30 **mineral assemblages suggest that Mars' climate was once warmer and liquid water flowed on the surface.**  
31 **These observations may indicate a substantially more massive atmosphere in the past, but there have been**  
32 **few observational constraints on paleoatmospheric pressures. Here we show how the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios of**  
33 **trapped gases within Martian meteorite ALH 84001 constrain paleoatmospheric pressure on Mars during the**  
34 **Noachian Era [~4.56-3.8 billion years (Ga)]. Our model indicates that atmospheric pressures did not exceed**  
35 **~1.5 bar during the first 400 million years (Ma) of the Noachian era, and were <400 mbar by 4.16 Ga. Such**  
36 **pressures of CO<sub>2</sub> are only sufficient to stabilize liquid water on Mars' surface at low latitudes during**  
37 **seasonally warm periods. Other greenhouse gases like SO<sub>2</sub> and water vapor may have played an important**  
38 **role in intermittently stabilizing liquid water at higher latitudes following major volcanic eruptions or impact**  
39 **events.**

40       The composition and mass of the ancient Martian atmosphere are key parameters of planetary evolution that  
41 remain poorly understood. Radiative transfer models suggest that a greater pressures of greenhouse gases in the past  
42 (e.g., >5 bars of CO<sub>2</sub>) were necessary to sustain surface temperatures above freezing for prolonged durations<sup>1-5</sup>.  
43 Alternatively, large impacts may have vaporized subsurface volatiles and generated relatively brief periods of warm  
44 and wet conditions (e.g., 10<sup>2</sup>-10<sup>3</sup> years)<sup>6</sup>, which may explain why a decrease in fluvial erosion appears to coincide  
45 with the end of the heavy impact bombardment<sup>7</sup>. Both explanations imply climate conditions during the Noachian  
46 era that were significantly different from the present. However, whereas prolonged periods of high concentrations  
47 of greenhouse gases implicate warm and wet surface environments conducive to life, intermittent impact-driven  
48 greenhouse events do not.

49       Observational constraints on past climate conditions on Mars are limited. The scarcity of carbonate minerals<sup>8-10</sup>  
50 (expected to form in low-SO<sub>2</sub> aqueous environments) and the apparently low partial pressures of CO<sub>2</sub> required to  
51 explain the alteration of Noachian surface rocks to clay minerals (0.001-0.01 bar)<sup>11</sup> suggest that a dense CO<sub>2</sub>-rich  
52 atmosphere did not persist throughout the Noachian. The identification of sulfate deposits in the Martian regolith<sup>12-14</sup>  
53 indicates that atmospheric SO<sub>2</sub> and H<sub>2</sub>S may have contributed to greenhouse warming. Modest influxes of SO<sub>2</sub> and  
54 H<sub>2</sub>S (e.g., ~2 × 10<sup>-6</sup> bar) in the presence of only 50 mbar CO<sub>2</sub> can promote transient periods of warm, wet  
55 conditions<sup>15,16</sup>. Despite these observations, whether a dense, CO<sub>2</sub>-rich atmosphere ever existed and the extent to

56 which other greenhouse gases contributed to warming remain poorly understood.

57 Martian meteorites contain trapped atmospheric gases<sup>17</sup> that provide chemical constraints on past atmospheric  
58 conditions. Cassata et al.<sup>18</sup> identified a trapped argon (Ar) component within maskelynite in the  $4.16 \pm 0.04$  Ga old  
59 Martian meteorite ALH 84001 with an  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of  $626 \pm 100$  (Fig. 1). Here we present the first attempt to use  
60 this isotopic composition to constrain atmospheric pressure on Mars between the time of planetary formation and the  
61 4.16 Ga age of the maskelynite. We discuss the implications of these pressure limits for greenhouse warming,  
62 atmospheric evolution, and climate on Mars during the Noachian era. Critical to our arguments is the assumption  
63 that the trapped argon component identified within maskelynite is atmospheric in origin and was emplaced in the  
64 meteorite at 4.16 Ga. The concordance of the maskelynite  $^{40}\text{Ar}/^{36}\text{Ar}$  vs.  $^{39}\text{Ar}/^{36}\text{Ar}$  isochron diagram (Fig. 1) provides  
65 strong support for such an interpretation; terrestrial feldspars and glasses with appreciably non-atmospheric trapped  
66 components generally fail to produce linear isochron diagrams (discussed in detail in the supplementary files).

67

### 68 **An atmospheric $^{40}\text{Ar}$ evolution model**

69 A comparison of the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios of Earth and Mars reveals significant differences in the  
70 evolution of the two atmospheres (Fig. 1). On Earth, the net transport of volatiles from the asthenosphere and  
71 lithosphere to the atmosphere has elevated the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio from its primordial ratio of  $\sim 10^{-3}$  at 4.56  
72 Ga<sup>19</sup> to the present value of  $>298$ <sup>20</sup>. Meteorite measurements indicate that on Mars, the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio  
73 increased from  $\sim 10^{-3}$  at 4.56 Ga, to  $626 \pm 100$  at 4.16 Ga, to the present value of  $\sim 1800$ <sup>17</sup>. Thus, the net effects of  
74 Martian planetary degassing and late stage planetary accretion increased the Martian atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio to  
75 more than twice the modern ratio on Earth, but over only  $\sim 1/10$  the duration ( $\sim 400$  Ma). The relatively rapid  
76 evolution in the Martian atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio suggests that one or more of the following is true:

- 77 (1) the potassium (K) concentration of Mars is greater than Earth, such that significantly more radiogenic  $^{40}\text{Ar}$   
78 was generated early on Mars,
- 79 (2) the  $^{36}\text{Ar}$  concentration of Mars' interior is lower than Earth's, such that extracted magmas had elevated  
80  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios relative to terrestrial magmas of equivalent age and K concentration,
- 81 (3) planetary degassing was more efficient on early Mars than Earth, such that a greater proportion of  
82 radiogenic  $^{40}\text{Ar}$  was delivered from the astheno-lithosphere to the atmosphere, and/or

83 (4) Mars had a thinner atmosphere than Earth (i.e., less atmospheric  $^{36}\text{Ar}$ ), such that a given quantity of  
84 degassed  $^{40}\text{Ar}$  more efficiently elevated the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio.

85 **In this paper, we use published constraints on (1) – (3) to assess whether or not (4) is a viable explanation for**  
86 **Mars' elevated  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio at 4.16 Ga.** We simulate planetary degassing under a broad range of atmospheric  
87 pressure conditions and explore the resulting evolution in the Martian atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio during the  
88 Noachian. Our objective is to place bounds on atmospheric pressures during the first ~400 Ma of Martian history  
89 that are consistent with an  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of  $626 \pm 100$  at 4.16 Ga. We begin with the following postulates:

90 (1) Mars was assembled from bodies that had an initial inventory of volatiles with  $^{40}\text{Ar}/^{36}\text{Ar} < 10^{-3}$  (ref. <sup>19</sup>).

91 (2) Planetary degassing and meteorite accretion added both radiogenic volatiles ( $^{40}\text{Ar}$ ) and non-radiogenic  
92 volatiles ( $^{36}\text{Ar}$ ,  $\text{N}_2$ , and  $\text{CO}_2$ ) to the atmosphere.

93 (3) Atmospheric loss due to impact erosion removed volatiles, but did not fractionate  $^{36}\text{Ar}$  and  $^{40}\text{Ar}$ <sup>21,22</sup>.

94 (4) At  $4.16 \pm 0.04$  Ga the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio was  $626 \pm 100$ , as indicated by the trapped component in  
95 ALH 84001 maskelynite<sup>18</sup>.

96 Under these conditions, the atmospheric molar abundance of Ar isotope  $X$  varies through time according to the  
97 following equation:

$$98 \quad \frac{d^X\text{Ar}}{dt} = N_X(t) - \left( {}^X\text{Ar} \frac{L(t)}{P(t)} \right), \quad (1)$$

99 where  ${}^X\text{Ar}$  denotes the total atmospheric abundance,  $N_X(t)$  is the rate of addition of isotope  $X$  to the atmosphere due  
100 to planetary degassing and meteorite accretion,  $P(t)$  is atmospheric pressure, and  $L(t)$  is the rate of atmospheric  
101 pressure loss due to impact erosion. The latter are related by:

$$102 \quad \frac{dP}{dt} = I(t) - L(t), \quad (2)$$

103 where  $I(t)$  is the total rate of atmospheric pressure increase due to planetary degassing of all gaseous species,  
104 which is essentially equal to the rate of increase in  $\text{CO}_2$  since it comprises >95% of the present atmosphere.

105 To constrain the initial Martian atmospheric pressure and its subsequent evolution, we simulated a range of  
106 hypothetical paleoatmospheric pressure paths. In each scenario,  $P(t)$  declines over time due to impact erosion of  
107 atmospheric gases (i.e.,  $L$  remains greater than  $I$ ). We assume that other escape processes that enrich  $^{40}\text{Ar}$  relative to  
108  $^{36}\text{Ar}$  (i.e., pick-up ion sputtering **and hydrodynamic escape**) were not significant during the first 400 million years of

109 the Noachian due to the existence of a magnetic dynamo<sup>18,21,23-25</sup>. Only minor differences in the inferred atmospheric  
110 pressures would results if such processes were included in our model (discussed below). We allow for initial  
111 atmospheric pressures between 0.1 and 10 bar, and then explore various scenarios in which pressure declines either  
112 randomly, exponentially with the same scale parameter as that of the Martian impact flux<sup>22</sup> (to approximate impact  
113 erosion in absence of planetary degassing), or linearly to final pressures of 0.01 to 1 bar at 4.16 Ga (to approximate  
114 an exponential rate of loss due to impact erosion damped by increases in pressure due to planetary degassing). Using  
115 these  $P(t)$  curves and a planetary degassing model (discussed below), we then solved Eqs. (1) and (2) to constrain  
116 paleoatmospheric pressure paths that yield  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios of  $626 \pm 100$  at 4.16 Ga. A detailed description of our  
117 implementation of equations (1) and (2) is given in the supplementary files.

118

### 119 **Model Parameters**

120 To calculate the production of atmospheric volatiles associated with surface, crustal, and upper mantle  
121 magmatic activity, we adopted the crustal growth model of Breuer and Spohn<sup>26</sup> for an initial mantle temperature of  
122 2000 K and no primordial crust (a summary of all model parameters is given in Table 1). Relative to other models,  
123 Breuer and Spohn<sup>26</sup> predict a higher rate of magma production and, therefore,  $^{40}\text{Ar}$  delivery to the atmosphere.  
124 Because a higher  $^{40}\text{Ar}$  production rate demands higher atmospheric pressure (i.e., more atmospheric  $^{36}\text{Ar}$ ) to  
125 maintain a given  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio, using Breuer and Spohn<sup>26</sup> places an upper bound on permissible atmospheric  
126 pressures during the Noachian. Less voluminous magmatic production models would predict up to an order of  
127 magnitude lower pressures during the Noachian. We assumed that magmas contain between 1300 ppm K (e.g.,  
128 Nakhla meteorite)<sup>27</sup> and 3300 ppm K (e.g., Mars' crust)<sup>28</sup>. To estimate the concentration of  $\text{CO}_2$  in magmas we used  
129 values published for melt inclusions in Martian meteorites, which typically range from 5-500 ppm<sup>29</sup>. This is  
130 consistent with estimates of magmatic  $\text{CO}_2$  concentrations based on thermodynamic equilibrium between dissolved  
131 carbon and graphite in the Martian mantle (50-500 ppm)<sup>30</sup>, and measurements of  $\text{CO}_2$  concentrations in MORB  
132 source regions (<250 ppm)<sup>31</sup>. No direct measurements of  $^{36}\text{Ar}$  concentrations in Martian meteorite melt inclusions  
133 have been published. We assumed that the  $^{36}\text{Ar}/\text{CO}_2$  ratio observed in ALH 84001 pyroxenes ( $\sim 10^{-8}$ - $10^{-9}$ )<sup>18,32</sup>

134 reflects that of mantle melts<sup>1</sup>. The model results differ by less than approximately a factor of two for the ranges in  
135 assumed magmatic K, <sup>36</sup>Ar, and CO<sub>2</sub> concentrations (see supplementary files).

136 To model the mass of <sup>40</sup>Ar added to the atmosphere by asteroids, we used the Martian impact flux derived by  
137 Melosh and Vickery<sup>22</sup> from the lunar cratering record of Neukum and Wise<sup>33</sup> following Manning et al.<sup>34</sup> (see  
138 supplementary files). We assumed that impacting asteroids contain a chondritic abundance of K (550 ppm)<sup>35</sup> and  
139 <sup>36</sup>Ar concentrations typical of H-, L-, and LL-chondrites (~15 ppt)<sup>36</sup>. Impact-derived <sup>40</sup>Ar is negligible in  
140 comparison to mantle-derived <sup>40</sup>Ar (<1%). We neglect the insignificant amounts of CO<sub>2</sub> and N<sub>2</sub> brought to Mars by  
141 impactors.

142

### 143 *The initial atmospheric <sup>36</sup>Ar/(N<sub>2</sub>+CO<sub>2</sub>) ratio*

144 The extent to which the addition of <sup>40</sup>Ar increases the atmospheric <sup>40</sup>Ar/<sup>36</sup>Ar ratio is inversely proportional to  
145 the abundance of atmospheric <sup>36</sup>Ar. Thus, an important variable in our model is the primordial abundance of  
146 atmospheric <sup>36</sup>Ar, which, in an atmosphere composed primarily of N<sub>2</sub> and CO<sub>2</sub>, can be expressed as initial  
147 atmospheric pressure ( $P_0$ ) multiplied by the initial atmospheric <sup>36</sup>Ar/(N<sub>2</sub>+CO<sub>2</sub>) ratio. The current Martian  
148 atmospheric <sup>36</sup>Ar/(CO<sub>2</sub>+N<sub>2</sub>) ratio is ~10<sup>-5</sup> (refs. 17,37)<sup>2</sup>, but this ratio may have been different in the past as  
149 atmospheric escape processes, mantle degassing, and authigenic mineralization of carbonates have fractionated N<sub>2</sub>,  
150 CO<sub>2</sub>, and Ar over time. To determine maximum atmospheric pressures during the Noachian we must estimate the  
151 minimum primordial <sup>36</sup>Ar/(CO<sub>2</sub>+N<sub>2</sub>) ratio; the lowest value *a priori* implies the greatest abundance of atmospheric  
152 CO<sub>2</sub> and N<sub>2</sub> for a given quantity of <sup>36</sup>Ar. We will ultimately assume an initial atmospheric <sup>36</sup>Ar/(CO<sub>2</sub>+N<sub>2</sub>) ratio of  
153 10<sup>-5</sup> for reasons discussed below.

154 Authigenic mineralization of carbonates enriches the relative concentration of atmospheric Ar by depleting  
155 CO<sub>2</sub>. While spectral observations have not identified massive near-surface carbonate deposits<sup>8,9</sup>, carbonate has been  
156 discovered in outcrops in the Nili Fossae region<sup>38</sup> and the Columbia Hills of Gusev crater<sup>39,40</sup>, in regolith at the  
157 Phoenix landing site<sup>41</sup>, and in some Martian meteorites (e.g., ALH 84001). We can estimate the extent to which CO<sub>2</sub>  
158 has been depleted relative to other atmospheric gases by comparing Mars' volatile budget with that of other  
159 terrestrial planets<sup>42</sup>. The atmospheres of Venus and Earth have similar C/N ratios of ~15 (ref. <sup>43</sup>) and 20 ± 10 (ref.

---

<sup>1</sup> <sup>36</sup>Ar/CO<sub>2</sub> ratio for ALH 84001 orthopyroxene based on 14-167 ppm CO<sub>2</sub> (Boctor et al., 2006) and 0.3 ppt <sup>36</sup>Ar (excludes cosmogenic <sup>36</sup>Ar; Cassata et al., 2010).

<sup>2</sup> Calculated assuming the Martian atmosphere contains 1.6% Ar by volume (Owen et al., 1977) with a <sup>40</sup>Ar/<sup>36</sup>Ar ratio of 1800 (Bogard et al., 2001).

160 <sup>42</sup>), respectively, when CO<sub>2</sub> bound in carbonates is considered in the terrestrial inventory. The similarity of these  
161 planetary volatile ratios presumably reflects derivation from common meteoritic sources that were also parental to  
162 the Martian atmosphere<sup>44</sup>. Mars' atmospheric C/N ratio is not directly comparable to that of Earth and Venus  
163 because non-thermal escape processes have fractionated C and N over time. Based on Mars' heavy <sup>15</sup>N/<sup>14</sup>N ratio<sup>1</sup>,  
164 these processes are estimated to have removed approximately 90% of Mars' atmospheric N not lost to space via  
165 impact erosion<sup>1</sup>. Assuming no loss of atmospheric CO<sub>2</sub> (as a limiting constraint), the fractionation-corrected Martian  
166 atmospheric C/N ratio is ~2. If we assume that the difference between this ratio and that of Earth and Venus (~15)  
167 reflects CO<sub>2</sub> bound in carbonates, then CO<sub>2</sub> has been depleted by up to ~87% (i.e., 13/15) relative to N. Similarly,  
168 Owen and Bar-Nun<sup>42</sup> estimated that CO<sub>2</sub> has been depleted by 90% relative to Kr based on differences between the  
169 Martian atmospheric <sup>84</sup>Kr/C ratio and that of Earth and Venus. The mass of near-surface carbonates associated with  
170 this CO<sub>2</sub> depletion depends on atmospheric pressures at times when deposition occurred.

171 The effect of the abovementioned CO<sub>2</sub> sequestration on the atmospheric <sup>36</sup>Ar/(CO<sub>2</sub>+N<sub>2</sub>) would be offset, at least  
172 in part, by the preferential atmospheric escape of Ar relative to CO<sub>2</sub>, and by mantle degassing. Based on Mars'  
173 elevated <sup>38</sup>Ar/<sup>36</sup>Ar ratio of ~0.24<sup>17</sup>, non-thermal escape processes are estimated to have removed approximately 50%  
174 of Mars' atmospheric Ar not lost to space via impact erosion<sup>1</sup>. If we assume no loss of atmospheric CO<sub>2</sub> (to be  
175 consistent with the constraints on CO<sub>2</sub> sequestration imposed above), then CO<sub>2</sub> has then been enriched by up to 50%  
176 relative to <sup>36</sup>Ar. Likewise, planetary degassing enriches the atmosphere in CO<sub>2</sub> as mantle-derived volatiles are  
177 depleted in <sup>36</sup>Ar relative to the atmosphere (discussed above). In our model, ~2 bars of mantle-derived CO<sub>2</sub> are  
178 degassed; the resulting enrichment in CO<sub>2</sub> relative to <sup>36</sup>Ar is directly proportional to atmospheric pressure, and is  
179 >25% at initial atmospheric pressures as high as 5 bars. Altogether, we expect that increases in the atmospheric  
180 <sup>36</sup>Ar/(CO<sub>2</sub>+N<sub>2</sub>) ratio due to CO<sub>2</sub> sequestration in carbonates (up to 90%) were approximately offset by decreases due  
181 to escape processes (up to 50%) and mantle degassing (>25%). Thus we use a primordial atmospheric  
182 <sup>36</sup>Ar/(CO<sub>2</sub>+N<sub>2</sub>) ratio of 10<sup>-5</sup> in our preferred model, with one log unit uncertainty. Fractionation of N<sub>2</sub> has been  
183 ignored because of its low abundance relative to CO<sub>2</sub>.

184

## 185 **Results and discussion**

186 In Figure 2, using our preferred model parameters (Table 1), we show a selection of linearly and exponentially  
187 decreasing paleoatmospheric pressure paths that yield an <sup>40</sup>Ar/<sup>36</sup>Ar ratio of 626 ± 100 at 4.16 Ga. A more extensive

188 array of pressure paths that succeed and fail to predict this ratio, along with an analysis of the model sensitivities to  
189 each of four variable parameters listed in Table 1, is given in the supplementary files. We find that low atmospheric  
190 pressures throughout the Noachian (<1 bar on average) are required to produce the observed  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio at 4.16  
191 Ga. Higher atmospheric pressures, and therefore greater *total* abundances of atmospheric  $^{36}\text{Ar}$ , preclude an adequate  
192 increase in the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio for the range in mantle degassing scenarios explored and our best estimates of  
193 planetary and atmospheric element abundances. All scenarios require atmospheric pressures of <400 mbar by 4.16  
194 Ga, which implies up to 3.5 bars of atmospheric  $\text{CO}_2$  were lost during the first 400 million years of the Noachian (~2  
195 bars of magmatic  $\text{CO}_2$  degassed from the mantle through time plus up to 1.5 bars of the initial atmospheric  $\text{CO}_2$ ).

196 In our model, we assume that the decline in atmospheric pressure is caused solely by impact erosion, which  
197 does not fractionate isotopes or chemical species. If, however,  $\text{CO}_2$  sequestration into carbonates also drove down  
198 atmospheric pressures, then we have overstated the loss of  $^{36}\text{Ar}$  by impact erosion and even lower atmospheric  
199 pressures are required to predict the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of  $626 \pm 100$  at 4.16 Ga. Conversely, if early hydrodynamic  
200 escape preferentially removed  $^{36}\text{Ar}$  relative to  $^{40}\text{Ar}$ , then we have understated the loss of  $^{36}\text{Ar}$  by impact erosion and  
201 greater atmospheric pressures are required. However, nitrogen isotopes in ALH 84001 maskelynite are significantly  
202 less fractionated than those in the modern Martian atmosphere<sup>17</sup>, which suggests that non-thermal escape occurring  
203 throughout the past ~4 Ga, not early hydrodynamic escape, may be principally responsible for heavy isotope  
204 enrichments. Therefore, because the modern Martian atmospheric  $^{38}\text{Ar}/^{36}\text{Ar}$  ratio is only enriched by 30% relative to  
205 the primordial value<sup>1</sup>, our model results would not differ significantly if early hydrodynamic escape were  
206 considered. **Moreover, if a less voluminous magma production model than Breuer and Spohn<sup>26</sup> was used, then even**  
207 **lower atmospheric pressures would be required (discussed above).**

208 In summary, our model results indicate that atmospheric pressures during the Early to Middle Noachian were  
209 likely less than ~1 bar. This suggests that a long-lived,  $\text{CO}_2$ -based greenhouse atmosphere with surface  
210 temperatures above the melting point of  $\text{H}_2\text{O}$  did not exist at that time. The apparent absence of massive carbonate  
211 deposits may be consistent with this result. The model results are also consistent with the observation that the  
212 formation of phyllosilicates observed in the Noachian crust required low partial pressures of atmospheric  $\text{CO}_2$ <sup>11</sup>.  
213 Although it is possible that an extended greenhouse climate may have existed after the period of our meteoritic  
214 constraint (i.e., after 4.16 Ga), geomorphic and spectral observations indicate that the Noachian was on average the  
215 warmest and wettest period on Mars<sup>9,45</sup>. Therefore, if the trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio observed in ALH 84001 is a sample

216 of the Noachian Martian atmosphere, then even during this putative warm period it appears that water was only  
217 intermittently stable in the liquid phase.

218 Impact events or intense volcanism may have caused such intermittent conditions by delivering other  
219 greenhouse gases to the atmosphere, such as SO<sub>2</sub>, H<sub>2</sub>S, and water vapor<sup>46</sup>. Given the partial pressures of CO<sub>2</sub>  
220 permitted by our model results, temporarily elevated partial pressures of these other atmospheric gases (e.g., ~2 ×  
221 10<sup>-6</sup> bars of SO<sub>2</sub>) could have stabilized liquid water on Mars' surface at high latitudes<sup>15,16,47</sup>. The discovery of sulfate  
222 deposits in the Martian regolith underscores the potential role of SO<sub>2</sub> and H<sub>2</sub>S as greenhouse gases. Even in the  
223 absence of such gases, liquid water would be stable at low latitudes during seasonally warm periods given the partial  
224 pressures of CO<sub>2</sub> permitted by our model results. Thus, existing observations of surface and meteorite mineralogy,  
225 coupled with the trapped Ar component identified in ALH 84001, suggest that the mean Noachian climate on Mars  
226 was cool (below freezing) and dry (without liquid water), with only intermittent periods of warm and wet conditions.

### 337 **Figure Captions**

338

339 **Figure 1: (left)**  $^{40}\text{Ar}/^{39}\text{Ar}$  isochron diagram for maskelynite in ALH 84001-1 (redrafted from Cassata et al.<sup>18</sup>).  
340 Correlation between the isotope ratios  $^{39}\text{Ar}/^{36}\text{Ar}$  and  $^{40}\text{Ar}/^{36}\text{Ar}$  measured during stepwise degassing of ALH 84001  
341 constrains the non-radiogenic argon component “trapped” in the glass from the y-intercept and the age from the  
342 slope. The isochron age ( $4.165 \pm 0.035$  Ga) is indistinguishable at  $2\sigma$  from recently reported Lu-Hf ( $4.09 \pm 0.03$   
343 Ga)<sup>49</sup> and Pb-Pb ( $4.074 \pm 0.099$  Ga)<sup>50</sup> ages. The  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of the trapped component in ALH 84001  
344 maskelynite is  $626 \pm 100$ . **(right)** Plot of the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios of trapped Ar components identified in Martian  
345 meteorites. ALH 84001 and Nakhlite data are from Cassata et al.<sup>18</sup>. Shergottite data are from Bogard et al.<sup>17</sup>. The  
346 Nakhlite  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio represents the weighted average of MIL 03346 and Nakhla meteorites (see supplementary  
347 files). Earth’s atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio is shown for comparison. Dashed lines linearly connect data points and  
348 do not represent the evolution of the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio on Earth or Mars.  
349

350 **Figure 2:** Modeled paleoatmospheric pressure paths (left) and corresponding evolution in the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$   
351 ratio (right) for the model parameters listed in Table 1. Dashed curves denote a constant rate of pressure change and  
352 solid lines an exponential decrease. Four atmospheric pressure models that predict an  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio within  $626 \pm$   
353  $100$  at 4.16 Ga are shown in black. For comparison, two models that fail to predict this ratio are shown in gray; an  
354 array of additional scenarios excluded by the ALH 84001 data is shown in the supplementary files. Linearly  
355 decreasing pressure paths were forced to evolve to pressures ranging between 10 mbar to 10 bar at 4.16 Ga; those  
356 forced to final pressures  $>400$  mbar predict  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios less than  $626 \pm 100$  and are therefore excluded. For  
357 clarity, only results for final pressures of 10 mbar, 100 mbar, and 400 mbar are shown. Exponential pressure models  
358 decline at the same rate as the Martian impact flux<sup>22</sup> (see supplementary files), with  $\sim 16\%$  of the initial pressures at  
359 4.16 Ga. The curves shown in black are representative of the range of permissible linear, exponential, and random  
360 solutions (see Fig. S1) and require  $<1$  bar of atmospheric pressure (on average) throughout most of the Early  
361 Noachian. A detailed analysis of the model sensitivity to input parameters is given in the supplementary files.

### Discussion S1: Calculation Details

The generalized equation describing the atmospheric molar abundance of isotope  $X$  is given by

$$\frac{d^X Ar}{dt} = N_X(t) - \left( {}^X Ar \frac{L(t)}{P(t)} \right). \quad (\text{Eq. S1})$$

In this section we define each term in Eq. (S1) and discuss our discretized implementation. A complete list of variables and the range of values explored can be found in Table 1.

i.)  ${}^X Ar$  is the atmospheric abundance of isotope  $X$  in moles or atoms.

At all  $t > t_0$ ,  ${}^X Ar$  reflects the integrated effects of production and loss. At  $t_0$ , the mass of atmospheric  ${}^{36}Ar$  is given by

$$m_{36_0} = \frac{R_{atm} \cdot P_0 \cdot 4\pi r^2}{g} \quad (\text{Eq. S2})$$

where  $P_0$  is total atmospheric pressure at  $t_0$ ,  $g$  is the gravitational constant ( $3.72 \text{ m/s}^2$ ),  $r$  is the radius of Mars ( $3397 \times 10^3 \text{ m}$ ), and  $R_{atm}$  is the atmospheric  ${}^{36}Ar/(CO_2 + N_2)$  ratio (i.e., the fractional abundance of atmospheric  ${}^{36}Ar$ ).  $P_0$  is a free parameter that is defined by hypothetical paleoatmospheric pressure paths. The molar abundance of atmospheric  ${}^{40}Ar$  at  $t_0$  is simply  $10^{-3}$  times the molar abundance of atmospheric  ${}^{36}Ar$  (Begemann et al., 1976).

ii.)  $N_X(t)$  is the rate of addition of isotope  $X$  to the atmosphere as a function of time due asteroid accretion and planetary degassing.

*Asteroid Accretion:*

To model the mass of  $^{40}\text{Ar}$  added to the atmosphere by asteroids, we use the Martian impact flux derived by Melosh and Vickery (1989) from the lunar cratering record of Neukum and Wise (1976) following Manning et al. (2006), given by

$$m_{\text{asteroid}}(t) = 6.85 * 10^{12} \left( 1 + 2300 e^{-\left(\frac{10^3 * (4.56-t)}{220}\right)} \right) \left( \frac{\text{kg}}{\text{Ma}} \right) \quad (\text{Eq. S3})$$

where  $m_{\text{asteroid}}$  is the mass of asteroid material and  $t$  is time ranging from 4.56 to 4.16 Ga. The amount of asteroid-derived  $^{40}\text{Ar}$  is given by

$$^{40}\text{Ar}(t) = ^{40}\text{K}_a \frac{\lambda_e}{\lambda} \left( e^{-\lambda(4.56-t)} \right) \quad (\text{Eq. S4})$$

where  $^{40}\text{K}_a$  is moles of  $^{40}\text{K}$  in a given mass of asteroid material,  $\lambda_e$  is the partial decay constant for electron capture ( $0.576 \times 10^{-1} \text{ Ga}^{-1}$ ) (Renne et al., 2011), and  $\lambda$  is the total decay constant ( $5.531 \times 10^{-1} \text{ Ga}^{-1}$ ) (Renne et al., 2011). We assume that impacting asteroids contain a chondritic abundance of K (550 ppm; McDonough and Sun, 1995) and  $^{36}\text{Ar}$  concentrations typical of H-, L-, and LL-chondrites (~15 ppt; Zahringer, 1966).

#### *Planetary degassing:*

To model the production of atmospheric volatiles associated with surface, crustal, and upper mantle magmatic activity, we use the crustal production model of Breuer and Spohn (2006), approximated between 4.56 and 4.16 Ga by the following expression:

$$V_{\text{magma}}(t) = \left[ \left( 1.7075 * 10^3 \right) t^3 - \left( 2.1989 * 10^4 \right) t^2 + \left( 9.4408 * 10^4 \right) t - \left( 1.3512 * 10^5 \right) \right] \frac{\text{km}^3}{\text{a}} \quad (\text{Eq. S5})$$

where  $t$  is time ranging from 4.56 to 4.16 Ga.

The mass of mantle-derived  $^{36}\text{Ar}$  is given by

$$m_{^{36}\text{Ar}_{\text{magma}}}(t) = V_{\text{magma}}(t) \rho_{\text{magma}} [\text{CN}]_{\text{magma}} R_{\text{magma}} \quad (\text{Eq. S6})$$

where  $\rho_{magma}$  is the magma density (3000 kg/m<sup>3</sup>),  $[CN]_{magma}$  is the magmatic concentration of N<sub>2</sub> + CO<sub>2</sub>, and  $R_{magma}$  is the magmatic <sup>36</sup>Ar/(CO<sub>2</sub> + N<sub>2</sub>) ratio.

The molar production of <sup>40</sup>Ar is given by

$${}^{40}\text{Ar}(t) = {}^{40}\text{K}_m \frac{\lambda_\varepsilon}{\lambda} \left( e^{-\lambda(4.56-t)} \right) \quad (\text{Eq. S7})$$

where  ${}^{40}\text{K}_m$  is moles of <sup>40</sup>K in a given volume of magma. We modeled scenarios in which magmas contain between 1300 and 3300 ppm K (Table 1).

iii.)  $\frac{L(t)}{P(t)}$  is the fractional loss rate of atmospheric gases due to impact erosion, which we assume does not

fractionate isotopes or chemical species (Brain and Jakosky, 1998; Melosh and Vickery, 1989).

$P(t)$  is atmospheric pressure (defined by the hypothetical paleoatmospheric pressure paths) and  $L(t)$  is the atmospheric pressure loss rate due to impact erosion, derived from the following equation:

$$\frac{dP}{dt} = I(t) - L(t), \quad (\text{Eq. S8})$$

where  $I(t)$  is the rate of increase in atmospheric pressure resulting from planetary degassing, given by the

following equation:

$$I(t) = \frac{V_{magma}(t) \rho_{magma} [CN]_{magma} g \text{ bar}}{4 \pi r^2 \text{ Ma}}. \quad (\text{Eq. S9})$$

Thus  $L(t)$  can be extracted from the discretized version of equation Eq. (S8), given by

$$P(t) = P(t-dt) + dt(-L(t) + I(t)), \quad (\text{Eq. S10})$$

where  $P(t)$  and  $P(t-dt)$  are two points on a hypothetical paleoatmospheric pressure path.

The discretized version of Eq. (S1) is then solved for both  $^{40}\text{Ar}$  and  $^{36}\text{Ar}$  according to the following:

$${}^x\text{Ar}(t) = \left(1 + dt \frac{L(t)}{P(t)}\right)^{-1} \left({}^x\text{Ar}(t-dt) + dtN_x(t)\right). \quad (\text{Eq. S11})$$

### Discussion S2: The origin of trapped Ar in ALH 84001

Critical to our argument is the assumption that the trapped argon component identified within maskelynite in ALH 84001 is atmospheric in origin and that it was acquired at 4.16 Ga. Although Xe isotopes in ALH 84001 confirm that atmospheric gas is present (Mathew et al., 1998; Swindle et al., 1995), it is conceivable that the  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of trapped gas within maskelynite (i) is contaminated by a mantle Ar component, (ii) is contaminated by a non-atmospheric upper crustal Ar component, or (iii) reflects a post-crystallization shock-implanted Ar component. We find these possibilities unlikely for reasons discussed below.

#### i.) A mantle Ar component

Argon is highly mobile in feldspars at temperatures as low as 300-400 °C (Cassata et al., 2009). As such, feldspars should continue to exchange Ar with the local environment during near-surface cooling, and are not expected to retain the isotopic composition of Ar in primary melts extracted from the Martian mantle, which have temperatures in excess of 1200 °C.

#### ii.) An upper crustal Ar component

Crystals generally incorporate excess argon as a result of (1) thermally-induced in-diffusion of grain boundary  $^{40}\text{Ar}$  or (2) growth within magmas and interaction with fluids characterized by supra-atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios. Given that three separate whole-rock fragments of ALH 84001 that each have different local maskelynite grain boundary environments and different grain size distributions yield indistinguishable trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios (Table S1), we consider it probable that maskelynite (or the precursor feldspar) equilibrated within a uniform Ar reservoir. When rocks are subjected to high Ar pressure and an elevated  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio produced by degassing of old, K-rich phases such as occurs in contact metamorphic aureoles (Harrison and McDougall, 1981; Renne et al., 1990) or in intrusions near such aureoles (Lanphere and Brent Dalrymple, 1976; Marzoli et al., 1999), the trapped “excess”  $^{40}\text{Ar}$  component is generally manifest in step-heating experiments by anomalously high apparent ages derived from low temperature steps, which typically decrease with increasing extraction temperature. This implies a decreasing proportion of trapped relative to radiogenic Ar components, generally interpreted as being due to some combination of the trapped component being (i) surface-correlated, i.e. through inward diffusion, and (ii) sited in vacancies or microfractures with low activation energies (Harrison and McDougall, 1981). Thus post-crystallization in-diffusion of grain-boundary  $^{40}\text{Ar}$  from degassing country rocks can be dismissed as a plausible source of Ar, as one would expect the trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio to be spatially variable.

If the trapped component observed in maskelynite reflects a uniformly distributed supra-atmospheric component, then the evolved parental magma to ALH 84001 must have incorporated and homogenized excess  $^{40}\text{Ar}$  from upper crustal rocks, possibly through interactions with crustal groundwater and pore gases. Such a scenario seems unlikely, as the trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios observed in petrogenetically similar feldspathic phases in Shergottites and Nakhilites (Table S1) do not exceed the inferred atmospheric value of ~1800 (Bogard et al., 2001; Cassata et al., 2010). Moreover, in our experience, such cases of feldspar and glass contamination with argon having an appreciably (e.g., >20%) supra-atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio generally fail to produce well-defined isochrons because the trapped component is not isotopically

homogeneous. Trapped components of Ar in terrestrial plagioclase, in both extrusive and intrusive rocks, commonly have atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  compositions as indicated in flat apparent age spectra (Ernesto et al., 1999; Renne et al., 1996) wherein apparent ages are computed using an air correction.

**iii.) A post-4.16 Ga shock-implanted Ar component**

ALH 84001 appears to have been subjected to a significant shock event at  $\sim 1$  Ga wherein both maskelynite and pyroxenes were locally heated to high temperatures, resulting in Ar loss (Cassata et al., 2010). Bogard et al. (1986) showed that unfractionated noble gases can be incorporated into crystals during such shock events. If the trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio observed within maskelynite reflects shock implanted atmospheric Ar associated with the  $\sim 1$  Ga event, then by implication the Martian atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio at  $\sim 1$  Ga was  $\sim 600$ . However, the  $\sim 1.3$  Ga Martian meteorites MIL 03346 and Nakhla yield a weighted average trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio of  $1600 \pm 200$ , which suggests the Martian atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio at  $\sim 1$  Ga was much greater than 600 (Table S1; Cassata et al., 2010). If the trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  reflects shock implanted Ar associated with a hitherto unrecognized shock event that occurred between 4.16 Ga and  $\sim 1$  Ga, then it must have been implanted without disturbance to the distribution of radiogenic  $^{40}\text{Ar}$  (see plateau in ALH-1 from Cassata et al., 2010), which requires shock pressures lower than 10-15 GPa (Bogard et al., 1988). At these low pressures, the implantation efficiency of atmospheric gases is greatly reduced (Bogard et al., 1986), and those gases that are implanted are degassed at low temperatures (i.e., they are surface correlated or contained within microfractures; Bogard et al., 1986). In ALH 84001, the trapped Ar component is pervasive, comprising more than 10% of the total  $^{40}\text{Ar}$  in the highest temperature maskelynite extractions (see Cassata et al., 2010). As such, we find it unlikely that a minor shock event between 4.16 and  $\sim 1$  Ga implanted the observed trapped component.

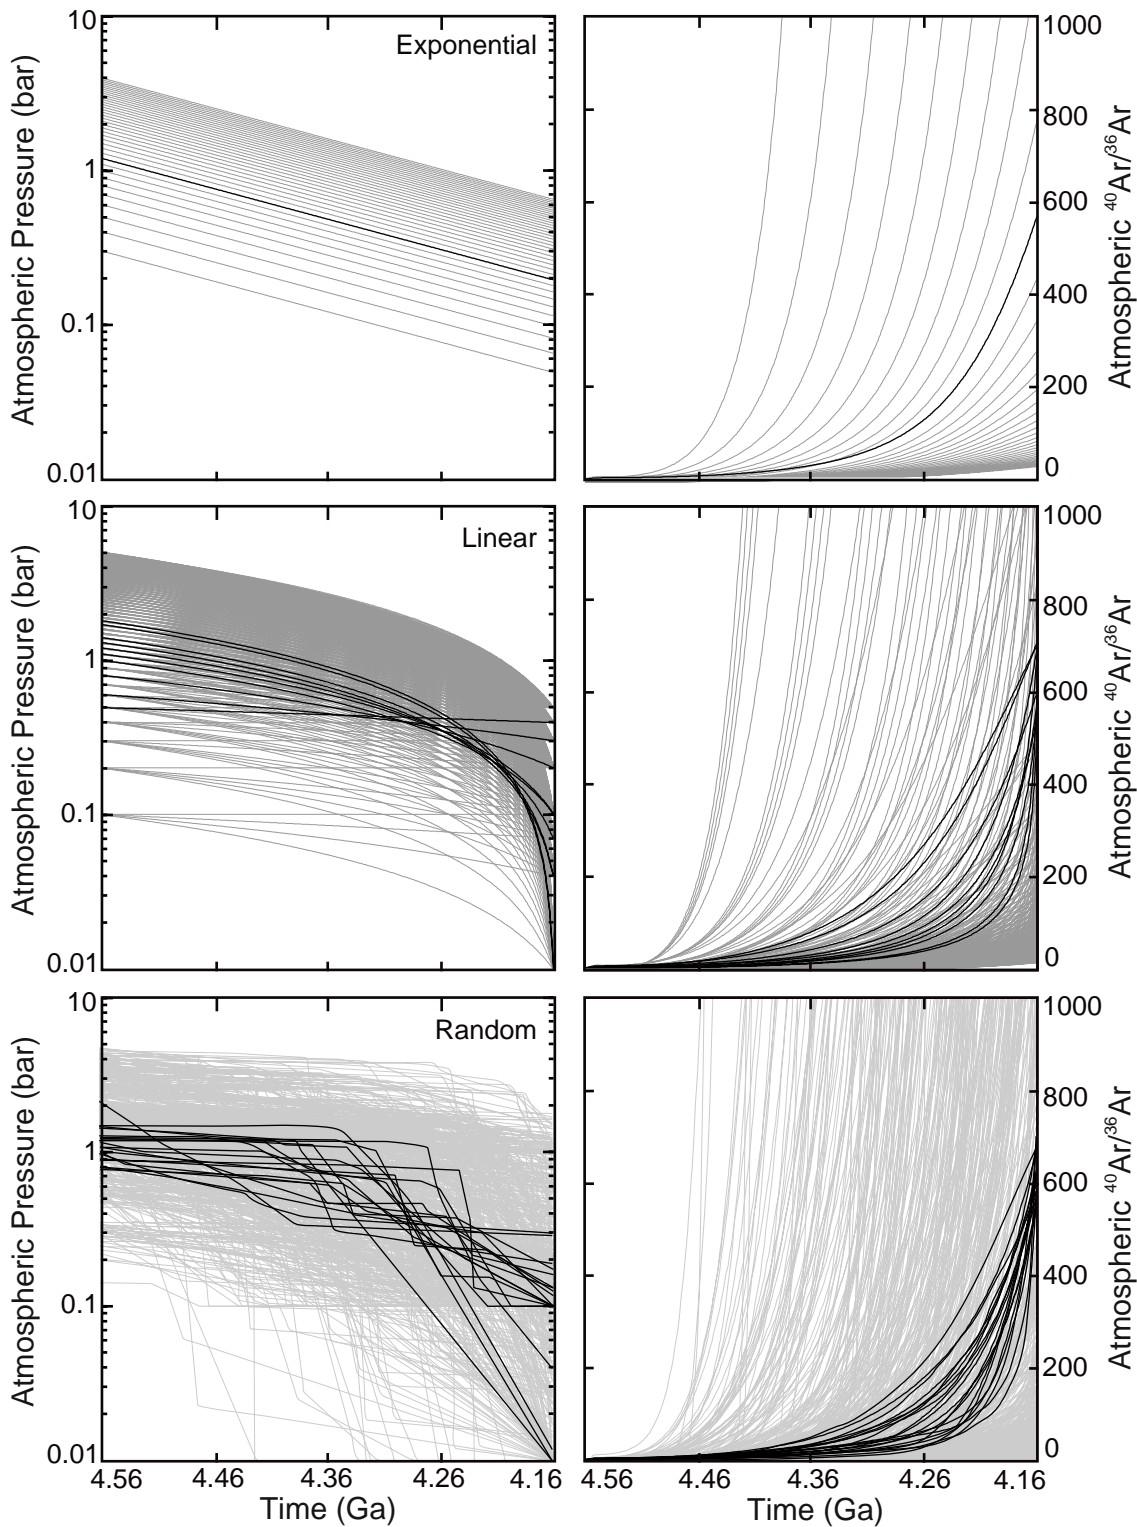

We hold that the simplest explanation for the trapping of Ar isotopes observed within maskelynite in ALH 84001 is equilibration with a near-atmospheric reservoir at 4.16 Ga.

**Figure S1:** Modeled paleoatmospheric pressure paths (left) and the corresponding evolution in the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio (right) for the model parameters listed in Table 1. Atmospheric pressure models that predict an  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio within  $626 \pm 100$  at 4.16 Ga are shown in black, and those that do not are shown in gray. Linearly decreasing models (middle) were forced to pressures of 10 mbar to 10 bar at 4.16 Ga; those forced to  $>400$  mbar at 4.16 Ga predict  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios lower than  $626 \pm 100$  and are therefore excluded by the ALH 84001 data. Exponential pressure models (upper) decline at the same rate as the Martian impact flux (see text for details), with  $\sim 16\%$  of the initial pressures at 4.16 Ga. Random pressure paths (lower) are well approximated by the linear and exponential models. The permissible solutions (shown in black) indicate that low atmospheric pressures ( $<1$  bar on average) prevailed throughout the Early Noachian. In subsequent figures, only the results for exponential paths and linear paths with final pressure of 10 mbar and 100 mbar are shown.

**Figure S2:** Illustration of the model sensitivity to the K concentration of extracted magmas. Magmas with higher concentrations of K, and therefore  $^{40}\text{Ar}$ , more efficiently elevate the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio. Thus higher atmospheric pressures (i.e., more atmospheric  $^{36}\text{Ar}$ ) are required to maintain a given  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio if the magmatic K concentration is raised, and vice versa. The center panels represents our preferred model (modified from Fig. 2 in the main text), wherein the K concentration is 2500 ppm.

**Figure S3:** Illustration of the model sensitivity to the  $\text{CO}_2$  and  $\text{N}_2$  concentration of extracted magmas. Because magmatic  $^{36}\text{Ar}/(\text{CO}_2 + \text{N}_2)$  ratios are lower than that of the primordial atmosphere (see text for discussion), magmas with higher concentrations of  $\text{CO}_2$  and  $\text{N}_2$  more efficiently dilute the concentration of atmospheric  $^{36}\text{Ar}$ . Thus higher atmospheric pressures (i.e., more primordial atmospheric  $^{36}\text{Ar}$ ) are required to maintain a given  $^{40}\text{Ar}/^{36}\text{Ar}$  if the magmatic concentrations of  $\text{CO}_2$  and  $\text{N}_2$  are raised, and vice versa. The center panels represents our preferred model (modified from Fig. 2 in the main text), wherein  $[\text{CN}]_{\text{magma}}$  is 250 ppm.

**Figure S4:** Illustration of the model sensitivity to the  $^{36}\text{Ar}$  concentration of extracted magmas. Magmas with lower concentrations of  $^{36}\text{Ar}$  more efficiently elevate the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio. Thus higher atmospheric pressures (i.e., more atmospheric  $^{36}\text{Ar}$ ) are required to maintain a given  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio if the magmatic concentration of  $^{36}\text{Ar}$  is lowered, and vice versa. The center panels represents our preferred model (modified from Fig. 2 in the main text), wherein  $[\text{CN}]_{\text{magma}}$  is 250 ppm.

**Figure S5:** Illustration of the model sensitivity to the primordial concentration of atmospheric  $^{36}\text{Ar}$ . Magmas more efficiently elevate the atmospheric  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio when the primordial concentration of atmospheric  $^{36}\text{Ar}$  is lower. Thus higher atmospheric pressures are required to maintain a given  $^{40}\text{Ar}/^{36}\text{Ar}$  ratio if the primordial concentration of atmospheric  $^{36}\text{Ar}$  is lowered, and vice versa. The center panels represents our preferred model (modified from Fig. 2 in the main text), wherein the primordial concentration of atmospheric  $^{36}\text{Ar}$  is 10 ppb.

Table S1: Summary of trapped  $^{40}\text{Ar}/^{36}\text{Ar}$  ratios

Sample	Phase	$^{40}\text{Ar}/^{36}\text{Ar}_i \pm 1\sigma$
<b>ALH 84001 (4.16 ± 0.04 Ga)</b>		
ALH 84001-1	Maskelynite	626 ± 100
