $c_{\geq j+2}$ from Proposition 3.2 we see that

$$\partial_t |E_{\geq j+2}| = \mathcal{O}(|E_{\geq j+2}| |g|^2) + \mathcal{O}(T^{2A_j^-+1} e^{-4\sqrt{3}T}).$$

From Gronwall’s inequality and (3.39) we conclude that

$$|E_{\geq j+2}(t)| = \mathcal{O}(T^{A_j^-} e^{-3\sqrt{3}T})$$

for all $0 \leq t \leq T$, and thus

$$c_{\geq j+2}(t) = e^{-2\sqrt{3}T} G_{\geq 2}(t) a_{\geq j+2} + \mathcal{O}(T^{A_j^-} e^{-3\sqrt{3}T}). \tag{3.41}$$

Improved control on c_{j+1} Now we consider the two leading secondary modes c_{j+1}^+, c_{j+1}^- simultaneously. From (3.20), (3.21), (3.37), (3.38), and Proposition 3.2 we have the system

$$\begin{aligned} \partial_t c_{j+1}^- &= -\sqrt{3}c_{j+1}^- + \mathcal{O}(g^2 c_{j+1}^-) + \mathcal{O}(g^2 c_{j+1}^+) + O(T^{A_j^-+1} e^{-4\sqrt{3}T}), \\ \partial_t c_{j+1}^+ &= \sqrt{3}c_{j+1}^+ + \mathcal{O}(g^2 c_{j+1}^+) + \mathcal{O}(g^2 c_{j+1}^-) + O(T^{A_j^-+1} e^{-4\sqrt{3}T} e^{\sqrt{3}t}). \end{aligned}$$

If we make the ansatz

$$c_{j+1}^- = e^{-2\sqrt{3}T} e^{-\sqrt{3}t} \tilde{a}_{j+1}^-(t); \quad c_{j+1}^+ = e^{-2\sqrt{3}T} e^{\sqrt{3}t} \tilde{a}_{j+1}^+(t)$$

to eliminate the constant coefficient terms, then the system becomes

$$\begin{aligned} \partial_t \tilde{a}_{j+1}^- &= \mathcal{O}(g^2 \tilde{a}_{j+1}^-) + \mathcal{O}(g^2 e^{2\sqrt{3}t} \tilde{a}_{j+1}^+) + O(T^{A_j^-+1} e^{-2\sqrt{3}T} e^{\sqrt{3}t}), \\ \partial_t \tilde{a}_{j+1}^+ &= \mathcal{O}(g^2 e^{-2\sqrt{3}t} \tilde{a}_{j+1}^-) + \mathcal{O}(g^2 \tilde{a}_{j+1}^+) + O(T^{A_j^-+1} e^{-2\sqrt{3}T}) \end{aligned}$$

with initial conditions $\tilde{a}_{j+1}^\pm(0) = a_{j+1}^\pm + O(T^{A_j^-} e^{-\sqrt{3}T})$. Writing $a_{j+1} := \begin{pmatrix} a_{j+1}^- \\ a_{j+1}^+ \end{pmatrix}$ and $\tilde{a}_{j+1}(t) := \begin{pmatrix} \tilde{a}_{j+1}^-(t) \\ \tilde{a}_{j+1}^+(t) \end{pmatrix}$, we can write this as

$$\begin{aligned} \partial_t \tilde{a}_{j+1}(t) &= A(t) \tilde{a}_{j+1}(t) + O(T^{A_j^-+1} e^{-2\sqrt{3}T} e^{\sqrt{3}t}); \\ \tilde{a}_{j+1}(0) &= a_{j+1} + O(T^{A_j^-} e^{-\sqrt{3}T}) \end{aligned} \tag{3.42}$$

where $A(t)$ is an explicit real 2×2 matrix (depending only on σ and t) which (by (3.35)) has bounds of the form

$$A(t) = \sigma^2 \begin{pmatrix} O(e^{-2\sqrt{3}t}) & O(1) \\ O(e^{-4\sqrt{3}t}) & O(e^{-2\sqrt{3}t}) \end{pmatrix}.$$

Unfortunately, the non-decaying coefficient $O(1)$ here prevents a direct application of Gronwall’s inequality from being effective. However, because this coefficient is located in a “nilpotent” part of the matrix, we can proceed using the following variant of Gronwall’s lemma.

Lemma 3.3 (Gronwall-type inequality) *Let $x(t), y(t)$ be vector-valued functions obeying the differential inequalities*

$$\begin{aligned} |\partial_t x(t)| &\lesssim \delta e^{-\alpha t} |x(t)| + \delta |y(t)| + |F(t)|, \\ |\partial_t y(t)| &\lesssim \delta e^{-\beta t} |x(t)| + \delta e^{-\gamma t} |y(t)| + |G(t)| \end{aligned}$$

for some $\alpha, \beta, \gamma > 0$, some $0 < \delta < 1$, all $0 \leq t \leq T$, and some forcing terms $F(t), G(t)$. Then we have

$$|x(t)| \lesssim (1+t)|x(0)| + t|y(0)| + \int_0^t (1+te^{-\beta s})|F(s)| + t|G(s)| ds,$$

$$|y(t)| \lesssim |x(0)| + |y(0)| + \int_0^t e^{-\beta s}|F(s)| + |G(s)| ds$$

for all $0 \leq t \leq T$, where the implicit constants are allowed to depend on α, β, γ . If $F = G = 0$ and δ is sufficiently small depending on α, β, γ , we also have the lower bound

$$|y(t)| \geq \frac{1}{2}|y(0)| - O(|x(0)|).$$

Proof Throughout this proof we assume that t lies in the range $0 \leq t \leq T$, and implied constants can depend on α, β, γ . From the equation for $\partial_t x(t)$ and the usual Gronwall inequality we have

$$|x(t)| \lesssim |x(0)| + \int_0^t |y(s)| + |F(s)| ds.$$

Writing $Y(t) := \sup_{0 \leq s \leq t} |y(s)|$, we conclude that

$$|x(t)| \lesssim |x(0)| + \int_0^t |F(s)| ds + tY(t). \tag{3.43}$$

On the other hand, from the equation for $\partial_t y(t)$ and Gronwall’s inequality we have

$$|y(t)| \lesssim |y(0)| + \int_0^t e^{-\beta s}|x(s)| + |G(s)| ds;$$

inserting (3.43) we conclude

$$|y(t)| \lesssim |y(0)| + \int_0^t e^{-\beta s} \left(|x(0)| + \int_0^s F(s') ds' \right) + |G(s)| ds + \int_0^t e^{-\beta s} Y(s) ds.$$

By Fubini’s theorem we have $\int_0^T e^{-\beta s} (|x(0)| + \int_0^s F(s') ds') ds \lesssim |x(0)| + \int_0^T e^{-\beta s} F(s) ds$. Taking suprema in t we conclude that

$$Y(t) \lesssim |y(0)| + |x(0)| + \int_0^t e^{-\beta s}|F(s)| + |G(s)| ds + \int_0^t e^{-\frac{\beta}{2}s} Y(s) ds$$

and hence by Gronwall’s inequality again

$$|y(t)| \lesssim Y(t) \lesssim |y(0)| + |x(0)| + \int_0^t e^{-\beta s} |F(s)| + |G(s)| \, ds.$$

The upper bounds on x and y now follows from (3.43).

Now suppose that $F = G = 0$ and δ is small. The triangle inequality gives us,

$$|y(t)| \geq |y(0)| - \int_0^t |\partial_s y(s)| \, ds.$$

With the given bound for $|\partial_s y(s)|$ and the upper bounds we just proved for $y(s), x(s)$, we conclude,

$$\begin{aligned} |y(t)| &\geq |y(0)| - \int_0^t C\delta e^{-\beta s} |x(s)| \, ds - \int_0^t C\delta e^{-\gamma s} |y(s)| \, ds \\ &\geq |y(0)| - \int_0^t C\delta(1+t)e^{-\beta s} (x(0) + y(0)) \, ds, \end{aligned}$$

and the final claim in the lemma follows by taking δ small enough. □

Let $G_{j+1}(t)$ be the transfer matrix associated to $A(t)$, i.e. $G_{j+1}(t)$ is the real 2×2 matrix solving the ODE

$$\partial_t G_{j+1}(t) = A(t)G_{j+1}(t); \quad G_{j+1}(0) = \text{id}.$$

Then from Lemma 3.3, the coefficients of G_{j+1} enjoy the bounds

$$G_{j+1}(t) = \begin{pmatrix} O(1+t) & O(t) \\ O(1) & O(1) \end{pmatrix}. \tag{3.44}$$

Since σ is small, we can also use the last part of Lemma 3.3 and conclude that the coefficient in the bottom right corner has magnitude at least $1/2$. (This will be important later when we “invert” $G_{j+1}(T)$.)

Now we return to (3.42), and use the ansatz

$$\tilde{a}_{j+1}(t) = G_{j+1}(t)a_{j+1} + E_{j+1}(t)$$

to obtain an equation for the error E_{j+1} :

$$\begin{aligned} \partial_t E_{j+1}(t) &= A(t)E_{j+1}(t) + O(T^{A_j^-+1} e^{-2\sqrt{3}T} e^{\sqrt{3}t}); \\ E_{j+1}(0) &= O(T^{A_j^-} e^{-\sqrt{3}T}) \end{aligned}$$

and then by Lemma 3.3 again we obtain the bounds

$$E_{j+1}(t) = O(T^{A_j^-+2} e^{-2\sqrt{3}T} e^{\sqrt{3}t}) + O(T^{A_j^-+1} e^{-\sqrt{3}T}) = O(T^{A_j^-+2} e^{-\sqrt{3}T}).$$

We thus conclude that

$$\begin{pmatrix} e^{2\sqrt{3}T} e^{\sqrt{3}t} c_{j+1}^-(t) \\ e^{2\sqrt{3}T} e^{-\sqrt{3}t} c_{j+1}^+(t) \end{pmatrix} = G_{j+1}(t) a_{j+1} + O(T^{A_j^-+2} e^{-\sqrt{3}T}). \tag{3.45}$$

3.7 Hitting the ricochet target

Our estimates are now sufficiently accurate to show that (M_j^-, d_j^-, R_j^-) can cover (M_j^0, d_j^0, R_j^0) . Consider an arbitrary point x_j^0 in M_j^0 , which in coordinates would take the form

$$\begin{aligned} c_{\leq j-1} &= c_{j+1}^- = 0, \\ c_{j+1}^+ &= z_{j+1}^+ e^{-\sqrt{3}T}, \\ c_{\geq j+2} &= z_{\geq j+2} e^{-2\sqrt{3}T} \end{aligned}$$

for some $z_{j+1}^+ \in \mathbb{R}$, $z_{\geq j+2} \in \mathbb{C}^{N-j-1}$ of magnitude at most r_j^0 . We need to locate a point x_j^- in M_j^- , which in coordinates takes the form

$$\begin{aligned} c_{\leq j-2} &= c_{j-1}^+ = 0, \\ c_{j-1}^- &= \sigma, \\ c_{j+1}^- &= a_{j+1}^- e^{-2\sqrt{3}T}, \\ c_{j+1}^+ &= a_{j+1}^+ e^{-2\sqrt{3}T}, \\ c_{\geq j+2} &= a_{\geq j+2} e^{-2\sqrt{3}T} \end{aligned}$$

for some $a_{j+1}^\pm \in \mathbb{R}$, $a_{\geq j+2} \in \mathbb{C}^{N-j-1}$ of magnitude at most $r_j^-/4$ (say) to be chosen later, such that given any data $c(0)$ which is within $R_j^- = T^{A_j^-}$ of x_j^- , thus in coordinates

$$\begin{aligned} c_{\leq j-2}(0) &= O(T^{A_j^-} e^{-2\sqrt{3}T}), \\ c_{j-1}^-(0) &= \sigma + O(T^{A_j^-} e^{-\sqrt{3}T}), \\ c_{j-1}^+(0) &= O(T^{A_j^-} e^{-4\sqrt{3}T}), \end{aligned}$$

$$\begin{aligned} c_{j+1}^-(0) &= a_{j+1}^- e^{-2\sqrt{3}T} + O(T^{A_j^-} e^{-3\sqrt{3}T}), \\ c_{j+1}^+(0) &= a_{j+1}^+ e^{-2\sqrt{3}T} + O(T^{A_j^-} e^{-3\sqrt{3}T}), \\ c_{\geq j+2}(0) &= a_{\geq j+2} e^{-2\sqrt{3}T} + O(T^{A_j^-} e^{-3\sqrt{3}T}), \end{aligned}$$

the evolution of this data after time T will lie within $R_j^0 = T^{A_j^0}$ of x_j^0 in the d_j^0 metric. Thus we aim to show,

$$\begin{aligned} &e^{2\sqrt{3}T} |c_{\leq j-2}(T)| + e^{\sqrt{3}T} |c_{j-1}^-(T)| + e^{3\sqrt{3}T} |c_{j-1}^+(T)| + e^{3\sqrt{3}T} |c_{j+1}^-(T)| \\ &\quad + e^{2\sqrt{3}T} |c_{j+1}^+(T) - e^{-\sqrt{3}T} z_{j+1}^+| + e^{3\sqrt{3}T} |c_{\geq j+2}(T) - e^{-2\sqrt{3}T} z_{\geq j+2}| \\ &< T^{A_j^0}. \end{aligned} \tag{3.46}$$

To establish this, we of course apply the bounds obtained in this section. From Proposition 3.2 we have

$$\begin{aligned} |c_{\leq j-2}(T)| &= O(T^{A_j^-} e^{-2\sqrt{3}T}); & c_{j-1}^-(T) &= O(e^{-\sqrt{3}T}); \\ c_{j-1}^+(T) &= O(T^{2A_j^-+1} e^{-3\sqrt{3}T}) \end{aligned}$$

and hence the contribution of the trailing modes $c_{\leq j-1}$ to (3.46) will be acceptable (recall that A_j^0 is ten times larger than A_j^-). From (3.41) we have

$$c_{\geq j+2}(t) = e^{-2\sqrt{3}T} G_{\geq 2}(T) a_{\geq j+2} + O(T^{A_j^-} e^{-3\sqrt{3}T}).$$

Thus if we set $a_{\geq j+2} := G_{\geq 2}(T)^{-1} z_{\geq j+2}$, then the contribution of the leading peripheral modes $c_{\geq j+2}$ to (3.46) is acceptable. Note that since $|z_{\geq j+2}| \leq r_j^0$, then $|a_{\geq j+2}| \leq r_j^-$ thanks to (3.40) and the construction of r_j^- large compared to r_j^0 .

Finally, we need to deal with the leading secondary modes. According to Proposition 3.2 the contribution of $c_{j+1}^-(t)$ to the left hand side of (3.46) is acceptable. As for c_{j+1}^+ , from (3.45) we have

$$\begin{pmatrix} e^{3\sqrt{3}T} c_{j+1}^-(T) \\ e^{\sqrt{3}T} c_{j+1}^+(T) \end{pmatrix} = G_{j+1}(T) a_{j+1} + O(T^{A_j^-+2} e^{-\sqrt{3}T}).$$

Now recall that the matrix $G_{j+1}(T)$ has the form (3.44), with the bottom right coefficient having magnitude comparable to 1. Because of this, and the

hypothesis that $|z_{j+1}^+| \leq r_j^0$, one can easily find coefficients a_{j+1}^-, a_{j+1}^+ of magnitude at most r_j^- (which is large compared to r_j^0) such that

$$G_{j+1}(T) \begin{pmatrix} a_{j+1}^- \\ a_{j+1}^+ \end{pmatrix} = \begin{pmatrix} \dots \\ z_{j+1}^+ \end{pmatrix}$$

where the exact value of the coefficient ... is not important to us since we already bounded $c_{j+1}^-(T)$ above. We thus have

$$c_{j+1}^+(T) = e^{-\sqrt{3}T} z_{j+1}^+ + O(T^{A_j^-+2} e^{-2\sqrt{3}T})$$

and conclude that the contribution of this term to (3.46) is also acceptable. This concludes the proof that (M_j^-, d_j^-, r_j^-) covers (M_j^0, d_j^0, r_j^0) .

3.8 Flowing from the ricochet target to the outgoing target

Again we fix $3 \leq j \leq N - 2$. We now show that (M_j^0, d_j^0, r_j^0) covers (M_j^+, d_j^+, r_j^+) . Broadly speaking, this will resemble a time-reversed version of the arguments in Sect. 3.6, though there are a number of technical differences. On the one hand, the trailing secondary modes are now much less important and do not require as delicate a treatment as in Sect. 3.6. On the other hand, the time reversal changes the role of σ ; instead of starting with a

Table 3 The evolution of a solution which is within the ricochet target (M_j^0, d_j^0, R_j^0) at time $t = 0$, and with a well-chosen (and small) leading unstable mode c_{j+1}^+ . The $a_{\geq 2}, a_{j+1}^+$ are explicit numbers defined below in (3.49), (3.55). The function $\tilde{g}(t)$ and the transfer matrix $\tilde{G}_{\geq j+2}(t)$ are explicit objects (depending only on σ) that will be defined below. The $t = 0$ configuration of the modes within the ricochet target is illustrated in Fig. 5. At $t = T$, the modes are within the outgoing target as illustrated in Fig. 6

Mode	$t = 0$	$0 < t < T$	$t = T$
$c_{\leq j-2}$	$O(T^{A_j^0} e^{-2\sqrt{3}T})$	$O(T^{A_j^0} e^{-2\sqrt{3}T})$	$O(T^{A_j^0} e^{-2\sqrt{3}T})$
c_{j-1}^-	$O(T^{A_j^0} e^{-\sqrt{3}T})$	$O(T^{A_j^0+1} e^{-\sqrt{3}T} e^{-\sqrt{3}t})$	$O(T^{A_j^0+1} e^{-2\sqrt{3}T})$
c_{j-1}^+	$O(T^{A_j^0} e^{-3\sqrt{3}T})$	$O(T^{A_j^0+1} e^{-3\sqrt{3}T} e^{\sqrt{3}t})$	$O(T^{A_j^0+1} e^{-2\sqrt{3}T})$
c_{j+1}^-	$O(T^{A_j^0} e^{-3\sqrt{3}T})$	$O(T^{2A_j^0+3} e^{-3\sqrt{3}T} e^{-\sqrt{3}t})$	$O(T^{2A_j^0+3} e^{-4\sqrt{3}T})$
c_{j+1}^+	$\sigma e^{-\sqrt{3}T} a_{j+1}^+ + O(T^{A_j^0} e^{-2\sqrt{3}T})$	$e^{-\sqrt{3}T} \tilde{g}(t) + O(T^{A_j^0+2} e^{-2\sqrt{3}T} e^{\sqrt{3}t})$	$\sigma + O(T^{A_j^0+2} e^{-\sqrt{3}T})$
$c_{\geq j+2}$	$e^{-2\sqrt{3}T} a_{\geq j+2} + O(T^{A_j^0} e^{-3\sqrt{3}T})$	$e^{-2\sqrt{3}T} \tilde{G}_{\geq j+2}(t) a_{\geq j+2} + O(T^{A_j^0} e^{-3\sqrt{3}T})$	$e^{-2\sqrt{3}T} \tilde{G}_{\geq j+2}(T) a_{\geq j+2} + O(T^{A_j^0} e^{-3\sqrt{3}T})$

stable trailing mode at size σ and ensuring that it decays in a controlled manner, we now are starting with an unstable leading mode c_{j+1}^+ of small size (like $e^{-\sqrt{3}T}$) and growing it so that it reaches σ almost exactly at time T .

Once again, we begin with upper bounds on the flow, though now we also need a smallness condition on the unstable mode $c_{j+1}^+(0)$ (to stop the evolution from moving too far away from \mathbb{T}_j by time T).

Proposition 3.3 (Upper bounds, outbound leg) *Let $b(t)$ be a solution to (3.1) such that $b(0)$ is within (M_j^0, d_j^0, R_j^0) . Let $c(t)$ denote the coordinates of $b(t)$ as in Proposition 3.1. Assume the smallness condition $c_{j+1}^+(0) = O(\sigma e^{-\sqrt{3}T})$. Then we have the bounds*

$$\begin{aligned} |c_*(t)| &= O(T^{A_j^0} e^{-2\sqrt{3}T}), \\ |c_{j-1}^-(t)| &= O(T^{A_j^0} e^{-\sqrt{3}T} e^{-\sqrt{3}t} (1 + T e^{-\sqrt{3}(T-t)})) \\ &\leq O(T^{A_j^0+1} e^{-\sqrt{3}T} e^{-\sqrt{3}t}), \\ |c_{j-1}^+(t)| &= O(T^{A_j^0+1} e^{-3\sqrt{3}T} e^{\sqrt{3}t}), \\ |c_{j+1}^-(t)| &= O(T^{2A_j^0+3} e^{-3\sqrt{3}T} e^{-\sqrt{3}t}), \\ |c_{j+1}^+(t)| &= O(\sigma e^{-\sqrt{3}T} e^{\sqrt{3}t}) \end{aligned}$$

for $0 \leq t \leq T$.

Proof From the hypotheses we easily verify that the bounds hold at time $t = 0$. As in the proof of Proposition 3.2, we use the continuity method. We again let C_0 be a large constant (depending only on N) to be chosen later, and suppose that $0 \leq T' \leq T$ is a time for which the bounds

$$\begin{aligned} |c_*(t)| &= O(C_0 T^{A_j^0} e^{-2\sqrt{3}T}), \\ |c_{j-1}^-(t)| &= O(C_0 T^{A_j^0} e^{-\sqrt{3}T} e^{-\sqrt{3}t} (1 + T e^{-\sqrt{3}(T-t)})), \\ |c_{j-1}^+(t)| &= O(C_0 T^{A_j^0+1} e^{-3\sqrt{3}T} e^{\sqrt{3}t}), \\ |c_{j+1}^-(t)| &= O(C_0 T^{2A_j^0+3} e^{-3\sqrt{3}T} e^{-\sqrt{3}t}), \\ |c_{j+1}^+(t)| &= O(C_0 \sigma e^{-\sqrt{3}T} e^{\sqrt{3}t}) \end{aligned}$$

are known to hold for all $0 \leq t \leq T'$. As before, it suffices to then deduce the same bounds without the C_0 factor.

From the above bounds we have

$$|c(t)| = O(C_0 T^{A_j^0+1} e^{-\sqrt{3}T} e^{-\sqrt{3}t} + C_0 \sigma e^{-\sqrt{3}T} e^{\sqrt{3}t})$$

which gives the bound (3.24) (taking σ small compared to C_0 . Lemma 3.2 now applies. From (3.28) we have

$$|c_*(t)| \lesssim |c_*(0)| \lesssim T^{A_j^0} e^{-2\sqrt{3}T}$$

which gives the desired control on the peripheral modes c_* . From (3.27) we have

$$|c_{j+1}(t)| \lesssim e^{\sqrt{3}t} |c_{j+1}(0)| \lesssim \sigma e^{-\sqrt{3}T} e^{\sqrt{3}t}$$

which gives the desired control on the unstable leading mode c_{j+1}^+ . Next, we apply (3.25) to obtain

$$|c_{j-1}^-(t)| \lesssim e^{-\sqrt{3}t} c_{j-1}^-(0) + \int_0^t e^{\sqrt{3}(t-s)} |c_{j-1}^+(s)| |c(s)|^2 ds$$

which after substituting the initial bound $c_{j-1}^-(0) = O(T^{A_j^0} e^{-\sqrt{3}T})$ and the above bounds on $c_{j-1}^+(s)$, $c(s)$ gives

$$|c_{j-1}^-(t)| \lesssim T^{A_j^0} e^{-\sqrt{3}T} e^{-\sqrt{3}t} (1 + T e^{-\sqrt{3}(T-t)})$$

which is the desired bound in the stable trailing mode c_{j-1}^- . Then, we apply (3.26) to obtain

$$|c_{j-1}^+(t)| \lesssim e^{-\sqrt{3}t} c_{j-1}^+(0) + \int_0^t e^{\sqrt{3}(t-s)} |c_{j-1}^-(s)| |c(s)|^2 ds$$

which after substituting the initial bound $c_{j-1}^+(0) = O(T^{A_j^0} e^{-3\sqrt{3}T})$ and the above bounds for c_{j-1}^- and c becomes

$$|c_{j-1}^+(t)| \lesssim T^{A_j^0+1} e^{-3\sqrt{3}T} e^{\sqrt{3}t}$$

which is the desired bound on the unstable trailing mode c_{j-1}^+ . These bounds imply in particular that

$$|c_{\neq j+1}(t)| \lesssim T^{A_j^0+1} e^{-\sqrt{3}T} e^{-\sqrt{3}t}$$

while from (3.25) we have

$$|c_{j+1}^-(t)| \lesssim e^{-\sqrt{3}t} c_{j+1}^-(0) + \int_0^t e^{-\sqrt{3}(t-s)} |c_{j+1}^+(s)| |c_{\neq j+1}^2(s)| ds.$$

Combining these bounds and also using the initial bound $c_{j+1}^-(0) = O(T^{A_j^0} e^{-3\sqrt{3}T})$ and the bound already obtained for c_{j+1}^+ , we conclude

$$|c_{j+1}^-(t)| \lesssim T^{2A_j^0+3} e^{-3\sqrt{3}T} e^{-\sqrt{3}t}$$

which is the desired bound on the leading stable mode c_{j+1}^- . □

Now we need more precise bounds on the leading modes. Here we will assume the initial data takes the form

$$\begin{aligned} c_{j+1}^+(0) &= \sigma e^{-\sqrt{3}T} a_{j+1}^+ + O(T^{A_j^0} e^{-2\sqrt{3}T}), \\ c_{\geq j+2}(0) &= e^{-2\sqrt{3}T} a_{\geq j+2} + O(T^{A_j^0} e^{-3\sqrt{3}T}) \end{aligned}$$

for some data $a_{j+1}^+ \in \mathbb{R}$, $a_{\geq j+2} \in \mathbb{C}^{N-j-1}$ of magnitude at most $O(1)$ and $r_j^0/2$ respectively, which we shall choose later. Henceforth the time variable is restricted to the interval $0 \leq t \leq T$.

Improved control of c_{j+1}^+ We begin by refining the control on the unstable leading mode. From Proposition 3.3 we see that any expression of the form $\mathcal{O}(c^3)$ splits as the sum of a term $\mathcal{O}((c_{j+1}^+)^3)$, plus an error of size $O(T^{3A_j^0+3} e^{-3\sqrt{3}T} e^{\sqrt{3}t})$. From (3.21) we thus have

$$\partial_t c_{j+1}^+ = \sqrt{3} c_{j+1}^+ + \mathcal{O}((c_{j+1}^+)^3) + O(T^{3A_j^0+3} e^{-3\sqrt{3}T} e^{\sqrt{3}t}).$$

Let us now compare this against the function \tilde{g} , defined as the solution of the associated equation

$$\partial_t \tilde{g} = \sqrt{3} \tilde{g} + \mathcal{O}(\tilde{g}^3)$$

with initial data

$$\tilde{g}(T) = \sigma, \tag{3.47}$$

at time T . If σ is small, then an easy continuity argument¹⁹ backwards in time shows that

$$|\tilde{g}(t)| \leq 2\sigma e^{-\sqrt{3}T} e^{\sqrt{3}t}.$$

¹⁹Alternatively, one could observe that \tilde{g} is basically the time reflection of the function g used in the preceding section.

In particular we have

$$\int_0^T |\tilde{g}(t)|^2 dt = O(1). \tag{3.48}$$

We now fix a_{j+1}^+ by requiring

$$\tilde{g}(0) = \sigma e^{-\sqrt{3}T} a_{j+1}^+, \tag{3.49}$$

thus $a_{j+1}^+ = O(1)$ as required. If we then use the ansatz

$$c_{j+1}^+ = \tilde{g} + E_{j+1}^+$$

then the error E_{j+1}^+ obeys the equation

$$\partial_t E_{j+1}^+ = \sqrt{3}E_{j+1}^+ + O(|\tilde{g}|^2|E_{j+1}|) + O(|E_{j+1}|^3) + O(T^{3A_j^0+3} e^{-3\sqrt{3}T} e^{\sqrt{3}t})$$

with initial data $E_{j+1}^+(0) = O(T^{A_j^0} e^{-2\sqrt{3}T})$. A simple application of the continuity method and Gronwall’s inequality (and (3.48)) then yields the bound

$$E_{j+1}^+(t) = O(T^{A_j^0} e^{-2\sqrt{3}T} e^{\sqrt{3}t})$$

for all $0 \leq t \leq T$. We thus conclude that

$$c_{j+1}^+(t) = \tilde{g}(t) + O(T^{3A_j^0+3} e^{-2\sqrt{3}T} e^{\sqrt{3}t}) \tag{3.50}$$

which then (in conjunction with the bounds in Proposition 3.3 implies that

$$\mathcal{O}(c^2) = \mathcal{O}(\tilde{g}^2) + O(T^{2A_j^0+2} e^{-2\sqrt{3}T}). \tag{3.51}$$

Improved control of $c_{\geq j+2}$ We now control the leading peripheral modes, by essentially the same argument used to control these modes in the previous section. From (3.17) and (3.51) we have

$$\partial_t c_{\geq j+2} = ic_{\geq j+2} + \mathcal{O}(\tilde{g}^2 c_{\geq j+2}) + O(T^{2A_j^0+1} e^{-2\sqrt{3}T} |c_{\geq j+2}|).$$

We approximate this by the corresponding linear equation

$$\partial_t u = iu + \mathcal{O}(u\tilde{g}^2)$$

where $u(t) \in \mathbb{C}^{M-j-1}$. This equation has a fundamental solution $\tilde{G}_{\geq j+2}(t) : \mathbb{C}^{M-j-1} \rightarrow \mathbb{C}^{M-j-1}$ for all $t \geq 0$, thus $G_{\geq j+2}(t)u(0) = u(t)$. From (3.48) and Gronwall’s inequality we have

$$|\tilde{G}_{\geq j+2}(t)|, |\tilde{G}_{\geq j+2}(t)^{-1}| = O(1). \tag{3.52}$$

We use the ansatz

$$c_{\geq j+2}(t) = e^{-2\sqrt{3}T} \tilde{G}_{\geq j+2}(t) a_{\geq j+2} + \tilde{E}_{\geq j+2}.$$

The error $\tilde{E}_{\geq j+2}$ then solves the equation

$$\partial_t \tilde{E}_{\geq j+2} = i \tilde{E}_{\geq j+2} + \mathcal{O}(\tilde{E}_{\geq j+2} \tilde{g}^2) + \mathcal{O}(T^{2A_j^0+2} e^{-2\sqrt{3}T} |c_{\geq j+2}|)$$

with initial data $\tilde{E}_{\geq j+2}(0) = \mathcal{O}(T^{A_j^0} e^{-3\sqrt{3}T})$. Applying the bound on $c_{\geq j+2}$ from Proposition 3.3 we see that

$$\partial_t |\tilde{E}_{\geq j+2}| = \mathcal{O}(|\tilde{E}_{\geq j+2}| |\tilde{g}|^2) + \mathcal{O}(T^{3A_j^0+2} e^{-4\sqrt{3}T}).$$

From Gronwall’s inequality and (3.48) we conclude that

$$|\tilde{E}_{\geq j+2}(t)| = \mathcal{O}(T^{3A_j^0+2} e^{-3\sqrt{3}T})$$

for all $0 \leq t \leq T$, and thus

$$c_{\geq j+2}(t) = e^{-2\sqrt{3}T} \tilde{G}_{\geq j+2}(t) a_{\geq j+2} + \mathcal{O}(T^{A_j^0} e^{-3\sqrt{3}T}). \tag{3.53}$$

3.9 Hitting the outgoing target

Our estimates are now sufficiently accurate to show that (M_j^0, d_j^0, R_j^0) can cover (M_j^+, d_j^+, R_j^+) . Consider an arbitrary point x_j^+ in M_j^+ , which in coordinates would take the form

$$\begin{aligned} c_{\leq j-1} &= c_{j+1}^- = 0, \\ c_{j+1}^+ &= \sigma, \\ c_{\geq j+2} &= z_{\geq j+2} e^{-2\sqrt{3}T} \end{aligned}$$

for some $z_{\geq j+2} \in \mathbb{C}^{N-j-1}$ of magnitude at most r_j^+ . We now specify a point x_j^0 in M_j^0 , which in coordinates has the form

$$\begin{aligned} c_{\leq j-1} &= c_{j+1}^- = 0, \\ c_{j+1}^+ &= \sigma e^{-\sqrt{3}T} a_{j+1}^+, \\ c_{\geq j+2} &= a_{\geq j+2} e^{-2\sqrt{3}T} \end{aligned}$$

with $a_{j+1}^+ = O(1)$ defined in (3.49) and some $a_{\geq j+2} \in \mathbb{C}^{N-j-1}$ of magnitude at most $r_j^0/2$ to be chosen later (see (3.55) below), such that given any data $c(0)$ which is within $R_j^0 = T^{A_j^0}$ of x_j^0 in the metric d_j^0 , thus in coordinates

$$\begin{aligned} c_{\leq j-2}(0) &= O(T^{A_j^0} e^{-2\sqrt{3}T}), \\ c_{j-1}^-(0) &= O(T^{A_j^0} e^{-\sqrt{3}T}), \\ c_{j-1}^+(0) &= O(T^{A_j^0} e^{-3\sqrt{3}T}), \\ c_{j+1}^-(0) &= O(T^{A_j^0} e^{-3\sqrt{3}T}), \\ c_{j+1}^+(0) &= \sigma e^{-\sqrt{3}T} a_{j+1}^+ + O(T^{A_j^0} e^{-2\sqrt{3}T}), \\ c_{\geq j+2}(0) &= a_{\geq j+2} e^{-2\sqrt{3}T} + O(T^{A_j^0} e^{-3\sqrt{3}T}) \end{aligned}$$

the evolution of this data at time T will lie within $R_j^+ = T^{A_j^+}$ of x_j^+ in the d_j^+ metric. Thus we aim to show,

$$\begin{aligned} &e^{2\sqrt{3}T} |c_{\leq j-1}(T)| + e^{4\sqrt{3}T} |c_{j+1}^-(T)| + e^{\sqrt{3}T} |c_{j+1}^+(T) - \sigma| \\ &+ e^{3\sqrt{3}T} |c_{\geq j+2}(T) - e^{-2\sqrt{3}T} z_{\geq j+2}| < T^{A_j^+}. \end{aligned} \tag{3.54}$$

We argue as in the previous section. From Proposition 3.3 we have

$$\begin{aligned} c_{\leq j-2}(T) &= O(T^{A_j^0} e^{-2\sqrt{3}T}), \\ c_{j-1}^-(T) &= O(T^{A_j^0+1} e^{-2\sqrt{3}T}), \\ c_{j-1}^+(T) &= O(T^{A_j^0+1} e^{-2\sqrt{3}T}), \\ c_{j+1}^-(T) &= O(T^{2A_j^0+3} e^{-4\sqrt{3}T}), \end{aligned}$$

which shows that the contribution of the trailing modes and the leading stable mode will be acceptable. From (3.50), (3.47) we have

$$c_{j+1}^+(T) = \sigma + O(T^{3A_j^0+3} e^{-\sqrt{3}T})$$

so the contribution of the leading unstable mode will also be acceptable. Finally, from (3.53) we have

$$c_{\geq j+2}(T) = e^{-2\sqrt{3}T} \tilde{G}_{\geq j+2}(T) a_{\geq j+2} + O(T^{A_j^0} e^{-3\sqrt{3}T})$$

so if we choose

$$a_{\geq j+2} = \tilde{G}_{\geq j+2}(T)^{-1} z_{\geq j+2} \tag{3.55}$$

then from (3.52) we see that $a_{\geq j+2}$ will have magnitude $O(r_j^+) \leq r_j^0/2$, and the contribution of the leading peripheral modes will also be acceptable. This completes the proof that (M_j^0, d_j^0, r_j^0) covers (M_j^+, d_j^+, r_j^+) .

3.10 Flowing from the outgoing target to the next incoming target

Fix $3 \leq j < N - 2$. To conclude the proof of Theorem 3.1 we need to show that (M_j^+, d_j^+, r_j^+) covers $(M_{j+1}^-, d_{j+1}^-, r_{j+1}^-)$. This turns out to be significantly simpler than the previous analysis because we will only need to flow²⁰ for a time $O(\log \frac{1}{\sigma})$ rather than time $O(T)$. This means that we can rely on much cruder Gronwall inequality-type tools than in preceding sections as we do not have to be so careful about exponential or even polynomial losses in T . On the other hand, the analysis here is more “nonperturbative” in that we are no longer close to a circle \mathbb{T}_j or \mathbb{T}_{j+1} but instead will be traversing the intermediate region connecting the two. Fortunately, we have an explicit²¹ solution (based on (3.7)) that we can follow (via standard perturbative theory) to carry us from one to the other without much difficulty.

We turn to the details. Before we begin, there is an issue of which coordinate system to use: the local coordinates around \mathbb{T}_j , the local coordinates around \mathbb{T}_{j+1} , or the global coordinates b_1, \dots, b_N . It is arguably more natural to use global coordinates for the transition from \mathbb{T}_j to \mathbb{T}_{j+1} , but we will continue using the local coordinates around \mathbb{T}_j since we have already built a fair amount of machinery in these coordinates. Also, these local coordinates have already quotiented out the phase invariance $x \mapsto e^{i\theta} x$ which would otherwise have required a small amount of attention.

Let us start with initial data within the outgoing target (M_j^+, d_j^+, r_j^+) . In the local coordinates around \mathbb{T}_j , such an initial data takes the form

$$\begin{aligned} c_{\leq j-1}(0) &= O(T^{A_j^+} e^{-2\sqrt{3}T}), \\ c_{j+1}^-(0) &= O(T^{A_j^+} e^{-4\sqrt{3}T}), \end{aligned}$$

²⁰Indeed, if we could take σ as large as $1/\sqrt{2}$ then we would not need to flow at all, and we could essentially match up the j th outgoing target with the $j + 1$ th incoming target. However we took advantage of the smallness of σ at too many places in the above argument, and so we are forced to add this bridging step as well.

²¹Actually, as in previous sections, the analysis can proceed without knowing the explicit form of this solution, only its qualitative properties, namely that it propagates from \mathbb{T}_j to \mathbb{T}_{j+1} using an unstable mode of the former and a stable mode of the latter. But as the solution is so simple, we will take advantage of its explicitness.

$$c_{j+1}^+(0) = \sigma + O(T^{A_j^+} e^{-\sqrt{3}T}),$$

$$c_{\geq j+2}(0) = e^{-2\sqrt{3}T} a_{\geq j+2} + O(T^{A_j^+} e^{-3\sqrt{3}T})$$

for some $a_{\geq j+2}$ of magnitude at most r_j^+ . Let us now consider the evolution of such data for times $0 \leq t \leq O(\log \frac{1}{\sigma})$. Because the unstable leading mode c_{j+1}^+ is already as large as σ , and is growing exponentially, we will no longer be in the perturbative regime covered by Lemma 3.2. However, we must necessarily stay within the region (3.23); note that the coordinate singularity $\{b_j = 0\}$ cannot actually be reached via the flow, because as remarked earlier the support of b is an invariant of the flow. The bound (3.23) will still allow us to use Gronwall-type arguments for a time period of $O(\log \frac{1}{\sigma})$, incurring (quite tolerable) losses which are polynomial in $1/\sigma$. (This is in contrast to the analysis of the previous sections, where such a crude argument would cost unacceptable factors of e^T .)

For the rest of this section we shall restrict the time variable t to the range $0 \leq t \leq 10 \log \frac{1}{\sigma}$ (say). From (3.17), (3.23) (and (3.19) for the trailing secondary mode) we have the crude estimates

$$\partial_t c_{\neq j+1} = O(|c_{\neq j+1}|)$$

so by Gronwall we have the crude bounds

$$c_{\neq j+1}(t) = O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-2\sqrt{3}T}\right). \tag{3.56}$$

We will return to establish more accurate bounds on the leading peripheral modes $c_{\geq j+2}$ shortly, but for now let us focus attention on the leading secondary modes c_{j+1}^-, c_{j+1}^+ . The stable leading mode c_{j+1}^- can be controlled by (3.20), which by (3.56) and (3.23) becomes

$$\partial_t c_{j+1}^- = O(|c_{j+1}^-|) + \frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}.$$

From Gronwall’s inequality we conclude that

$$c_{j+1}^-(t) = O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}\right). \tag{3.57}$$

Now we turn to the most important non-primary mode, namely the unstable leading mode c_{j+1}^+ . Because we are no longer in the perturbative regime, the schematic equation (3.21) has a form which is a little bit too crude for our purposes. Instead we return to (3.19). Taking advantage of the bounds (3.57),

(3.56) just obtained (as well as (3.23)), we can take the c_{j+1}^+ component of this equation and obtain

$$\partial_t c_{j+1}^+ = \sqrt{3}(1 - |c_{j+1}^+|^2)c_{j+1}^+ + O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}\right).$$

Now let us define \hat{g} to be the solution to the scalar ODE

$$\partial_t \hat{g} = \sqrt{3}(1 - |\hat{g}|^2)\hat{g} \tag{3.58}$$

with initial data $\hat{g}(0) = \sigma$. We can easily compute \hat{g} explicitly²² as

$$\hat{g}(t) = \frac{1}{\sqrt{1 + e^{-2\sqrt{3}(t-t_0)}}}$$

where the time t_0 is defined by the formula

$$\frac{1}{\sqrt{1 + e^{2\sqrt{3}t_0}}} = \sigma.$$

This is of course closely related to the slider solution (3.7) (see also Remark 3.4). Also observe that

$$\hat{g}(2t_0) = \frac{1}{\sqrt{1 + e^{-2\sqrt{3}t_0}}} = \sqrt{1 - \sigma^2}$$

and that $2t_0 \leq 10 \log \frac{1}{\sigma}$ if σ is small enough.

As in previous sections, we now use the ansatz

$$c_{j+1}^+ = \hat{g} + E_{j+1}^+$$

where (thanks to the boundedness of both \hat{g} and c_{j+1}^+) the error E_{j+1}^+ obeys the equation

$$\partial_t E_{j+1}^+ = O(|E_{j+1}^+|) + O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}\right)$$

with initial data $E_{j+1}^+(0) = O(T^{A_j^+} e^{-\sqrt{3}T})$. From Gronwall we thus have

$$E_{j+1}^+(t) = O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-\sqrt{3}T}\right)$$

²²For our analysis, the only property one needs of \hat{g} is that it flows from σ to $\sqrt{1 - \sigma^2}$ in finite time (the fact that this time is $O(\log \frac{1}{\sigma})$ is not essential to the argument). This is immediate from an inspection of the vector field associated to the ODE (3.58), but the argument via the explicit solution is equally brief.

and hence

$$c_{j+1}^+(t) = \hat{g}(t) + O\left(\frac{1}{\sigma O(1)} T^{A_j^+} e^{-\sqrt{3}T}\right). \tag{3.59}$$

In particular this (together with (3.57), (3.56)) implies that

$$O(c^2) = O(\hat{g}^2) + O\left(\frac{1}{\sigma O(1)} T^{A_j^+} e^{-\sqrt{3}T}\right). \tag{3.60}$$

Now we can return to improve the control on the leading peripheral modes $c_{\geq j+2}$. From (3.60), (3.56) and (3.17) we have

$$\partial_t c_{\geq j+2} = i c_{\geq j+2} + O(\hat{g}^2 c_{\geq j+2}) + O\left(\frac{1}{\sigma O(1)} T^{2A_j^+} e^{-3\sqrt{3}T}\right).$$

As in previous sections we approximate this flow by the linear equation

$$\partial_t u = i u + O(u \hat{g}^2)$$

where $u(t) \in \mathbb{C}^{N-j-1}$. This equation has a fundamental solution $\hat{G}_{\geq j+2}(t) : \mathbb{C}^{N-j-1} \rightarrow \mathbb{C}^{N-j-1}$ for all $t \geq 0$; from the boundedness of \hat{g} and Gronwall’s inequality we have

$$|\hat{G}_{\geq j+2}(t)|, |\hat{G}_{\geq j+2}(t)^{-1}| \lesssim \frac{1}{\sigma O(1)}. \tag{3.61}$$

We use the ansatz

$$c_{\geq j+2}(t) = e^{-2\sqrt{3}T} \hat{G}_{\geq j+2}(t) a_{\geq j+2} + E_{\geq j+2}$$

where the error $E_{\geq j+2}$ obeys an equation of the form

$$\partial_t E_{\geq j+2} = O(|E_{\geq j+2}|) + O\left(\frac{1}{\sigma O(1)} T^{2A_j^+} e^{-3\sqrt{3}T}\right)$$

with initial data $E_{\geq j+2}(0) = O(T^{A_j^+} e^{-3\sqrt{3}T})$. From Gronwall’s inequality we conclude

$$E_{\geq j+2}(t) = O\left(\frac{1}{\sigma O(1)} T^{2A_j^+} e^{-3\sqrt{3}T}\right)$$

and hence

$$c_{\geq j+2}(t) = e^{-2\sqrt{3}T} \hat{G}_{\geq j+2}(t) a_{\geq j+2} + O\left(\frac{1}{\sigma O(1)} T^{2A_j^+} e^{-3\sqrt{3}T}\right). \tag{3.62}$$

We specialize the above bounds to the time $t = 2t_0 \leq 10 \log \frac{1}{\sigma}$, and conclude that

$$\begin{aligned} c_{\leq j-1}(2t_0) &= O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-2\sqrt{3}T}\right), \\ c_{j+1}^-(2t_0) &= O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}\right), \\ c_{j+1}^+(2t_0) &= \sqrt{1-\sigma^2} + O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-\sqrt{3}T}\right), \\ c_{\geq j+2}(2t_0) &= e^{-2\sqrt{3}T} \hat{G}_{\geq j+2}(2t_0) a_{\geq j+2} + O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-3\sqrt{3}T}\right). \end{aligned}$$

Using (3.16), we conclude that

$$r = \sigma + O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-\sqrt{3}T}\right).$$

The phase θ is unspecified, but this will not concern us. We can now move back to the global coordinates b_1, \dots, b_N and conclude that

$$\begin{aligned} b_{\leq j-1}(2t_0) &= O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-2\sqrt{3}T}\right), \\ b_j(2t_0) &= \left(\sigma + \operatorname{Re} O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-\sqrt{3}T}\right)\right) e^{i\theta}, \\ b_{j+1}(2t_0) &= \left(\sqrt{1-\sigma^2} + \operatorname{Re} O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-\sqrt{3}T}\right)\right) \omega^2 e^{i\theta} \\ &\quad + O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}\right), \\ b_{\geq j+2}(2t_0) &= e^{i\theta} e^{-2\sqrt{3}T} \hat{G}_{\geq j+2}(2t_0) a_{\geq j+2} + O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-3\sqrt{3}T}\right) \end{aligned}$$

where we have inserted real parts in front of some error terms for emphasis.

We now recast this in terms of the local coordinates around \mathbb{T}_{j+1} ; to avoid confusion with the local coordinates \mathbb{T}_j , we shall denote these new coordinates with tildes, thus $\tilde{r}, \tilde{\theta}, \tilde{c}_{\leq j-1}, \tilde{c}_j^-, \tilde{c}_j^+, \tilde{c}_{j+2}^-, \tilde{c}_{j+2}^+, \tilde{c}_{\geq j+2}$. Firstly, $b_{j+1}(2t_0)$ is certainly non-zero (it has magnitude close to $\sqrt{1-\sigma^2}$), and an inspection of the phase of $b_{j+1}(2t_0)$ shows that

$$\tilde{\theta}(2t_0) = \theta + \frac{4\pi}{3} + O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}\right).$$

We then conclude that

$$\begin{aligned} \tilde{c}_{\leq j-1}(2t_0) &= O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-2\sqrt{3}T}\right), \\ \tilde{c}_j^-(2t_0) &= \sigma + O\left(\frac{1}{\sigma^{O(1)}} T^{A_j^+} e^{-\sqrt{3}T}\right), \\ \tilde{c}_j^+(2t_0) &= O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-4\sqrt{3}T}\right), \\ \tilde{c}_{\geq j+2}(2t_0) &= \omega e^{-2\sqrt{3}T} \hat{G}_{\geq j+2}(2t_0) a_{\geq j+2} + O\left(\frac{1}{\sigma^{O(1)}} T^{2A_j^+} e^{-3\sqrt{3}T}\right). \end{aligned}$$

From this and (3.61) it is an easy matter to show that $(M_{j+1}^-, d_{j+1}^-, R_{j+1}^-)$ is covered by (M_j^+, d_j^+, R_j^+) , by choosing $a_{\geq j+2}$ appropriately (note that any losses arising from (3.61) will be acceptable since r_j^+ is assumed to be much larger than r_{j+1}^- depending on σ).

4 Construction of the resonant set Λ

Fix $N \geq 2$. We begin by constructing an abstract combinatorial model $\Sigma = \Sigma_1 \cup \dots \cup \Sigma_N$ for the collection $\Lambda = \Lambda_1 \cup \dots \cup \Lambda_N$ of frequencies. Each element $x_0 \in \Sigma$ corresponds to a unique element $n_0 \in \Lambda$ and encodes both how n_0 is related to other elements of Λ , and (at least approximately) where n_0 is located in \mathbb{Z}^2 . The relationship between Σ and Λ will be made explicit later when we construct an embedding of Σ into \mathbb{Z}^2 and define Λ to be this image. Throughout this section, we identify the frequency lattice \mathbb{Z}^2 with the Gaussian integers $\mathbb{Z}[i] \subset \mathbb{C}$ in the usual manner $(n_1, n_2) \leftrightarrow n_1 + in_2$. Whereas Λ lives in the frequency lattice \mathbb{Z}^2 , Σ will live in a more abstract set (\mathbb{C}^{N-1} , to be precise).

To construct Σ , we define the *standard unit square* $S \subset \mathbb{C}$ to be the four-element set of complex numbers

$$S = \{0, 1, 1 + i, i\}.$$

We split $S = S_1 \cup S_2$, where $S_1 := \{1, i\}$ and $S_2 := \{0, 1 + i\}$. The combinatorial model Σ is a subset of a large power of the set S . More precisely, for any $1 \leq j \leq N$, we define $\Sigma_j \subset \mathbb{C}^{N-1}$ to be the set of all $N - 1$ -tuples (z_1, \dots, z_{N-1}) such that $z_1, \dots, z_{j-1} \in S_2$ and $z_j, \dots, z_{N-1} \in S_1$. In other words,

$$\Sigma_j := S_2^{j-1} \times S_1^{N-j}.$$

Note that each Σ_j consists of 2^{N-1} elements, and they are all disjoint. We then set $\Sigma = \Sigma_1 \cup \dots \cup \Sigma_N$; this set consists of $N2^{N-1}$ elements. We refer to Σ_j as the *j*th generation of Σ .

For each $1 \leq j < N$, we define a *combinatorial nuclear family connecting generations* Σ_j, Σ_{j+1} to be any four-element set $F \subset \Sigma_j \cup \Sigma_{j+1}$ of the form

$$F := \{(z_1, \dots, z_{j-1}, w, z_{j+1}, \dots, z_N) : w \in S\}$$

where $z_1, \dots, z_{j-1} \in S_2$ and $z_{j+1}, \dots, z_N \in S_1$ are fixed. In other words, we have

$$F = \{F_0, F_1, F_{1+i}, F_i\} = \{(z_1, \dots, z_{j-1})\} \times S \times \{(z_{j+1}, \dots, z_N)\}$$

where $F_w = (z_1, \dots, z_{j-1}, w, z_{j+1}, \dots, z_N)$. It is clear that F is a four-element set consisting of two elements F_1, F_i of Σ_j (which we call the *parents* in F) and two elements F_0, F_{1+i} of Σ_{j+1} (which we call the *children* in F). For each j there are 2^{N-2} combinatorial nuclear families connecting the generations Σ_j and Σ_{j+1} . One easily verifies the following properties:

- (Existence and uniqueness of spouse and children) For any $1 \leq j < N$ and any $x \in \Sigma_j$ there exists a unique combinatorial nuclear family F connecting Σ_j to Σ_{j+1} such that x is a parent of this family (i.e. $x = F_1$ or $x = F_i$). In particular each $x \in \Sigma_j$ has a unique spouse (in Σ_j) and two unique children (in Σ_{j+1}).
- (Existence and uniqueness of sibling and parents) For any $1 \leq j < N$ and any $y \in \Sigma_{j+1}$ there exists a unique combinatorial nuclear family F connecting Σ_j to Σ_{j+1} such that y is a child of the family (i.e. $y = F_0$ or $y = F_{1+i}$). In particular each $y \in \Sigma_{j+1}$ has a unique sibling (in Σ_{j+1}) and two unique parents (in Σ_j).
- (Nondegeneracy) The sibling of an element $x \in \Sigma_j$ is never equal to its spouse.

Example If $N = 7$, the point $x = (0, 1 + i, 0, i, i, 1)$ lies in the fourth generation Σ_4 . Its spouse is $(0, 1 + i, 0, 1, i, 1)$ (also in Σ_4) and its two children are $(0, 1 + i, 0, 0, i, 1)$ and $(0, 1 + i, 0, 1 + i, i, 1)$ (both in Σ_5). These four points form a combinatorial nuclear family connecting the generations Σ_4 and Σ_5 . The sibling of x is $(0, 1 + i, 1 + i, i, i, 1)$ (also in Σ_4 , but distinct from the spouse) and its two parents are $(0, 1 + i, 1, i, i, 1)$ and $(0, 1 + i, i, i, i, 1)$ (both in Σ_3). These four points form a combinatorial nuclear family connecting the generations Σ_3 and Σ_4 . Elements of Σ_1 do not have siblings or parents, and elements of Σ_7 do not have spouses or children.

Now we need to embed Σ into the frequency lattice \mathbb{Z}^2 . As mentioned above, we shall abuse notation and identify this lattice \mathbb{Z}^2 with the Gaussian integers $\mathbb{Z}[i]$ in the usual manner. We shall need a number of parameters:

- (Placement of initial generation) We will need a function $f_1 : \Sigma_1 \rightarrow \mathbb{C}$ which assigns to each point x in the first generation, a location $f_1(x)$ in the complex plane (eventually we will choose f to take values in the Gaussian integers).
- (Angle of each nuclear family) For each $1 \leq j < N$ and each combinatorial nuclear family F connecting the generations Σ_j and Σ_{j+1} , we need an angle $\theta(F) \in \mathbb{R}/2\pi\mathbb{Z}$.

Given the placement function of the first generation, and given all the angles, we can then recursively define the placement function $f_j : \Sigma_j \rightarrow \mathbb{C}$ for later generations $2 \leq j \leq N$ by the following rule:

- If $1 \leq j < N$ and $f_j : \Sigma_j \rightarrow \mathbb{C}$ has already been constructed, we define $f_{j+1} : \Sigma_{j+1} \rightarrow \mathbb{C}$ by requiring

$$f_{j+1}(F_{1+i}) = \frac{1 + e^{i\theta(F)}}{2} f_j(F_1) + \frac{1 - e^{i\theta(F)}}{2} f_j(F_i),$$

$$f_{j+1}(F_0) = \frac{1 + e^{i\theta(F)}}{2} f_j(F_1) - \frac{1 - e^{i\theta(F)}}{2} f_j(F_i)$$

for all combinatorial nuclear families F connecting Σ_j to Σ_{j+1} .

In other words, we require $f_j(F_1), f_{j+1}(F_{1+i}), f_j(F_i), f_{j+1}(F_0)$ to form the four points of a rectangle in \mathbb{C} , with the long diagonals intersecting at angle $\theta(F)$. Note that this definition is well-defined thanks to the existence and uniqueness of parents.

We define $f : \Sigma \rightarrow \mathbb{C}$ to be the function formed by concatenating the individual functions $f_j : \Sigma_j \rightarrow \mathbb{C}$. The function f will be referred to as the *complete placement function*.

A prototype embedding We present here a prototype for the embedding $f : \Sigma \rightarrow \mathbb{Z}^2$ which we eventually use. More precisely, we present a specific initial placement function f_1 , and choice of angle $\theta(F)$ for each nuclear family, which are a first step towards the eventual choices of f_1 and $\theta(F)$'s which determine Λ .

Let \mathcal{R} be a large integer, and let the initial placement function be

$$f_1(z_1, \dots, z_{N-1}) := \mathcal{R}z_1 \dots z_{N-1} \in \{\mathcal{R}, i\mathcal{R}, -\mathcal{R}, -i\mathcal{R}\}$$

for all $(z_1, \dots, z_{N-1}) \in \Sigma_1$.

Set all the angles $\theta(F)$ to equal $\pi/2$. Then one can show inductively that

$$f_j(z_1, \dots, z_{N-1}) := \mathcal{R}z_1 \dots z_{N-1}$$

$$\in \{0, (1+i)^{j-1}\mathcal{R}, i(1+i)^{j-1}\mathcal{R}, -(1+i)^{j-1}\mathcal{R}, -i(1+i)^{j-1}\mathcal{R}\}$$

for all $(z_1, \dots, z_{N-1}) \in \Sigma_j$.

Note that as the generations increase, an increasing majority of the points in that generation will get mapped to zero by the placement function, but an increasingly small minority will get mapped to larger and larger frequencies. For the final generation Σ_N , there is a single element $(1 + i, \dots, 1 + i)$ which is mapped to the very large frequency $(1 + i)^N \mathcal{R}$, whereas all the other $2^{N-1} - 1$ frequencies are mapped to zero. Notice that in each combinatorial nuclear family $F = \{F_0, F_1, F_{1+i}, F_i\}$ connecting Σ_j to Σ_{j+1} , the two parents F_1 and F_i get mapped to frequencies of equal magnitude (indeed, $f_j(F_i) = if_j(F_1)$), but of the two children, F_0 and F_{1+i} , one of the children (the “under-achiever” F_0) gets mapped to 0, whereas the other child (the “over-achiever” F_{1+i}) gets mapped to a frequency of magnitude $\sqrt{2}$ as large as that of its parents. Our *RFNLS* solution will distribute mass evenly from F_1 and F_i to F_0 and F_{1+i} , but will distribute the energy from F_1 and F_i almost entirely to F_{1+i} , thus sending the energy to increasingly high frequencies. Indeed by simply counting the number of nonzero frequencies in each generation of the prototype, one easily verifies that

$$\sum_{n \in f(\Sigma_{N-2})} |n|^{2s} = 2^{s(N-3)+2} \mathcal{R}^{2s}$$

and

$$\sum_{n \in f(\Sigma_3)} |n|^{2s} = 2^{2s+N-3} \mathcal{R}^{2s}$$

and so there is a norm explosion by a factor of $2^{(s-1)(N-5)}$ in the prototype family of frequencies.

Figure 7 contains a sketch of the prototype complete placement function’s image in the case $N = 5$. (We emphasize that this function is not injective—for example every generation after the first has several 4-tuples mapped to the origin.)

Fig. 7 The prototype embedding of frequencies in the case $N = 5$

The prototype embedding turns out not to be directly usable for us because it is highly non-injective, and also contains a large number of unwanted rectangles. But this can be fixed by a perturbation argument:

Theorem 4.1 (Construction of a good placement function) *Let $N \geq 2, s > 1$, and let \mathcal{R} be a sufficiently large integer (depending on N). Then there exists an initial placement function $f_1 : \Sigma_1 \rightarrow \mathbb{C}$ and choices of angles $\theta(F)$ for each nuclear family F (and thus an associated complete placement function $f : \Sigma \rightarrow \mathbb{C}$) with the following properties:*

- (Nondegeneracy) *The function f is injective.*
- (Integrity) *We have $f(\Sigma) \subset \mathbb{Z}[i]$.*
- (Magnitude) *We have $C(N)^{-1}\mathcal{R} \leq |f(x)| \leq C(N)\mathcal{R}$ for all $x \in \Sigma$.*
- (Closure and Faithfulness) *If $x_1, x_2, x_3 \in \Sigma$ are distinct elements of Σ are such that $f(x_1), f(x_2), f(x_3)$ form the three corners of a right-angled triangle, then x_1, x_2, x_3 belong to a combinatorial nuclear family.*
- (Norm explosion) *We have*

$$\sum_{n \in f(\Sigma_{N-2})} |n|^{2s} > \frac{1}{2} 2^{(s-1)(N-5)} \sum_{n \in f(\Sigma_3)} |n|^{2s}.$$

Providing this theorem is true, we see that the frequency set $\Lambda := f(\Sigma)$, with generations $\Lambda_j := f(\Sigma_j)$, obey all the required properties described in Sect. 2 above. (See e.g. the statement of Proposition 2.1.)

Proof To prove this theorem, we begin by a number of reductions which allow us to remove several of the constraints required on the placement function.

First we remove the requirement that the construction work for \mathcal{R} sufficiently large, by observing that as soon as we obtain an example involving a single $\mathcal{R} = \mathcal{R}_0$, we also get examples for any integer multiple $\mathcal{R} = k\mathcal{R}_0$ of \mathcal{R}_0 simply by multiplying f_1 (and hence f) by k . Since \mathcal{R} only appears in the magnitude hypothesis, we also get the same claim for any $\mathcal{R} > \mathcal{R}_0$ since any such \mathcal{R} is comparable up to a factor of two to an integer multiple of \mathcal{R} .

Thus we only need to exhibit an example for a single $\mathcal{R} = \mathcal{R}(N)$. But then the magnitude hypothesis would follow from the weaker hypothesis

- (Non-zero) $f(x) \neq 0$ for all $x \in \Sigma$

and we can now drop the magnitude hypothesis.

Next, we can weaken the integrality hypothesis $f(\Sigma) \subset \mathbb{Z}[i]$ to a rationality hypothesis $f(\Sigma) \subset \mathbb{Q}[i]$, since by dilating f_1 (and hence f) by a suitable large integer (the least common denominator of all the coefficients of $f(\Sigma)$).

Now observe that in order for $f(\Sigma)$ to lie in the complex rationals $\mathbb{Q}[i]$, it would suffice (by an easy induction argument) for the initial placement function f_1 to take values in $\mathbb{Q}[i]$, and for all the phases $\theta(F)$ to be *Pythagorean*, i.e. $e^{i\theta(F)} \in \mathbb{Q}[i]$. (A typical example of a Pythagorean phase is $\tan^{-1} \frac{3}{5}$.) So we may replace the rationality hypothesis by the hypothesis that the initial placement function is complex-rational and all the phases are Pythagorean.

However, the complex rationals $\mathbb{Q}[i]$ are dense in \mathbb{C} , and the Pythagorean phases are dense in $\mathbb{R}/2\pi\mathbb{Z}$ (indeed they form an infinite subgroup of this unit circle). Thus by a perturbation argument we may dispense with these conditions altogether. Note that the remaining conditions required are all open conditions, in that they are stable under sufficiently small perturbations of the parameters. Thus any non-rational solution to the above problem can be perturbed into a rational one.

We have now eliminated the integrality and magnitude hypotheses. We now work on eliminating the non-zero, injectivity, and closure/faithfulness hypotheses. The point is that in the parameter space (the space of initial placement functions f_1 and phases $\theta(F)$), the set of solutions to the norm explosion property is certainly an open set, so it is either empty or has positive measure. So it suffices to show that the sets where each of the non-zero, injectivity, and closure/faithfulness fail is a measure zero set, and thus they have no impact as to whether a solution actually exists or not.

Let's begin with the injectivity condition. We need to show that for each distinct $x, y \in \Sigma$, that we have $f(x) \neq f(y)$ for almost every choice of parameters f_1, θ . Without loss of generality we may take $x \in \Sigma_j$ and $y \in \Sigma_{j'}$ where $j \geq j'$. We induct on j . When $j = 1$ the claim is clear since in that case $f(x) = f_1(x)$ and $f(y) = f_1(y)$, and since there are absolutely no constraints on f_1 we see that $f_1(x) \neq f_1(y)$ for almost every choice of f_1 (the angles $\theta(F)$ are not relevant in this case).

Now suppose $j > 1$. Since $x \in \Sigma_j$, there is a unique combinatorial family $F := \{x, x', p, p'\}$ where $p, p' \in \Sigma_{j-1}$ are the parents of x and x' is the sibling of x . By induction hypothesis, we have $f(p) \neq f(p')$ for almost every choice of parameters. Now note that $f(x)$ lies on the circle with diameter $f(p), f(p')$, with the location on this circle determined by the angle $\theta(F)$. This angle $\theta(F)$ is a free parameter and will not influence the value of $f(y)$, unless y is equal to the sibling x' of x . But in the latter case $f(y) = f(x')$ will be diametrically opposite to $f(x)$ and thus unequal to $f(x)$ (since $f(p) \neq f(p')$). In all other cases we see that for almost every choice of $\theta(F)$, $f(x)$ will not be equal to $f(y)$, simply because a randomly chosen point on a circle will almost surely be unequal to any fixed point. This establishes injectivity almost everywhere.

A similar argument establishes the non-zero property almost everywhere: if x is in the first generation Σ_1 then it is clear that $f(x) = f_1(x) \neq 0$ for almost every f_1 , and for x in any later generation, $f(x)$ again ranges freely

on the circle generated by its two parents $f(p)$, $f(p')$ (which are distinct for almost every choice of parameters), determined by some angle parameter $\theta(F)$ and thus will be non-zero for almost all choices of $\theta(F)$.

Now we establish closure and faithfulness. Suppose $x \in \Sigma_{j_x}$, $y \in \Sigma_{j_y}$, $z \in \Sigma_{j_z}$ with $j_x \geq j_y \geq j_z$ are distinct and do not all belong to the same combinatorial nuclear family. We need to show that $f(x)$, $f(y)$, $f(z)$ do not form a right-angled triangle (with either $f(x)$, $f(y)$, or $f(z)$ being the right angle) for almost all choice of parameters.

We induct on j_x . When $j_x = 1$, we have $f(x) = f_1(x)$, $f(y) = f_1(y)$, $f(z) = f_1(z)$ and since f_1 is completely unconstrained it is clear that these three points will not form a right-angled triangle for almost all choices of parameters. Now we assume inductively that $j_x > 1$ and that the claim has already been proven for smaller values of j_x .

As before, x belongs to a family $F = \{x, x', p, p'\}$ consisting of x , its sibling, and its parents, ranges freely on the circle C with diameter $f(p)$, $f(p')$ generated by its two parents, with the position on this circle determined by the angle $\theta(F)$; recall that $f(p) \neq f(p')$ for almost all choices of parameters. This angle $\theta(F)$ will not influence either of $f(y)$ or $f(z)$ unless y or z is equal to the sibling x' , in which case $f(x')$ is the point diametrically opposite to $f(x)$. To proceed further, we next claim that the circle C contains no elements of $\Lambda_1 \cup \dots \cup \Lambda_{j_x}$ other than $f(x)$, $f(x')$, $f(p)$, $f(p')$. To see this for the first $j_x - 1$ generations $\Lambda_1 \cup \dots \cup \Lambda_{j_x-1}$ follows from the induction hypothesis, because if C contained a point $f(u)$ from one of those generations then $f(p)$, $f(p')$, $f(u)$ would be a right-angled triangle, contradicting the induction hypothesis for almost all choices of parameters. To see the claim for the last generation Λ_{j_x} , we note that any point $f(v)$ from that generation ranges on another circle C' spanned by the parents q, q' of v ; since $f(q)$ and $f(q')$ do not lie on C we know that C' is not co-incident to C , and so for almost all choices of the angle parameter determining $f(v)$ from $f(q)$ and $f(q')$ we know that $f(v)$ does not lie on C .

To summarize, we know that $f(x)$ varies freely on the circle C as determined by the angle $\theta(F)$, that $f(x')$ is diametrically opposite to $f(x)$, that $f(p)$, $f(p')$ are also diametrically opposite points on C , and all other points in $\Lambda_1 \cup \dots \cup \Lambda_{j_x}$ lie outside of C and are not affected by $\theta(F)$ (for almost all choices of parameters). Since $\{x, y, z\} \not\subset F = \{x, x', p, p'\}$ by hypothesis, this shows that for almost all choices of $\theta(F)$, $f(x)$, $f(y)$, $f(z)$ do not form a right-angled triangle.

From the preceding discussion we see that all we need to do now is establish a single example of parameters which exhibits the norm explosion property. But this was already achieved by the prototype embedding described above, and we are done. \square

Appendix: Cubic NLS on \mathbb{T}^2 has no asymptotically linear solutions

The main result of this paper is the construction of solutions to cubic NLS on the torus in which energy is transferred to higher frequencies—in particular the higher Sobolev norms grow to any (finite) extent desired. Because of the global well-posedness theory in H^s for this equation, and the fact that we're only describing the solution on a finite time interval, our main result does hold for a non-empty open set of data in H^s , but it's a small open set. In other words, the construction is not generic (though it is conjectured that this behavior *is* generic).

The motivation for this appendix is to establish rigorously that the explicit single-mode solutions (which are phase rotations of the linear solutions) are definitely not the generic behavior. This result is not surprising, and the aim of this appendix is provide a rigorous proof of the statement, independent of heuristics.

Consider H^1 solutions $u : \mathbb{R} \times \mathbb{T}^2 \rightarrow \mathbb{C}$ to the defocusing periodic NLS

$$-iu_t + \Delta u = |u|^2 u \quad (5.1)$$

on the torus \mathbb{T}^2 . We do not expect such solutions to scatter to a free solution $e^{-it\Delta} u_+$. Indeed, the explicit solutions to (5.1)

$$u(t, x) = A e^{i\kappa} e^{in \cdot x} e^{i|n|^2 t} e^{i|A|^2 t} \quad (5.2)$$

for $A \geq 0$, $\kappa \in \mathbb{R}/2\pi\mathbb{Z}$, $n \in \mathbb{Z}^2$ do not converge to a free solution, due to the presence of the phase rotation $e^{i|A|^2 t}$ caused by the nonlinearity. One may still hope that a solution to (5.1) scatters “modulo phase rotation”. However, the following result shows that this is only the case for the explicit solution (5.2) mentioned above.

Theorem 5.1 (No non-trivial scattering modulo phase rotation) *Let $u : \mathbb{R} \times \mathbb{T}^2 \rightarrow \mathbb{C}$ be an H^1 solution to (5.1) which scatters modulo phases in H^1 in the sense that there exists $u_+ \in H^1(\mathbb{T}^2)$ and a function $\theta : \mathbb{R} \rightarrow \mathbb{R}/2\pi\mathbb{Z}$ such that*

$$\|u(t) - e^{i\theta(t)} e^{-it\Delta} u_+\|_{H^1(\mathbb{T}^2)} \rightarrow 0$$

as $t \rightarrow +\infty$. Then u is of the form (5.2) for some $A \geq 0$, $\kappa \in \mathbb{R}/2\pi\mathbb{Z}$, $n \in \mathbb{Z}^2$.

To prove this theorem, we first need some harmonic analysis lemmas.

Lemma 5.1 (Compactness) *For any $u_+ \in H^1(\mathbb{T}^2)$, the set $\{e^{i\theta} e^{-it\Delta} u_+ : \theta \in \mathbb{R}/2\pi\mathbb{Z}, t \in \mathbb{R}\}$ is precompact (i.e. totally bounded) in H^1 .*

Proof By taking Fourier transforms, we see that it suffices to show that the set $\{e^{i\theta} e^{it|\cdot|^2} \widehat{u_+} : \theta \in \mathbb{R}/2\pi\mathbb{Z}, t \in \mathbb{R}\}$ is precompact in $l^2(\langle n \rangle^2 dn)$. But by monotone convergence, for every $\varepsilon > 0$ there exists $R > 0$ such that

$$\sum_{n \in \mathbb{Z}^2: |n| \geq R} \langle n \rangle^2 |\widehat{u_+}(n)|^2 \leq \varepsilon$$

from which we easily conclude that the set $\{e^{i\theta} e^{it|\cdot|^2} \widehat{u_+} : \theta \in \mathbb{R}/2\pi\mathbb{Z}, t \in \mathbb{R}\}$ is covered by finitely many balls of radius $O(\varepsilon)$, and the claim follows. \square

Lemma 5.2 (Diamagnetic inequality) *If $u \in H^1(\mathbb{T}^2)$, then $|u| \in H^1(\mathbb{T}^2)$ and $\| |u| \|_{H^1(\mathbb{T}^2)} \leq \|u\|_{H^1(\mathbb{T}^2)}$.*

Proof By a limiting argument (and Fatou’s lemma) it suffices to verify this when u is smooth. Observe that for any $\varepsilon > 0$ we have

$$\begin{aligned} 2|\sqrt{\varepsilon^2 + |u|^2} \nabla \sqrt{\varepsilon^2 + |u|^2}| &= |\nabla(\varepsilon^2 + |u|^2)| \\ &= 2|\operatorname{Re}(\bar{u} \nabla u)| \\ &\leq 2|u| |\nabla u| \end{aligned}$$

and hence

$$|\nabla \sqrt{\varepsilon^2 + |u|^2}| \leq |\nabla u|.$$

(This can also be seen by observing that the map $u \mapsto \sqrt{\varepsilon^2 + |u|^2}$ is a contraction.) Taking distributional limits as $\varepsilon \rightarrow 0$ we obtain the claim. \square

Lemma 5.3 (H^1 has no step functions) *Let $u \in H^1(\mathbb{T}^2)$ be such that $u(x)$ takes on at most two values. Then u is constant.*

Proof Without loss of generality we may assume that u takes on the values 0 and 1 only, thus $u^2 = u$. Differentiating this we obtain $2u \nabla u = \nabla u$, thus $(1 - 2u) \nabla u = 0$. But since $u^2 = u$, $(1 - 2u)^2 = 1$, and so $\nabla u = 0$, and so u is constant as required. (Note that all these computations can be justified in a distributional sense via Sobolev embedding since u lies in both H^1 and L^∞ , and thus lies in $L^p(\mathbb{T}^2)$ for every $1 \leq p \leq \infty$.) \square

Proof of Theorem 5.1 Let u, u_+, θ be as above. We may of course assume that u has non-zero mass. From Lemma 5.1 (and the continuity in H^1 of the

solution $t \mapsto u(t)$) we see that the set $\{u(t) : 0 \leq t \leq +\infty\}$ is precompact in H^1 . Thus we can find a sequence $t_m \rightarrow \infty$ such that $u(t_m)$ converges in H^1 to some limit v_0 . Applying Lemma 5.1 and passing to a subsequence, we can also assume that $e^{-it_m\Delta}u_+$ converges in H^1 to a limit v_+ . Since u has non-zero mass, we see on taking limits that v_+ also has non-zero mass.

Now let $v^{(m)} : \mathbb{R} \times \mathbb{T}^2 \rightarrow \mathbb{C}$ be the time-translated solutions $v^{(m)}(t) := u(t + t_m)$, thus $v^{(m)}(0)$ converges in H^1 to v_0 . Let $v : \mathbb{R} \times \mathbb{T}^2 \rightarrow \mathbb{C}$ be the solution to NLS with initial data $v(0) = v_0$. By the H^1 local well-posedness theory we conclude that $v^{(m)}$ converges uniformly in H^1 to v on every compact time interval $[-T, T]$. On the other hand, by hypothesis, for every t we have

$$\|v^{(m)}(t) - e^{i\theta(t+t_m)}e^{-i(t+t_m)\Delta}u_+\|_{H^1} \rightarrow 0$$

as $m \rightarrow \infty$. Since $e^{-it_m\Delta}u_+$ converges to v_+ , we conclude (since $e^{-it\Delta}$ is unitary on H^1) that

$$\|v^{(m)}(t) - e^{i\theta(t+t_m)}e^{-it\Delta}v_+\|_{H^1} \rightarrow 0.$$

On taking limits, we conclude that

$$v(t, x) = e^{i\alpha(t)}e^{-it\Delta}v_+(x) \tag{5.3}$$

for some $\alpha(t) \in \mathbb{R}/2\pi\mathbb{Z}$. In particular, since v_+ has non-zero mass, we have the identity

$$e^{i\alpha(t)} = \frac{1}{\|v_+\|_{L^2}^2} \int_{\mathbb{T}^2} v(t) \overline{e^{-it\Delta}v_+} dx.$$

From (5.1) and Sobolev embedding we see that $v(t)$ is continuously differentiable in $H^{-1}(\mathbb{T}^2)$, and so from the above identity we see that α is continuously differentiable in time.

Now we apply $(-i\partial_t + \Delta)$ to both sides of (5.3). Using the NLS equation, we conclude that

$$|v(t, x)|^2 v(t, x) = \alpha'(t) e^{i\alpha(t)} e^{-it\Delta} v_+(x)$$

and thus by (5.3) we have

$$|v(t, x)|^2 = \alpha'(t)$$

whenever $v(t, x) \neq 0$. Thus we see that for each time t , $|v(t, x)|$ takes on at most two values. By Lemmas 5.2 and 5.3, we conclude that $|v(t, x)|$ is constant in x ; by (5.3), we see that the same is true for $|e^{-it\Delta}v_+|$. By mass conservation we conclude that $|e^{-it\Delta}v_+|$ is also constant in time. Since v_+ has non-zero mass, we can thus write

$$e^{-it\Delta}v_+ = A\phi$$

almost everywhere for some function $\phi : \mathbb{R} \times \mathbb{T}^2 \rightarrow S^1$ and some constant amplitude $A > 0$. Since v_+ was in H^1 , we see that $\phi(t)$ is in H^1 also for every t . Differentiating the identity $\phi\bar{\phi} = 1$, we see that $\partial_j\phi\bar{\phi}$ is imaginary almost everywhere for $j = 1, 2$, thus $\partial_j\phi(t, x)$ is an imaginary multiple of $\phi(t, x)$ for almost every (t, x) . This implies that the imaginary vector field $\nabla\phi\bar{\phi}$ is curl-free (and also in L^2 uniformly in t), and thus by Hodge theory (and periodic extension from \mathbb{T}^2 to \mathbb{R}^2) we may write $\nabla\phi\bar{\phi} = i\nabla\omega$ for some $\omega : \mathbb{R} \times \mathbb{R}^2 \rightarrow \mathbb{R}$ which is locally in H^1 uniformly in t . This implies that $\nabla(\phi e^{-i\omega}) = 0$; thus by adjusting ω by a constant independent of space we may assume that $\phi = e^{i\omega}$, thus

$$e^{-it\Delta}v_+ = Ae^{i\omega(t,x)}.$$

Applying $(-i\partial_t + \Delta)$ to both sides, we conclude that

$$0 = Ae^{-i\omega}(\omega_t + i\Delta\omega - |\nabla\omega|^2)$$

in the sense of distributions. Since A is non-zero, we conclude that

$$\omega_t + i\Delta\omega - |\nabla\omega|^2 = 0.$$

Taking imaginary parts we conclude that $\Delta\omega = 0$, and in particular at time $t = 0$ ω is a harmonic function from \mathbb{R}^2 to \mathbb{R} . On the other hand, from the identity $\nabla\phi\bar{\phi} = i\nabla\omega$ we know that $\nabla\omega$ is periodic, so ω has at most linear growth. Thus (by Liouville’s theorem) ω must in fact be linear. Descending back to \mathbb{T}^2 , we conclude that $e^{i\omega(0,x)} = e^{i(n\cdot x + \beta)}$ for some $n \in \mathbb{Z}^2$ and $\beta \in \mathbb{R}/2\pi\mathbb{Z}$. Thus we have

$$v_+(x) = Ae^{i\beta}e^{in\cdot x}.$$

Since $e^{it_m\Delta}u_+$ converges to v_+ , $e^{-it_m\Delta}v_+$ converges to u_+ . But $e^{-it_m\Delta}v_+$ is a multiple of $Ae^{in\cdot x}$ by a phase; thus we have

$$u_+(x) = Ae^{i\gamma}e^{in\cdot x}.$$

Applying phase rotation and Galilean symmetry (noting that the conclusion of the theorem is invariant under these symmetries) we may assume $\gamma = n = 0$. Thus $u_+ = A$, and we have

$$\|u(t) - e^{i\theta(t)}e^{-it\Delta}A\|_{H^1(\mathbb{T}^2)} \rightarrow 0 \quad \text{as } t \rightarrow \infty.$$

From mass and energy conservation we conclude

$$\int_{\mathbb{T}^2} |u(t, x)|^2 dx = A^2|\mathbb{T}^2|$$

and

$$\int_{\mathbb{T}^2} \frac{1}{2} |\nabla u(t, x)|^2 + \frac{1}{4} |u(t, x)|^4 dx = \frac{1}{4} A^4 |\mathbb{T}^2|.$$

On the other hand, from Hölder's inequality we have

$$\int_{\mathbb{T}^2} \frac{1}{4} |u(t, x)|^4 dx \geq \frac{1}{4 |\mathbb{T}^2|} \left(\int_{\mathbb{T}^2} |u(t, x)|^2 dx \right)^2 = \frac{1}{4} A^4 |\mathbb{T}^2|.$$

Thus we must have

$$\int_{\mathbb{T}^2} \frac{1}{2} |\nabla u(t, x)|^2 dx = 0,$$

thus u is constant in space, and thus is of the form $u(t, x) = Ae^{i\kappa(t)}$. Applying (5.1) we see that $u(t, x) = Ae^{i\kappa(0)} e^{i|A|^2 t}$, and the claim follows. \square
