Joint Nuclear Research Center Karlsruhe Establishment - Germany

European Institute for Transuranium Elements

SUMMARY

Between January and October 1966, 2115 Mascurca fuel elements containing 175 kg plutonium were fabricated in the Institute for Transuranium Elements. Kadsruhe. Two sorts of plutonium metal were used, containing 8.4 and 3.8% Pu-240 respectively. The elements were required to be 101.6 and 203.2 mm long and have an outer diameter of 12.7 mm. Each element consists of a fine steel can and a core of a plutonium alloy with depleted uranium and a little iron. The composition of the quality with 8.4% Pu-240 is 25 wt. % Pu. 1 wt. % Fe and 75 wt. % U.

The original metals were first melted together in a vacuum-induction furnace. The alloy was then cast in rod form in a centrifugal furnace, the rods were machined on a lathe and placed in cans plugged at one end. After decontamination of the open end, insertion of the second plug and welding with an electron beam unit, various inspections were carried out including a leaktightness inspection with a helitest apparatus and a check on the fissile material by spontaneous neutron counting.

The finished elements met the specifications. The plutonium losses were about 0.1 % of the quantity used. A staff of 22 was directly engaged in the fabrication. The labour-time was 1.79 man/day per element. Special attention was paid to work organization and radiation protection.

PREFACE

The fabrication of the elements for MASURCA was carried out by the Metallurgy Section of the European Transuranium Institute in Karlsruhe. It should, however, be stressed that colleagues from other sections of the Institute made important contributions and played a remarkable part in the success of the work.

Leading European fuel element manufacturing firms sent engineers; some were present as observers, others cooperated directly in solving various problems.

The Metallurgy Division of the Argonne National Laboratory was of valuable assistance during the early work of developing the centrifugal casting process.

1. INTRODUCTION

n 1997 - El 1997 - El 1997 - El 1997 - El 1998 - E El 1997 - E

MASURCA (<u>Maquette Surgénératrice Ca</u>darache) is the name of a fast, critical zeropower assembly constructed at the "Centre d'Etudes Nucléaires de Cadarache". It is used for the experimental measurement of various physics parameters. important for the design of planned prototype fast power reactors, which cannot be computed with sufficient accurancy from theory.

A wide variety of cores can be built and measured in MASURCA. It is possible, by using a kind of modular principle, to simulate cores made of metals, oxides, carbides, nitrides or other possible fuel materials and at the same time to examine the influence, for example, of sodium and steel. The core volume can be varied between 200 and 6000 l. Maximum output is 1 kW. This assembly has been described in various publications (1,2).

In spring 1964, the CEA awarded the contract for the fabrication of the first batch of MASURCA fuel elements, containing 175 kg Pu to the European Research Centres. From the beginning of 1965 onwards, the furnaces and machinery necessary for element fabrication were installed in Wing G of the Institute, which had been completed during the intervening period. Then the fabrication equipment was tested together with the glove boxes and caissons. The first plutonium was transferred into the glove boxes shortly before the end of 1965. The fabrication chain could then be tested with the actual MASURCA U-Pu-Fealloy.

Fabrication ended on 18th October 1966. It was the first closed, large fabrication of plutonium-containing fuel elements in Europe.

This report describes the fabrication process and should familarize all interested parties with the problems of such an undertaking.

II

2. DESCRIPTION OF ELEMENTS AND EXTENT OF DELIVERY

2.1 Construction of Elements

Each element consisted of a cylindrical core made from the plutonium alloy, a steel can and two seal-welded plugs, also of steel. The outer diameter of the elements was 12.7 mm and the length either 101.6 mm or 203.2 mm. Details of construction dimensions and tolerances of the elements are given in Figs. 1 and 2.

2.2. Initial quantity of plutonium and number of elements

Euratom purchased 187 kg of plutonium - about 22 kg with a 3.8% Pu-240 content and about 165 kg with a 8.4% Pu-240 content - from USAEC stocks. It became evident during fabrication that these quantities would be sufficient for producing the desired number of elements and that additional plutonium would not be required, as originally thought.

The fabrication plan was :

80 short elements with 3.8% Pu-240 160 long elements with 3.8% Pu-240 620 short elements with 8.4% Pu-240 1240 long elements with 8.4% Pu-240

2.3 The Uranium-Plutonium-Iron Alloy

2.3.1 Composition of the alloy

Since higher U/Pu ratios than 3/1 are of no interest for fast reactors, an uranium alloy with a maximum plutonium content of 25 w/o was chosen for MASURCA. According to the previously mentioned modular principle, it is possible, if necessary, to dilute this plutonium in the MASURCA assembly with more uranium to simulate lower plutonium contents. The prescribed Pu content for the alloy was 24.0 ± 0.5 w/o for plutonium with 3.8% Pu-240 and 25.0 \pm 0.5 w/o for that with 8.4% Pu-240.

For metallurgical reasons it was found that an iron content of 1.1 ± 0.1 w/o was necessary. Burning U-Pu alloys of this composition range are very susceptible to corrosion and to disintegrate into powder in a damp atmosphere and can even ignite. This is caused by the zeta phase, which occurs in the U-Pu system in medium concentrations. The zeta fraction in the structure is decreased by the addition of small quantities of iron, $(U,Pu)_6$ Fe being formed, which has considerable resistance to humidity. The $(U,Pu)_6$ Fe portion is 29-35% in the MASURCA alloy with 1.1 ± 0.1 w/o Fe. This was sufficient to improve the corrosion properties of the alloy considerably.

Depleted or natural uranium could be used for the alloy.

The maximum impurity content allowed was 500 ppm C and a total of 1200 ppm of the elements Mg, Zr, Cr, Mu, Mo, Ni and Si.

The MASURCA alloy melts between 700 and 800° C and is relatively hard and brittle. Detailed examinations of its properties have been published ³⁾. The density value determined by us was 18.65 g/cm^3 .

2.3.2 Fissile material content of the alloy

and the second second second second

As discussed in Section 2.3.1, the alloy contained either 24 or 25 w/o Pu according to the Pu-240 content. The difference arose through the requirement that the fissile isotope content (Pu-239 and Pu-241) should have been kept constant for elements of the same size but of different Pu isotope composition. Deviations of up to 1% from the average fissile material weight P_1 for short elements and P_2 for long elements were allowed.

It was further required that P_1 be half of P_2 , i.e., two short elements should always contain as much fissile material as one long element. Here again maximum deviations of 1% were allowed from P_1 :

$$\begin{bmatrix} \mathbf{P}_2 & \mathbf{P}_1 \\ 2 & \mathbf{P}_1 \end{bmatrix} \neq 0.01$$

2.3.3 Core_dimensions

The diameter of all MASURCA fuel alloy cores was fixed as 12.10 + 0 mm (see also plan in Figs. 1 and 2). On the other hand, no exact length was stipulated for the cores, in order to facilitate establishing P₁ and P₂ values by varying the length of fuel.

2.4 Various specifications

AISI Type 304 L stainless steel was specified for cans and plugs. The can wall thickness was to be 0.25 ± 0.025 mm and the outer diameter 12.70 ± 0 mm. The material was required to be in perfect condition and contain no faults such as microcracks, holes or porous spots. The plug dimensions are given in Figs. 1 and 2. An important requirement was that there should be a good mechanical contact between the core and the caps. This guaranteed that longitudinal expansion of the core, due, for instance, to a reactor excursion, would be accompanied by an expansion of the whole element or column of several elements, thus leading to an automatic reduction in the reactivity of the system. It was decided to insert suitable thin steel plates between the core and the upper cap to fill up the space caused by the different lengths of the cores and also to assure good mechanical contact. Another requirement was that the can was evacuated and had a leak rate of less than 10^{-8} Nml/sec. Furthermore, the bow of the long elements had to be 0.10 mm and that of the short elements <0.05 mm. All elements had clearly visible numbers engraved on one of the caps.

st yedl land; str st

It was required that no free contamination was to be detectable on the finished elements. A maximum value of 600 decompositions per minute per element was allowed as the fixed α -contamination. Using a measuring rate of 30% for the α -monitors used, this value corresponded to a pulse count of 180 per minute.

3. STARTING MATERIALS

3.1 Plutonium

The plutonium metal ingots supplied by the USAEC were in rod form. They were approximately 160 mm long and had a diameter of about 40 mm. Each vacuum cast ingot weighed between 3.8 and 4.1 kg.

I7

Analysis samples were taken by boring in the USA before shipment. Each ingot was then sealed in a plastic bag and placed in a suitable can, the lid of which was fastened with adhesive tape. This can was put into another of approximately 2 liters capacity, whose lid was mechanically rolled in and therefore airtight (can sealing). The remaining space was filled with aluminium scrap to ensure better thermal conductivity between the cans.

The large box was placed in an airtight, bolted steel cylinder, and this container was placed in an LLD Standard Birdcage which was also sealed airtight.

When the metal was unpacked in the Transuranium Institute, it could be seen that the surface of the ingots was slightly oxidized. The oxide, removed by brushing, weighed 12 g but there were considerable deviations from this value. Some of the ingots had casting wrinkles and others had cracks. These ingots showed a greater degree of oxidation on the surface than the smooth ingots, one of which is shown in Fig. 3.

3.2 Uranium

The depleted uranium was obtained from NUKEM of Wolfgang-in-Hanau in the form of rods with diameters of 10 and 30 mm and various lengths. It was made by reduction from high purity UF_{ls} .

Analyses of the metal gave the following values :

C	70 -	150	ppm
Fe	13 -	31	ppm
Mg		1	ppm
U-235	0.22	<u>+</u> 0,	.01%.

I8

3.3 Iron

Pure iron, supplied by Cacermet of Brussels in the form of foil with >99.9% Fe and approximately 200 ppm C, was used as the alloying addition.

3.4 Cans

These were made from type 304 L austenitic steel; the required dimensions of which were $12.70 \pm \frac{0}{0.05}$ mm diameter and 0.25 ± 0.025 mm wall thickness.

Mannesmann of Düsseldorf were chosen as suppliers after tenders had been submitted.

3.4.1 Fabrication and pretreatment_

The cans were cold-drawn, passivated and cleaned. After the last annealing they were subjected to calibrated drawing, which yielded the desired tolerances, but no cold-work-hardening of above 10% occurred. The cans were delivered in lengths of 102 and 204 mm.

3.4.2 Tests

Mannesmann conducted the following tests on the cans :

- measurement of outer diameter
- measurement of bow in 1 m lengths
- tensite test on 1% of the cans
- expansion test on both ends of all fabricated lengths (3 - 5 m)
- chemical analysis of the starting material
- grain disintegration test on 1% of the cans
- eddy current testing of all cans
- pressure test with 5 atm. of air under water

- roughness check on 1% of the cans
- metallographic examination of 1% of the manufacturing lengths
- chemical analysis on 1% of the cans
- wall thickness check on all cans.

3.4.2.1 Outer diameter :

One batch of cans had to be sent back to the suppliers because acceptance tests showed the outer diameters to be about 12.72 mm. The error was caused by measuring with normal micrometers. Through these, the thin-walled cans undergo slight elastic deformation. An exact measurement would have to be carried out with a smooth caliper and a sensitive measuring device. The outer diameters of the remaining batches lay within the tolerances.

3.4.2.2 There was a difference of opinion here concerning the agreed tolerance values. A maximum bowing of 0.05 mm in the short cans and 0.10 mm in the long ones was first allowed by the Transuranium Institute, this being subsequently amended to 0.10 and 0.20 respectively. A maximum deviation of 1 mm per m tube from the straight line was guaranteed by the supplier which gave the same tolerance values according to our interpretation. However, this estimate was so interpreted by the supplier that one or several bowings should be permissible in cans one meter long if each deviation from the straight line is less than 1 mm. However, it was found that the different interpretation of the data had no practical signification since only about 2% of the cans were questionable in this respect. 3.4.2.3 Tensile and expansion tests : due of the result of the state of the second of

The results of these tests were acceptable. The tensile test to failure gave the following values :

yield point :	53 - 59 kg/mm ²
tensile strength :	65 - 68 kg/mm ²
elongation $L = 5 d$:	34 - 42%

3.4.2.4 Chemical analysis of the starting material : chemical analyses gave the values permitted for 304 L :

Table 3 :

Element	Values of two a	nalyses in wt%	rated values for 304 L
С	0.02	0.02	0.03

Ni	10.85	10.77	8.0-12.0
В		0.0005	
Co		0.0150	
		<i>,</i>	

The boron and cobalt content was determined at the request of the CEA. This lay well below the limits allowed for MASURCA for neutron physics reasons.

3.4.2.5 Grain disintegration, eddy current and density tests : The results of these tests were satisfactory.

3.4.2.6 Roughness check :

This check was carried out with a Peth-O-Meter and gave a maximum Rt value of 4-6 /u.

3.4.2.7 Metallographic examinations :

The micrographs showed pure, austentic structures (Fig. 4).

3.4.2.8 Chemical control analyses :

These analyses agreed with the values given in Table 3.

3.4.2.9 Wall thickness control :

The wall thicknesses were measured by means of a β -testing device. It was shown that the required tolerances were obtained. A typical strip chart for three can lengths is given in Fig. 5.

3.5 Plugs and discs :

German steel with "Werkstoffnummer 4306" was used as material for the plugs and the thin discs mentioned in 2.5. This metal corresponds to AISI 304 L. The plugs and discs were manufactured in line with plans 1 and 2.

4. DESCRIPTION OF THE FABRICATION PROCESS OF 1 Day Latosyche war

F ADER of BEERS STAR Element fabrication was carried out in Wing G of the Transuranium Institute (Fig. 6). The most important work was performed in glove boxes mounted in so-called "caissons". These stand in the technology hall of the Institute. The caissons (Figs. 7 and 8) are large, leaktight chambers made from sheet steel and plate glass in which a constant slight underpressure is maintained with respect to the hall by means of a separate ventilation system. They are normally entered only via a lock and are used to ensure the "double containment" required when working with plutonium. They prevent the whole hall from becoming contaminated in the event of a small to medium incident.

Les es en transforment des entres de transforment de transforment de transforment de transforment de transforme Work rationalization reasons and problems of criticality strictly forced us to follow a predesigned working schedule during the fabrication. The whole process was thus divided into several stages so that each stage could be safely accomplished with a proportional quantity of material and personnel in a previously determined time. Plutonium zones were assigned to each work stage, information on their position being given in the plan of Wing G. Each zone had first of all to be cleared of plutonium, the processed or controlled charge before the new charge could be put in. The problems which arose in connection with this practice are reported in a later chapter. The individual work stages are described in detail below.

Preparation of the Starting Materials 4.1 £ 5 . .

Plutonium, uranium and iron were prepared in plutonium zone A in caisson 2a.

л. .

4.1.1 Plutonium

192**9**4 . . .

÷ 13

After the bird cages had been transported from the main storage facility to plutonium zone A, the plutonium ingot

was unpacked and freed from adherent oxide by means of a hard brush (Section 3.1). A weight control, exact to 1 gram, then followed.

For reasons of criticality a maximum of only 2.5 kg of plutonium could be handled in the remaining zones, work had to be carried out with charges containing a maximum of 10 kg alloy (25 w/o Pu) It was also necessary to crush the plutonium ingots.

In the very first charge (Ma-1), an ingot was recast into a ring which could easily be broken into many pieces. In subsequent charges, however, the as received ingots were directly broken into two pieces with a hydraulic hand press. They were placed horizontally in a steel case with thin ends resting on two V-shaped pieces and were centrally pressed from above with the chiselshaped head of the press stamp. The pressures necessary to produce fracture were between 5 and 18 t/cm^2 . The ingots usually broke at the sampling borehole (Fig. 9). The individual pieces weighed between 1.6 and 2.4 kg. In order to obtain the 2.5 kg Pu necessary for a charge, the remaining pieces of alloy from previous charges could also be used with the exception of Ma-1 (Section 4.1.4).

4.1.2 Uranium

A supply of differently sized pieces was cut from the thin uranium rods on a lathe to ensure that the exact quantity of uranium, calculated from the quantity of plutonium, was available at all times. In this way, a suitable selection of thick and thin rods and rod segments was available when a charge was prepared.

4.1.3 Iron

Because the metal was in the form of thin flakes no major problems resulted from weighing the iron.

4.1.4 Calculations

The amounts of uranium, iron and alloy scrap required for a charge were carefully calculated as soon as the exact weight of the plutonium charge was known. The calculation chart of charge Ma-11 is given in Fig. 10 as an example. In addition to a 1889 g Pu piece, pieces of alloy from charges Ma-2 and Ma-8 were used, resulting in a total Pu weight of 2532 g. When the amounts of uranium and iron in the alloy pieces had been allowed for, the necessary addition of pure uranium and iron was determined.

la servita de la secología e servita de la visión de la secolo de la secolo de la secolo de la secolo de la se

The calculations carried out in the chart below (Fig. 10) are connected with the control of the fissile plutonium content (Section 2.3.2).

A plutonium content of 25.0% was always aimed at in charges with 8.4% Pu-240 and one of 23.8% in charges with 3.8% Pu-240.

4.2 First casting ______ is a second of the control of a second sec

The charge was prepared by melting the constituents together in a vacuum induction furnace and pouring this melt into a steel chill. The furnace was situated in plutonium zone A in caisson 2a.

4.2.1 The vacuum induction furnace

This furnace was a variation of the standard model produced by HERAEUS of Hanau, modified for use in the glove box (Fig. 11). It had a maximum output of 40 kW and worked at a frequency of 4 kcs. The drum containing the crucible could be tipped so that the melt could be poured sideways. Casting could also be performed by bottom tapping. The furnace had a revolving thermocouple which could be dipped into the melt and a charging device for the addition of alloy components to the melt. The crucibles for the MASURCA melts were made from graphite and had a capacity of approximately 1 litre. On the inside, they were hived with a good adhesive layer of $MgZrO_3$ a few tenths of a millimeter thick. The layer was applied by means of a plasma spray device.

The actual furnace chamber was surrounded by a large, watercooled jacket which could be opened horizontally. The vacuum was created by three pumps : a backing pump with an evacuation rate of $180 \text{ m}^3/\text{hr}$, a Roots pump with $1500 \text{ m}^3/\text{hr}$ and an oil diffusion pump with a rate of 8000 l/sec. The furnace was equipped with a variety of control and safety systems.

In addition to creating a vacuum, the oversized Roots pump, had to remove as much water as possible from the furnace chamber and hence from the vicinity of the plutonium should a serious water leakage have occurred. This measure was necessary in view of the criticality danger. For the same reason, the furnace cooling water was divided into five separate circuits, each of these holding a maximum of 30 1 water. This water was cooled by a heat exchanger. If an accident had occurred where all control and safety systems failed simultaneously and all the 30 1 had flowed into the furnace and formed a homogeneous mixture with the plutonium, the total amount in the reservoir would only have been 5 cm deep and therefore geometrically safe.

4.2.2 Casting procedure

Uranium, iron and pieces of alloy were placed in the crucible (Fig. 12). The plutonium metal was placed in the charging device. After the furnace jacket had been closed and pumped down to approximately 1.10^{-4} mm Hg, the crucible was heated to about 1220°C until the charge was melted. The temperature of the melt was then lowered to close to the freezing temperature and plutonium added. The melt temperature was lowered to minimize

the loss of plutonium through evaporation and sprinkling. Heating was recommenced and the melt was homogenized in approximately 20 minutes at $1000-1050^{\circ}$ C and maintained at a vacuum of $5 \cdot 10^{-5} - 1 \cdot 10^{-4}$ mm Hg. Casting then followed by tipping the contents of the crucible into a steel chill, previously spray coated with MgZrO₃, in which the alloy soon solidified into a cake-like form (Fig. 13). The centre hole in the ingot was necessary for subsequent use in the centrifugal casting furnace. The ingots often had a vertical crack, probably caused by stresses set up during cooling. These ingots could always be separated fairly easily from the chill, which could be dismantled into individual pieces.

In general, only a thin layer of slag intermingled with the alloy residue remaining in the crucible after casting. This could easily be removed if the crucible was new and the MgZrO₃ layer undamaged. All the clean slag (that with a pronounced metallic appearance and containing no particles of graphite of MgZrO₃) was separated and collected. From time to time this was melted with turnings obtained at a later stage. In this way part of the material could be metallurgically recovered and added to later charges as an alloy.

The slag which could not be readily separated from the graphite and $MgZrO_3$, as well as dust and dirt from the glove boxes and the furnace, were collected as plutonium waste for chemical reprocessing at a later date.

At the beginning, the crucibles could be used two or three times and later three or four times. When fabrication began and the technique of spraying the crucible with $MgZrO_3$ was not as not yet properly mastered, the useful life was usually limited by spalling of the ceramic layer and later through the excessive gamma activity of the crucible.

za do juar en esperante de la composición de la composición de la composición de la composición de la composici

No major technical problems were encountered in the preparation of the 115 MASURCA castings. On one occasion faulty operation accompanied by simultaneous failure of a warning device led to the spindle being left without cooling water when the crucible was heated. The only consequence of this was that some of the spindle retaining pieces were burnt through.

4.2.3 Material balances

Table 4 gives the Ma-28 charge balance

Table 4

ingot : sla g : waste :	10056 g alloy 127 g	2514 g Pu 32 g Pu 4 g Pu
starting quantity	:	2550 g Pu

The amounts of slag were normally between 70 and 200 g. In some cases these were considerably higher, especially when the piece of plutonium used had surface folds and difficulties were encountered in brushing away the oxide layer. The largest amount of slag was 403 g, found after casting charge Ma-91. It was also shown that the alloy contained only 23.44% Pu instead of the planned 23.80%. The piece of plutonium used was probably severely oxidized on the inner surfaces. Moreover, this melt was the only one which had to be discarded or remelted with additional plutonium because its deviation from the required plutonium content was too marked.

The amounts of waste which could not be reprocessed contained amounts of plutonium which varied between 1 and 40 g. There were marked variations in the amount of slag because in some cases much slag remained stuck to the crucible and was removed as waste whereas in other cases all slag could easily be removed. Since dust and dirt (see Section 4.2.2) were also regarded as waste in addition to the graphite and MgZrO₃ contaminated slag, and bearing in mind that during fabrication no permanent analyses of this product could be made, the normal amount of plutonium lacking in the balance was assumed as present in the waste. A detailed report on the subsequent handling of this difficult problem is given in a later section (7.1).

In the melting of clean slag and turnings, described in Section 4.2.2, the yield of good alloy material was between 55 and 65%. The unmeltable remainder was taken as waste.

4.3 Second casting

The central stage of the whole fabrication process was the casting of the alloy into rods. A possible method here was the so-called centrifugal casting process, which is frequently used for manufacturing specific castings, especially in the jewellery industry. Its advantages over other processes are as follows : good yield, very high dimensional precision and high casting density, plus good alloy homogeneity.

The centrifugal casting process had already been used for fuel element fabrication (Ref. 4). It was possible to carry out a series of experiments on casting MASURCA rods at the Argonne National Laboratory at the beginning of 1964 with one of the furnaces available there. The furnace used for fabrication in the Transuranium Institute was designed by Heraeus of Hanau from results determined from the above experiments. It is situated in plutonium zone B, in caisson 2a.

4.3.1 The centrifugal casting furnace

The layout of this furnace is shown schematically in Fig. 14. A crucible with a pouring hole was situated in the firmly mounted spindle. A hopper was fitted underneath the hole,

stopping just short of the chill distributor. The four chill segments (Fig. 15) could be tightly bolted to the chill plate, which revolved around a central axis. The pouring hole was closed with a stopper rod and only opened when casting conditions were obtained. The melt then fell vertically in a straight line and passed via a distributor (Fig. 14) into the 22 holes in the rotating chill, where it quickly solidified.

The 1 liter capacity crucibles used were graphite and sprayed with $MgZrO_3$. The stopper rod and the stopper also had a protective layer of the same ceramic material over the graphite.

The first distributor pieces were also of graphite but were later manufactured from steel since it was found thatthey often disintegrated after just one casting. An adhesive layer of MgZrO₃ was also applied to the steel parts; it was, however, necessary first of all to clean and roughen the surface by sandblasting. The layer remained firm despite the great thermal shocks during castings. The only place severely attacked was at the point where the stream of molten metal from the crucible landed. It sufficed, however, simply to replace the small middle section of the lower part of the distributor from time to time and not the whole unit.

The first chill was made from copper. It was impossible to manufacture the boring with the required precision (H-7) because of the softness of this metal. Consequently this chill was replaced by one made from steel. Despite the lower thermal conductivity compared with copper, the steel chill proved to be good. It was found, however, that some diametrical irregularities could be traced back to small faults in the chill. Further details are given in Section 4.4.

The furnace pivot was water-cooled. It could take a maximum current of 4.5 kW, should preheating of the chill and distributor have been required. It was thus possible to reach a chill temperature of 190° C and a distributor temperature of 700° C in one hour,

which was particulary desirable when casting alloys with high melting points. The distributor temperature could be measured by means of a thermocouple, also led through the axis. The rotational velocity of the chill and the axis lay between O and 600 rpm, infinitely variable and could be read off from a rev counter.

es d'alle d'an a an la cleatheachtaire ann an bhaile bhailteachta

The water-cooled furnace jacket and lid could be lifted from the base plate (Fig. 17). The vacuum connection led off sidewards from one of the jacket nozzles, over a "tombac" bellows to the side plate of the glove box and from there to the pumps. The backing and Roots pumps had the same pumping capacity as those in the other furnace (Section 4.2.2). On the other hand an oil diffusion pump of 2000 l/sec was selected since only decontaminated material was melted in this furnace. The safety devices, control systems and cooling circuits were also similar to those in the other furnace. Safetameters and a similar

When the preliminary tests were being carried out, a few breakdowns resulted, caused above all by the complex layout of the axis. These problems were solved after design improvements and the whole fabrication program of 108 centrifugal castings was completed without difficulties.

an in the first second second

4.3.2 Carrying_out_centrifugal_castings

4.3.2.1 Preliminary tests :

After the furnace went into service, it was necessary to determine the most favourable casting conditions. First of all, a total of 19 castings with alloys of non-active materials (Al -10 w/o Fe and Ag - 28 w/o Cu) were carried out in addition to 23 ingots with an uranium-iron alloy (U - 6 w/o Fe) which approximated to the density, melting range and other properties of the MASURCA alloy. Before examining the results in more detail, attention should be first of all drawn to one characteristic of the process used.

3I

It appeared possible that the molten alloy could be poured directly into the final steel can, seal-welded on one side, without fear of a reaction between the steel and the alloy. This was effected by having the jacket can surrounded by a close fitting chill, with a sufficient heat capacity, in order to obtain a good heat transfer. The molten alloy then solidified almost immediately after contact without reacting or deforming the can. Good rods were successfully fabricated directly in the final cans in this way. All that remained was for these rods to be turned at the head and be fitted with a second cap. However it became evident that much time was lost in the decontamination of such elements because their cans had been handled in heavily contaminated glove boxes, and that it would therefore be more economical to discard the cans used in casting and to place the rods in new cans after turning them to the exact length and cleaning their surfaces. However, the process of direct casting into the final cans was feasible and could be recommended in the case of complex ingots where filling difficulties were encountered.

The cans used in casting were provided with a thin inner layer of SiO_{2} for the following practical reasons :

- the layer facilitated the removal of the can after casting; usually the rod could then be extracted easily.
- the layer enabled lower casting temperatures to be used which, among other things, led to an improvement in rod surface quality.

SiO₂ was chosen as most suitable after detailed study. It had been shown that thin, uniform and sufficiently adhesive SiO₂ layers, approximately 4 um thick, could be prepared simply and reliably from inexpensive, commercial aqueous suspensions (Soltex 20M manufactured by Degussa of Frankfurt).
The can end turned inwards towards the distributor was fitted with a narrow graphite ring to stop the can edges from coming into direct contact with the melt.

and an A

The preliminary tests with the centrifugal casting furnace did not always lead to perfect rods. The alloy was homogeneous and fine-grained (Fig. 18) but some rods showed a definite surface fault at the same place as well as a slight dent (Fig. 19). Each time the fault occurred right behind the head of the rod in question and was 10-30 mm long, 10 mm wide and 0.2-0.6 mm deep. In each case the material directly beneath the fault was completely sound.

When the fault did not appear in the cans, it occurred directly on casting into the chill.

During the preliminary tests and during the fabrication proper, the number and size of these defective spots were successfully reduced, but could not be eliminated entirely.

Rods with no or barely perceptible faults were used to fabricate long elements and the remainder cut up and made into short elements. In general no important obstacles to fabrication came from this partial imperfection of the rods.

Casting experiments with the Al-Fe and Ag-Cu alloys served principally to verify the overall functional capacity of the furnace and to carry out necessary improvements before the whole installation became contaminated. The main reason of experiments with U-6 w/o Fe was to determine the most favourable casting parameters.

A somewhat surprising result of these experiments with the uranium-iron alloy was that within certain limits there was no marked correlation between rod quality and the casting parameters examined. The following were varied :

- the melt temperature between 830 and 1110°C (melting range of U-6 Fe 725-800°C), the distributor temperature being between 380 and 750°C;
- the rotation velocity between 60 and 400 rpm;
- the diameter of the crucible pouring hole between 8 and 24 mm and the casting time between approximately 14 and 3 sec;
- the length and free inner diameter of the graphite rings in the open ends of the cans and the depth to which the rings penetrated the distributor.

The angle between the rod holes in the chill and the distributor (Fig. 15) could not be varied since the amount of material required for fabrication of the chill with close tolerances and the time taken testing several chills with various angles seemed too great.

The most favourable angle, i.e., the angle at which the melt flowed into the chill holes with the least resistance at a specific rotation velocity, was almost impossible to calculate in practice since the viscosity of the melt flowing through the distributor and the frictional resistance of the distributor surface must be known in addition to other details. An angle of 90° was selected which seemed to be favourable for rotation velocities of 100-200 rpm, although it is quite possible that the fault already mentioned in some rods could be eliminated by choosing a different angle.

4.3.2.2 Fabrication :

Conditions were altered even during the 108 centrifugal castings in the fabrication process to improve results still

further, but these were not on the same scale as during the preliminary tests. A survey of the temperatures and rotation velocities applied is given in Table 5 (see next page).

المراجع والمعاور مراجع والمراجع

The most important alterations during fabrication were :

- no heating of the distributor and chill from Ma-30 onwards (the 35-45°C given were caused by heat radiated from the crucible).
- use of a steel chill instead of a copper one from Ma-66 onwards.

Both alterations reduced the number of faulty elements produced. The use of the steel chill eliminated the slightly oval shape of the cross-section which had previously occurred in some rods. This fault was directly linked with the relatively high deformability of the copper chill. It was mainly the rods at the edge of the individual mould segments which had this oval shape. Details of the rod diameters and the extent of the ovality are given in a later section.

The diameter of the crucible pouring hole - 10 mm - was not altered during fabrication. The melt took 11 seconds to flow from the crucible. The 9 mm inner diameter of the graphite rings attached to the cans remained unchanged.

The melting procedure was as follows : the alloy ingot weighing approximately 10 kg was placed in the crucible and the stopper rod inserted into the pouring hole through the hole provided in the charge ingot. The 22 steel cans fitted with an inner SiO_2 layer and an inserted plug at the lower end were placed in the chill holes and the chill and furnace were then closed. When a good vacuum had been obtained, the crucible was heated and the desired casting temperature set. A thermocouple,

	Crucible temperature during casting C	Distributor temperature before casting	Rotation velocity (rpm)	Vacuum during casting (mm Hg)

·. ,•

36

placed in a hole in the center of the blocking rod, was used for exact temperature measurements. The chill was then rotated and the blocking plug raised. The melt fell as a uniform stream into the distributor in approximately 11 seconds, followed by single drops. The chill was stopped some three minutes later. The total time between the beginning of pumping out and casting was 40-60 min. The furnace could be opened after a further 60 minutes and the rods removed, but usually, in accordance with the work schedule planned, this was not done until the following morning.

Fig. 20 shows the partially opened chill after a casting. The distributor lid is also removed. In this figure, the filled cans with the graphite rings protruding somewhat into the distributor, and the alloy residue remaining in the distributor can be distinguished. Since the amounts of material are so chosen that only a very small amount of alloy remains in the distributor, the individual filled cans could be easily separated and removed from the chill. The rods were then taken from the cans, brushed and the graphite rings removed (Figs. 21, 22 and 23).

Exact analyses of samples taken from various parts of a rod showed a satisfactory alloy homogeneity regarding the plutonium and iron contents.

The subsequent treatment of slag and alloy residue which remained in the melting pot is as described in Section 4.2.2.

On the whole, no incidents worthy of mention occurred during the 108 castings. On three occasions the melt began to drip through the base hole before casting because of minor faults in the blocking rod. In one case, usuable rods were obtained by immediate casting, but in the other two the operation had to be repeated.

4.3.3 Material balance sheet

Table 6 gives the balance-sheet for charge Ma-53 :

Table 6 : material balance of a charge after centrifugal casting

outflow :	10238	g	alloy	=	2560	g	Pu	 	
waste :				=	2	g	P u		•
slag	285	g		Ξ	71	g	Pu		
alloy residue :	461	g	11	=	115	g	Pu		
22 rods :	9489	g	alloy	=	2372	g	Pu		

The quantities of slag and waste were of the same order as in the first casting. More detailed data on the amount of waste are to be found in Section 7.1.

Clean alloy residue, for instance, excess material from the distributor, could be used directly for subsequent charges.

4.4 Processing of the Cast Rods

4.4.1 Lathe work

After being transferred to caisson 1, zone C, the good rods were separated from the defective ones. Either one long core or two short ones could be made from the good rods. The other rods each yielded one short core. The rods were cleaned on a lathe by means of a steel brush and then cut to a length of some 3 mm over the final length (Fig. 24). Turnings were taken from the centre of a rod and used as samples for analysis. Each rod was inserted between the chuck and centre of the lathe, the maximum diameter being controlled and, if necessary, corrected by slight turning. This was necessary to eliminate the oversizing in certain places along the diameter caused partially by the lack of roundness (see Section 4.3.2.2) of individual rods. After the steel chill had been used, the diameter was 12.10 ± 0.05 mm, the maximum ovality remaining also in this range.

The purpose of the turning was to adjust the diameters of the rods to the inner diameters of the cans. It was found that in the event of further decontamination a great deal of time and energy could be saved if the rods could be inserted into the cans with relative ease, i.e., with a play of approximately 0.06 mm over the diameter. Otherwise the upper, most exposed inner edge of the can was often scratched which caused great decontamination difficulties. Since the inner diameters of the cans varied within the permitted tolerance limits of 12.10 - 12.25 mm, cans of the same size were selected for each charge and the rods turned to the corresponding diameters, 0.06 mm smaller. The resulting amount of scrap was exceptionally small.

After this, the top and bottom surfaces were turned until the core lengths were about 1 mm greater than the normal length. The tapered core headpiece was also fabricated at this stage. Weighing was then carried out. It was possible to determine the necessary final length of all cores on the basis of the knowledge of the individual weights. These were chosen so that as much use as possible could be made of 5.1 mm thick standard support discs (Fig. 1) in the long elements when the core weight was at the same time still in the desired region of 400 + 1 g. No discs were normally planned for the short elements (Fig. 2) and the desired core weight was 200.0 + 0.5 g. Definite weights had to be adhered to in order to be certain of reaching the required constant fissile material content (Section 2.3.2). It was often the case that discs 3 or 6 mm thick also had to be used with long elements and discs 1.0 or 1.5 mm thick with short elements to meet this requirement. Occasionally, greater deviations from the average weights were required. Values of 400 ± 2 or 200 ± 1 g were not, however, exceeded.

The tapered core headpiece was also allowed for during the turning. On completion of this work the cores had a shiny, metallic appearance (Fig. 25).

4.4.2 Material balance

Table 7 shows the balance of charge Ma-53 after turning

Table 7 :

9 long elements :	3601	g	alloy	=	900	g	P u
13 short elements	2599	g	11	=	650	g	P u
alloy residu e	2868	g	11	=	717	g	Pu
coarse turnings	398	g	**	=	100	g	Pu
fine turnings	4	g	"	=	1	g	Pu
analysis sample for TU-Institute	8	g	e H	1	2	g	Pu
analysis sample for CEA	5	g	11	=	1	g	Pu
waste		-			1	g	Pu
starting quantity	9487	g e	alloy	=	2372	g	Pu

To facilitate plutonium accounting, it was at this time that the plutonium content in elements with 8% Pu-240 was fixed at 100 g for long cores and 50 g for short cores. In the other elements these figures were 95 and 47 g Pu respectively. These amounts were corrected only on the basis of analysis data and individual weights after the completion of a charge.

The alloy residue could be reused for the composition of other charges. The coarse turnings were fused with clean melt slag (see Section 4.2.2) and the fine turnings generally treated as waste.

4.5 Element_assembly

The cores were reweighed immediately after the final machining and rubbed with Kleenex, moistened with absolute alcohol, to remove the dust and were inserted into suitable cans. Fast

working was advisable in this instance since the plutonium allow formed a thin surface oxide when placed in the glove box atmosphere (N_2 with approximately 1% O_2 and 10 - 50 ppm H_2O). After the insertion of such a weakly oxidized core in a can, the open end of the can was correspondingly harder to decontaminate because of the formation of PuO_2 dust. Fig. 26 shows how a core was inserted in a can. At this stage the cans were already provided with the lower plug, onto which successive numbers had been engraved to a depth of 0.5 mm before cladding. They were also covered on the outside with a layer of strippable film paint for protection against contamination.

nteres dant adde wat die ter dae e date oord

After the cores had been inserted in the cans, the elements, open on one side, were transferred from severely contaminated lathe glove boxes to a relatively clean glove box. The first procedure was coarse cleaning of the open, inner end of the can with Q Tips *). The open end was then sealed with a round Scotch Tape disc and inserted in a clean decontamination glove box through a narrow tube. The open, inner and the outer end of the can were then carefully rubbed with Q Tips (Fig. 27) until practically no free contamination was detectable by alphamonitoring. Before use, the Q Tips were very slightly moistened with absolute ethyl alcohol. After this decontamination stage and when necessary for length adjustment (Section 4.4.1), a steel disc was placed on the core, the plug carefully inserted and the strippable film paint removed. The whole operation decontamination, insertion of the plug and stripping of the paint - lasted, on average, five minutes for each element. A further alpha-control was carried out before the elements were packed in clean plastic sheats and sent to the welding machine. On the still unwelded plugs, measurements of 100 -400 cps were recorded for the most part. The contamination that could be removed should not, however, be detectable. The relatively high count was caused partly by alpha-particles emitted by the Pu alloy, i.e., the core surface, through the narrow gap between the can and the plug. The remaining element surface was practically completely free from contamination.

*) Trade mark for small wooden sticks with a cottonwool head.

4I

In almost all cases the elements prepared in this way were immediately welded because, even after a few hours storage, free contamination became evident on the unwelded ends. This was probably due to the extremely fine oxide particles which were detached from the alloy surface by alpha-recoil and subsequently strayed to the outside.

4.6 Welding-Seal of Plugs

Both plugs of each element were welded by means of an electron beam unit manufactured by Sciaky (Fig. 28). The working of the electron gun was 30 kV and the maximum output 7.5 kW. A glove box was attached to the unit from which the element could be inserted in the furnace and in which the finally welded element could be controlled.

4.6.1 Preparation of cans and plugs

It was shown after a series of preliminary tests that various requirements were necessary :

- the can ends must be clean and rectangulary trimmed,
- cans and plugs must be cleaned and completely grease-free,
- the gap between plug and can calculated over the diameter should be approximately 0.07 mm.

The first requirement - right-angled edges - was satisfied by grinding all the can edges, the second accomplished by means of an ultrasonic cleaning bath. The uniform good seating of the plug could only be attained by suitable adaption of the outer diameter to the average diameter of the particular can charge. Since the inner diameter of all the cans fluctuated between 12.10 and 12.25 mm within the permitted tolerance limits, the plugs were not turned to the final outer diameter until after the cans had been delivered. The can manufactures were able to keep to constant diameters and wall thickness (the inner diameters in one of the delivered charges were 12.18 ± 0.01 mm for instance), but for a large consignment made up of several charges they could only guarantee the tolerances given above, which incorporate the permitted fluctuations of the outer diameter and wall thickness.

4.6.2 Preliminary Tests

Extensive preliminary investigations were made before the best welding parameters were determined. These covered micrographic examinations, tensile tests, dimensional controls and visual inspection. Welding proper began only after sufficient experience had been gained. The two lastnamed non-destructive tests were mainly used for assessing the quality of the first cap weld seam, only spot-check micrographs were made. The only tests carried out during actual fabrication of the second cap were non-destructive.

Typical examples of regular welding seams are shown in Fig. 29. It can be seen from these that the seams are sufficiently deep and relatively little grain growth occurred.

Tensile tests were carried out to verify these results. A schematic diagram of the testing machine is given in Fig. 30. Table 8 gives the results and it can be seen that it was the can and not the weld seam which cracked first in 50% of the cases. However, with tubes which after visual inspection appeared to be satisfactorily welded, tensile strengths corresponding to the material values for 304L or slightly below were always obtained.

Yield point for 304L: $53 - 59 \text{ kg/mm}^2$

Table 8 : Results of tensile tests

*) Visual inspection before testing had shown that cans 914 and 1556 were not reliably welded and were thus rejected.

Measurements of the diameters were required after welding since it became evident that even with seams too deeply welded by just a fraction, the outer diameter at this point exceeded the tolerance limit of 12.70 mm by up to a maximum of 0.05 mm. This phenomenon occurred in a great number of cans. This slight excess was, however, eliminated simply by clamping them onto a lathe. This treatment had no influence whatsoever on the quality of the welds which could be determined by exact controls and comparison.

Special value was attached to visual examination of the welding seams, since, apart from the density control with the helium testing (Helitest) device, this was the only non-destructive quality control performed in the second batch of welds. A satisfactory weld is shown in Fig. 31.

4.6.3 Practical execution of welding

A device with rotating clamps in which six units could be fixed at any one time (Fig. 32) was used for holding the cans or elements. The plugs were pressed firmly on to their supports over small springs. The depth of penetration into the can was determined in the case of the first plug by its small collar and in the second by the contact with the core of the element in question or the supporting disc placed above (Figs. 1 and 2).

When the revolving unit had been inserted in the vacuum chamber and the doors closed, the chamber was evacuated until a pressure of 2.10^{-4} mm Hg was reached, which required about 10 minutes. Before welding it was necessary to focus the electron beam (0.05 mm) exactly on the right spot. The upper surface of the collar was the target in the first plug and the gap between can and plug in the second.

Welding was always done with a voltage of 19.2 kV and a vertical electron beam directed from above, i.e., a beam directed parallel to the element axis. Each welding operation was composed of three stages :

- the actual welding,

- rewelding of the same for improved homogeneity,
- subsequent annealing to remove stresses.

The exact parameters are given in Table 9, (see next page).

A cooling period lasting a few minutes followed the welding, after which the chamber was flooded with nitrogen and the cans or elements taken from the revolving apparatus. The elements were tested for contamination and taken from the glove box after a thorough visual examination.

The following can be said concerning contamination. A large number of the first plugs were welded in the installation without the need for subsequent testing. The rest all required testing, because plutonium bearing samples had been previously

Table 9 : Welding parameters

cut leaving the machine in a contaminated condition. These setting tests gave negative results, but in spite of this those cans closed on one side were, once again, cleaned in an ultrasonic bath before being handled in the open.

The position was somewhat different with the second plug, which had given an alpha pulse count of 100 - 400 even before welding. Afterwards these values were generally reduced to about 25% of the original values. However, elements were found with practically no contamination and others with too much. This contamination was localized in the welding seam. Even after months of storage it could not be freed and brushed off and thus represented no danger when handling elements outside a glove box. For safety reasons, however, the closed elements were also cleaned in an ultrasonic bath, but only after the completion of further work stages.

The total welding process for each batch of six plugs, i.e., loading of the revolving apparatus, evacuation of the chamber welding, cooling, flooding of the chamber, unloading, visual inspection of the weld seam and contamination control, took some 45 minutes.

Most of the badly welded elements (120) and those with too much contamination (80) were opened immediately after welding in another glove box. This enabled the cores to be re-canned and rewelded. A small number of faulty elements were, however, taken from the charges concerned for reasons of work organization and the cores remelted.

4.7 Cap Grinding

Both element caps were ground after welding since this was the only way to ensure that the exact end dimensions with the narrow tolerance of \pm 0.05 mm were adhered to and that the large outer cap surfaces were perpendicular to the element axis and completely flat. The caps were therefore made somewhat thicker than required, giving an excess of about 0.3 mm over the length of the element.

an an an tha she and the second se

The surface grinding machine used was a standard commercial model which only had to be very slightly altered for installation in a glove box (Fig. 33). It was decided to use a glove box for safety reasons even though the elements were closed and practically free from contamination at this stage of fabrication.

The long and short elements in a charge were ground seperately. The short elements were first of all mounted together in a compact jig firmly attached to the table of the machine in such a way that the first caps - those with the numbers engraved on them - were on top. The maximum difference in the height between the individual elements was 0.1 - 0.2 mm. This was followed by dry grinding until traces revealed that the top side of the cap of the longest element had been completely machined. This element was then removed and the grinding wheel slowly lowered until the next element(s) were reached. This process prevented the engraved number from becoming illegible or removed.

and the second second

The elements were rotated after this first grinding, positioned with the clean surfaces of the first cap on a smooth plate and mounted in the jig together with a standard rod, whose exact length had been set at 25°C. The elements were left standing for 30 minutes for an uniform temperature to be attained. This was followed by slow grinding in which no special coolant was used. The exact length could be attained by comparison with the standard rod and with the help of a firmly mounted, sensitive gauge (Fig. 34).

14. S. 1. S. 1.

• A CARLER AND A CARLER AND A CARLER AND A REPORT

Approximately three hours were necessary for grinding a complete charge. The whole surface of the elements was then polished on a lathe with ultra-fine emergy paper. This process removed a slight burr which had formed on some of the caps during grinding. The lathe was situated in a contamination-free glove box. The subsequent cleaning, on the other hand, took place in a normal chemical hood. On completion, the elements could be openly

handled, i.e., outside the glove boxes and hoods, since no more alpha-contamination was detectable on the surface. I usu when the second since the second second we deduce a second seco

4.8 Density Check

At this stage of the fabrication of an element charge, it had not yet been verified whether the weld seams in the second caps were completely airtight or whether any damage had been caused to the elements during the subsequent machining. Serious faults would have been seen at once or ascertained by the appearance of free contamination. However, such phenomena as new microcracks in the cans or porous spots in the weld seams could not be detected in this way. All elements were therefore tested with a helium testing (Helitest) device (Fig. 35).

The charge elements were left overnight in a container under a pressure of 30 atm helium, the container being opened on the following morning. The elements were left for an hour in the open air before measuring began to remove any helium that may have been adsorbed from outside. Either three long or six short elements were then placed in the measuring chamber, which was evacuated. Only two cases of leakage, greater than the permitted treshold of 10^{-8} Nml/sec for each individual element were detected during the subsequent measurement.

A set of the set of th

4.9 Spontaneous Neutron Counting

The counting of neutrons, produced by spontaneous fissions of Pu-240 is one of the methods for the non-destructive measurement of plutonium contents. Especially for metallic fuels, where the contribution of (α,n) reactions is negligible, this method is a very precise and valid one. Consequently it was used for the standard independent control of the fission material content of each be element.

The neutron tank (Figs. 36 and 37) was calibrated by means of two fuel rods of precisely known weight and Pu-240 content, which were selected as standards of reference for the corresponding series of elements. Their count rates were regularly controlled before and after every charge, in order to avoid systematic errors owing to slight changes in counter efficiency. The fuel elements were placed one after the other in the counter; their count rates compared with the relative standard and their Pu-240 content directly calculated.

The main characteristics of the standards are given in Table 10. The data used to calculate the total neutron emission from spontaneous fission are taken from Refs. 6, 7 and 8.

It follows from the data reported in Table 10 that Pu-240 is by far the strongest neutron source. The total neutron count rate was assumed to be proportional to the total Pu-240 content in the element.

It is interesting to compare the average values of the different Pu-240 determination methods.

8.510 and 3.929 w/o Pu-240	by neutron counting of all
	elements,
8.454 and 3.920 w/o Pu-240	by mass spectrometric analysis
	of all Pu ingots at the TU
	Institute,
8.383 and 3.832 w/o Pu-240	by mass spectrometric analysis
	of all Pu ingots at the USAEC

With regard to our mass spectrometric values, which form the basis of the fission material calculations for P_1 and P_2 , there seems to be a very small systematic error in the neutron counting values.

19 and an and

and the second

The statistical measurement error was in the order of 0.3% with a $me_{a}suring$ time of 10 and 20 min respectively for the long and the short fuel rods.

The results of all measurements can be found in Appendix 1.

To prepare the counter, a cylindrical tank, 1050 mm high and with a diameter of 900 mm, was filled with paraffin. Along the central axis a hole of 32 mm I.D. was drilled through which the fuel elements were introduced for measurement (Fig. 37); 48 BF₃ tubes (Frieseke and Hoepfner Type NZ) were placed around the central hole in three concentric circles, each of 16 counters. They were fed with 3100 volts from an FHT 101 A high voltage unit and connected in groups of nine or ten to five transistorized preamplifiers placed in the tank.

A conventional counting chain composed of an impulse mixer, a bias amplifier (FHT 200 C), a timer (FHT 120 A 1), a scaler (FHT 120 A2) and an automatic printer (Kienzle) was used. A cadmium cylinder was placed around the counter assembly to reduce background caused by external neutrons. The tank was earthed to achieve a complete Faraday cage (Ref. 8).

The vertical sensitivity of the neutron tank was measured with a Ra-Be source of about 5 millicuries. The resulting curve is asymmetrical because of the reduced thickness of the paraffin layer of the moveable top. The rapid variation of the sensitivity with the vertical position of the source in the tank required accurate control of the position of the fuel elements by means of adequate supports.

4.10 Final Controls and Facking

During the final controls, the following were carefully tested : outer diameter, deflection, weight and contamination. The elements were also examined for possible can damage, such as dents.

The most important features of all finished elements are given in Appendix 1. Two finished elements are shown in Fig. 38. About 130 elements were discaded after the final controls. Since in the

majority of cases they revealed only exterior faults, the cores could have been directly recanned. However, it proved easier, for reasons of accounting, to remelt them and use them again in later charges.

For the same reasons, work organization and plutonium accounting, some elements which had previously been found to be faulty, underwent the final controls and were only then discarded. The most frequent fault in long elements was excessive deflection, i.e., the tolerance limit of 0.10 mm was exceeded.

In one series of short elements, the outer diameter was too close to the lower tolerance limit of 12.65 mm and a considerable number of elements had to be rejected on these grounds.

en en ante en la companya de la comp

and the second of the second second

Again, the contamination count was carried out with a high degree of accuracy. It became evident that the alpha-monitors used were susceptible to neutrons, hence the measured alpha-impulse count had to be somewhat corrected. Values of less than 100 impulses per minute were recorded for the majority of the elements.

Single finished elements were also radiographed (Fig. 39).

The elements, in sets of two short elements, were sealed in plastic tubing and packed into special steel containers with threaded covers. Each container could hold 1.5 kg Pu - 15 long elements or 30 short ones. The containers were placed in twos inside the steel case of CEA-birdcages.

4.11 Waste of a state of the transmission of the state of

The problem of concentrated plutonium-containing waste is dealt with in this section.

Low-concentration waste such as Kleenex from the decontamination stage, gloves and glove-box filters, etc., appear in the material balance sheet (see Section 6.2) as waste.

Concentrated waste usually comes from one of three sources :

4.

- fine powder from comparatively pure PuO₂, resulting from brushing of the ingots;
- fine to coarse powder and both small and large pieces of slag from the crucibles;
- fine turnings and dust swept up from the glove boxes.

The first-named material was homogenized and analyzed. The value of the plutonium assay for powder with 8.4% Pu-240 and 3.8% Pu-240 was 87.71% Pu. The remaining waste was collected together and completely ground to powder in 11 portions weighing between 2 and 6 kg. It was then passed through a sieve with a 1 mm mesh and thoroughly homogenized. A sample was taken in the conventional way from each of the 11 portions. The average values used in the material balance-sheet (Section 2.5) for this type of waste were calculated according to the individual analysis results. The average results for 8.4% Pu-240 were : 22.83% Pu, 67% U, 9% C and 1% Fe.

The results for 3.8% Pu-240 were as follows : 22.71% Pu, 68% U, 8% C and 1% Fe.

The alloy is therefore largely one which is well mixed with crucible graphite and is only slightly oxidized.

4.12 Calculation of the Fissile Material Content

The individual P_1 and P_2 values of all elements can be found in Appendix 1. These were calculated using :

an an ar an ar a

11 A. 1993

- the core weights,

てんわら 日本 竹

Max 2.5 Ar

- the analytically determined plutonium content,

- the isotopic composition of the charge.

In order to obtain a common starting point, the calculations were based on the isotopic concentrations which had been determined in a previously described process (Fig. 10) from mass spectrometric analyses of the plutonium ingots. The measuring of the Pu-240 content by spontaneous neutron counting, carried out on every element, served as a control of these calculated isotopic compositions.

The totals of the calculated Pu (239 + 241) contents and the Pu-240 content determined by spontaneous neutron measurement, given in the third column in Appendix 2, were on average 100.01%. Allowance should nevertheless be made for the fact that spontaneous neutron measurement values appear to be some-what too high owing to a small systematic error, for the Pu-242, some 0.04% is missing from the total. When both these factors have been allowed for, the agreement can be regarded as very satisfactory.

As we described in Section 2.3.2, only small deviations of the fissile material contents P_1 and P_2 , were permitted from the average values for short or long elements. However, these average values could not be known with any degree of accuracy until after fabrication, so that other methods had to be found. This was done by keeping the weight of the alloy cores and the plutonium content of the alloy constant at 25.0 and 23.8 w/o respectively and by continuously performing intermediate calculations.

The average values for short elements were 45.75 g Pu (239 + 241) and 91.47 g Pu (239 + 241) for long elements. Thus the ratio between P_1 and P_2 at ≤ 0.01 was correctly forecast by the formula given in Section 2.3.2. The actual value was 0.0003.

The number elements which had to be rejected owing to their fissile material contents being either too high or too low was relatively small (see Section 6.1).

4.13 Heat Treatment of an Element

MASURCA is a zero-power assembly, i.e., during neutron physica measurements, virtually the only source of heat was the alpha decay of the plutonium. Maximum operational temperatures were therefore 50°C but far higher temperatures can occur when the assembly "runs away".

In order to test heat treatment behaviour in the finished elements, two long elements, heated at a rate of 150°C per hour, were heated to 500°C and air cooled down to room temperature. A comparison of various dimensions and other values before and after treatment is given in Table 11.

Contamination Imp/min	20	20	180	180

Table 11 : Changes in the properties of two elements after heat treatment

....

The table shows that the external appearance of both elements remained almost unchanged. However, an inconsistent result was obtained with a "rattling test", in which a horizontally placed element was slowly rotated manually around its longitudinal axis. If the core rests firmly between the two end plugs, it cannot rotate independently of the can. Should it be only somewhat loose, a slight noise can be heard. This test is very sensitive. Whereas the cores had not moved in the can before the heat treatment, they did so afterwards and the noise was audible. Radiographs of the element heads (Fig. 40) revealed that in one element, especially (no. 1225), a distinct gap appeared between the plug and the supporting disc. For comparison, reference should be made to the radiograph of a sound element (Fig. 39) in which the plug is firm. The exact width of the gap in elements which had undergone heat treatment was hardly measurable and radiographs of samples with defined gaps were prepared to obtain an approximate estimate. These showed that the gaps in treated elements could be only some 0.02-0.03 mm wide.

5. CHEMICAL ANALYSIS

During the production of the MASURCA fuel elements, fabrication was controlled by chemical analysis, namely by determining the percentages of plutonium and iron. However, traces of carbon and, by emission spectrographic analysis, traces of silicon, magnesium, manganese, chorium, nickel and molybdenum were determined in order to check whether the amounts of these elements remained below certain specified values.

A total of 108 samples were analyzed. This large number of results enabled some conclusions to be formulated on the accuracy of the analyses and the reproducibility of the production process.

The analytical methods applied are standard methods, as described in detail in Appendix 5. No serious difficulties were encountered in carrying out these determinations.

The majority of the fuel elements had to contain 25% of plutonium, 74% of uranium and 1% of iron. A minimum 23.8% of plutonium, 75.2% of uranium and 1% of iron was specified.

5.1 Plutonium content

Plutonium was determined according to the following method (9):

"Dissolve about 500 mg of the alloy in a mixture of nitric and hydrofluoric acid. Add to an aliquot of this solution silver (II) oxide and after 15 minutes remove the excess of the oxidant by heating. Add an iron (II) solution in excess to the plutonium present and titrate the excess of iron (II) with a standardized cerium (IV) solution, locating the end point by constant current potentiometry".

Several factors contributed to the final accuracy of the results. The following sources of variation could be distinguished :

- the dissolution inclusive of weighing of the sample;
- the determination itself (manipulations, apparatus, readings, etc.);
- differences between samples caused by variations in the production conditions.

In order to distinguish between the contributions of these three sources of variation, seven samples of different casts were analyzed according to Scheme I in Table 12 and six samples according to Scheme II. The results of these determinations are given in Table 13.

First, it was established whether the data in the tables contained exceptions. For that purpose the upper control limits for the range were calculated for both parts of the table in Ref. 10. The mean ranges, \overline{R}_1 and \overline{R}_2 , were found to be 0.070 and 0.117 respectively and so the upper control limits, G_1 and G_2 , amounted to :

$$G_1 = D_4 \cdot \overline{R}_1 = 2.282 \cdot 0.070 = 0.160$$
(1)

$$G_2 = D_4 \cdot \overline{R}_2 = 2.282 \cdot 0.117 = 0.270$$
(2)

From Table 13 it followed that no range value exceeded these limits hence it was concluded that all values were under control. Consequently all values could be used for further analysis.

Next, a variance analysis (Ref. 11) was carried out with the two parts of Table 13 and the results are given in Table 14.

Table 14 shows that all sources of variation (samples, weighing/dissolution and analysis) contributed significantly to the final scatter. The estimates of these contributions were calculated according to the following equations :

Т	a	b	1	е	1	2

 $s'_{e} = 0.071$ " $\gamma = 5$
 $s_{dwe} = 0.055$ " $\gamma = 18$

 s_o and s'_o were estimates of the same \mathfrak{S}_o . No significant difference between s_o and s'_o was detectable using the F-test (Ref. 12) and these two values were, therefore, combined in order to find a better estimate based on a larger number of degrees of freedom. The same remark could be made concerning the values s_e and s'_e . Finally, the following values were found for the respective contributions (see Table 15).

It should be noticed that the values in Table 15 are absolutes, since the final result of the determination is given as a percentage.

The accuracy of the determination itself ($s_a = 0.027\%$ or 0.027 mg under the actual conditions of the analysis) was very satisfactory. This value was in very good agreement with the value found from the results of the determinations of plutonium in 45 pure solutions of plutonium nitrate which were prepared for other purposes. These solutions contained from 2 to 45 mg of plutonium per ml and were analyzed in duplicate, taking 1 ml samples. The standard deviation of a single determination, calculated from the mean range, was found to be 0.025 mg.

It follows from Table 15 that in the analysis of the alloy, the final result was more affected by the scatter due to the dissolution of the sample than by the determination itself.

In short it can be said that so far very reliable results had been obtained. Therefore it was decided to reduce the number of analyses per sample : two portions from each sample were weighed out, each portion was dissolved and solution analyzed once. In this way two results per sample were obtained.

In order to check the reliability of these results obtained with the resulting samples, the upper control limits for the range and the control limits for the mean were calculated (Ref. 10).

The standard deviation of a single determination, $s'_{dwa'}$ was calculated from the mean range of the results, obtained with 94 samples.

The result was :

 $\mathbf{s'}_{dwa} = 0.038\%$ with $\varphi = 93$

This value is significantly lower on the 0.05 level than that of s_{dwa} , mentioned above, namely 0.055, as follows from the application of the F-test. This improvement can possibly be explained by the fact that while carrying out this large series of analyses, the analysts became more and more experienced, resulting in greater accuracy. With the value of s' the upper control limit of the range, G_2 , was calculated and found to be :

 $G_2^* = 3.686 \cdot 0.038 = 0.140$ (8)

No range value of these samples exceeds the control limit. Next, the control limits for the mean were calculated (Ref. 10). In general, these limits are equal to

$$/^{u} = \frac{3}{\sqrt{n}} o_{\mathbf{x}}$$
(9)

so that estimates for μ and σ_x had to be made. The best estimate of μ was the mean value of all results for all samples. The best estimate of σ_x was calculated as follows : from the results obtained with 94 samples s_0'' (the overall standard deviation) was found to be 0.082. This value was not significantly lower than that mentioned in Table 15, namely $s_0'' = 0.100$, s_0'' and s_0''' could therefore be combined to give s_0''''' as the best estimate of σ_0 . The following was found : $s_0'''' = 0.089$.

Of course, s'_{dwa} could also have been used as an estimate of δ'_{χ} , but in that case a certain number of values would have exceeded the limits because "the analysis was more accurate than the production process".

All possibilities discussed are summarized in Table 16.

From Appendix 3 it can be seen that three values exceed the limits : those of samples 5, 26 and 99. Apart from these few values, it may be concluded that the production process was well under control.

5.2 Iron Content

Iron was determined according to the following method (Ref. 13) : "Dilute a suitable aliquot of the solution obtained by dissolving the shavings and add a buffer solution pH = 3, hydroxylamine hydrochloride and orthophenan@roline hydrochloride solution. Dilute to a certain volume and measure the absorbance at 508 mm in a 1 cm cell against a blank. Calculate the amount of iron with the aid of a calibration graph".

In this case one aliquot was taken from each of the two solutions used for the determination of plutonium. Each solution was analyzed once and so two results per sample were obtained.

In order to check the raliability of the results, control limits for the range and for the mean were calculated as described in the previous paragraph.

•
From the results obtained with 108 samples, the mean range was calculated to be 0.0137% and so the upper control limit, G_2 , was :

$$3.686 \cdot 0.0137 = 0.0505$$

Three values lay outside the limit : those of samples 1, 14 and 52. On rejection of these values and the recalculation of the upper control limit, $G_2^{\prime\prime}$, the following was found : $G_2^{\prime\prime\prime\prime} = 3.686 \cdot 0.0121 = 0.0446$. Even in this case one value (sample 81) was not under the limit. On rejection of this value, the upper control limit became :

$$G_2''' = 3.686 \cdot 0.0117 = 0.0431$$
 (10)

The standard deviation from the mean range mentioned in eq. (10), of a single determination including the contribution of weighing and dissolution was calculated :

 $s_{dwa}^{\prime \prime \prime} = 0.0104\%$ with = 103 (11)

The total standard deviation s_0^V was also calculated and found to be 0.039%. The control limits for the mean, calculated using s_{dwa}^{iii} and s_0^V , are given in Table 17.

Only one value is outside the limits : that of sample 108. The conclusion, therefore, must be the same as that at the end of Section 5.1, namely, that the production process is well under control.

It should be noted that a significant difference can be detected on the 0.05 level between $s_{dwa}^{\prime\prime}$ and s_{o}^{V} . This means that it must be assumed that two sources of variations contribute significantly to the final accuracy : variations between samples and the analysis itself, including the dissolution.

Under the actual conditions of the analysis, the standard deviation of a single determination was 0.52 /ug of iron.

5.3 Carbon Content

The principle of the method is as follows :

"Remove traces of grease from the sample, incinerate it in a high-frequency induction furnace and absorb the carbon dioxide evolved in a solution of sodium hydroxide. Measure the decrease of the conductivity of this solution".

The carbon content was not constant but depended upon the purity and the nature of the materials used for the preparation of the fuel element. This content, therefore, varied considerably and a variance analysis was pointless. The same conclusion applied to the control limits for the mean. The only means of checking the reliability of the results was to calculate the control limit for the range.

The aim of the carbon determination was to check if the amount of carbon was less than 500 ppm. Only two samples had carbon contents of more than 500 ppm : samples 30 and 100. The average results per sample are given in Appendix 3.

Ten samples were analyzed in triplicate and all other samples in duplicate. Based on the results obtained for 107 samples, the standard deviation of a single determination was calculated to be 6.3 ppm. This standard deviation amounted to 6.3 μ g, since 1 g of sample was taken for analysis.

From this standard deviation the following values for the upper control limits were found :

 $G_3 = 27.3 \text{ ppm}$ (n = 2) $G_2^V = 23.1 \text{ ppm}$ (n = 2)

Three values were not under control : samples 12, 32 and 53. An absolute calibration of the method was not possible, since no plutonium standard with a known carbon content exists. Therefore, in order to be certain that the results found were accurate, steel standards with known carbon contents, obtained from the "Bundesanstalt für Materialprüfung", Berlin-Dahlem, Germany, were analyzed at regular intervals and used for calibration of the analyses of the fuel element samples. No deviations from the certified values could be detected. It was assumed, therefore, that the results for the Pu samples were equally accurate.

5.4 <u>Impurities</u> (silicon, magnesium, manganese, chromium, nickel and molybdenum)

The elements mentioned above were determined by emission spectrographic analysis according to the carrier distillation method. The detailed procedure is given in Appendix 5 and the results summarized in Table 18.

From Table 18 it followed that the sum of these impurities was normally less than 225 ppm. In the most unfavourable case (sample 4) the maximum amount was 580 ppm, but even this was well within the specified limits.

5.5 Conclusion

- In the plutonium and iron determination there were three sources of error which significantly affected the final results : the

7I

Table 18

- Scatter between samples, dissolution of shavings and the determination itself.
- The scatter of the plutonium and iron determination between samples makes the most important contribution to the final accuracy.
- The production process was well under control, only in a few cases were the values for plutonium, iron and carbon outside the statistical control limits.

5.6 Mass Spectrometric Isotope Analyses

In all, 48 analyses were carried out on Pu samples taken from the original batch (acceptance control) as well as 78 analyses on Pu-U samples from the finished fuel element charges and two samples from the reprocessed plutonium residue. Measurements were carried out with a CH_4 mass spectrometer manufactured by Atlas Mat of Bremen, fitted with a TO-4 ion source and a secondary electron multiplier. A sample of 5-10 manograms Pu was applied to a rhenium strip which had been folded into a boat. The mass discrimination of the unit was determined by the uranium standard of the National Bureau of Standards, Washington DC, since there were no plutonium standards available.

The accuracy reached with samples having 8% Pu-240, 0.8% Pu-241 and 0.04% Pu-242 was :

Ratio 240/239 : 0.6 - 1% in the ratio, or 0.05 - 0.08% in % 240 Ratio 241/239 : 3 - 5% in the ratio, or 0.025 - 0.04% in % 241 Ratio 242/239 :10 - 20% in the ratio, or 0.004 - 0.008% in % 242

The accuracy of the Pu-241 determination was less satisfactory by a factor of 2 - 3 in older samples because of the higher Am-241 content.

The results of analyses of charges Ma-1 to Ma-77 and Ma-100 are given in Appendix 4. Not all the analyses were performed since the results agreed well with the calculated values (Appendix 2); and in addition an independent means of controlling the isotopic composition available through spontaneous neutron counting was used.

6. RESULTS AND MATERIAL BALANCE-SHEET

ler malite anditupen edu erro men lainteelu maan

Fabrication was completed within nine months, well inside the time laid down in the contract. All the specifications were almost entirely satisfied. Only in two charges was the carbon content slightly higher than specified limits (see Appendix 3).

6.1 Individual Castings Balance-Sheet

Numerical data is given in Table 19 :

Table 19 : MASURCA element castings

	8.4% Pu-240 long short		3.8% H long	total	
elements fabricated	1236	624	172	83	2115
Rated numbers	1240	620	160	80	2100

A total of 108 charges were necessary to fabricate 2115 elements. The number of elements in each charge can be seen in Table 20. Charge Ma-91 had to be completely rejected because it appeared that the piece of plutonium used in this charge was very severely oxidized on the inside and the plutonium content of the alloy was too low (see Section 4.2.3). Other charges yielded only a small number of elements since the castings were not satisfactory or not sufficient material was available (Ma-100 and Ma-108). More than 22 elements were made from some charges because certain long and selected castings, each one capable of yielding two short pieces, were broken in the middle. This process was used principally towards the end of fabrication when it became evident that the required casting ratio of one to two, between short and long elements, was more favourable to the long elements. The decision on how may short and long elements should be obtained from any one charge was made before the 22 unfinished rods of a centrifugal casting were turned on a lathe. The criterion was the quality of the ingots.

Total Plutonium Weight : 175 098.8 g

÷ .

ł

1.

ł

In theory it should have been possible to fabricate 1900 long elements and 950 short elements, i.e., a total of 2850, from 108 charges and with the determined casting ratio. The resulting figure of 2115 corresponds to a yield of 74.2%. Fabrication losses, not to be confused with material losses, since faulty pieces were remelted, were 25.8%. This percentage is divided up into various items in Table 21.

Table 21 : List of causes of faults.

Type of fault	Percentage of total fabrication bath
Faulty alloy composition after the first casting (Ma-91)	0.9%
Faulty rods after centrifugal casting	20.3%
Excessive deflection of finished elements	1.1%
Diameter of elements outside the tolerance limits	1.1%
Fissile material content outside the tolerance limits	0.7%
Miscellaneous (faults in the weld, seam, too much contamination, can damage)	1.7%
	25.8%

The above shows very clearly that the greatest losses occurred during casting. Improvements would be advisable in any future fabrication of a similar nature.

6.2 <u>Material Balance-sheet</u>

2.2

The fabrication process is not only of interest for purely economical reasons but also for the material balance, owing to the shortage of the element and the present high prices in Europe.

Originally 200 kg of plutonium metal were to be made available for the fabrication of the 175 kg of plutonium in the form of MASURCA elements. The intermediate balance-sheets following the first charges showed that this amount was more than required; consequently the amount was reduced to 187 kg.

The material balance of the total fabrication gives the following result :

Table 22 : Overall summary of the material balance-sheet

		1519	g Pu	
Loss	5 88			

154767 g Pu = 93.53%

21858 g Pu = 100.0%

The total material yield of approximately 93.5% of finished elements is satisfactory, but can be improved, for similar fabrications in the future. An increase in the number of pieces produced per casting and thus a decrease in the number of castings necessary would, for instance, be one way of reducing the amount of slag and waste.

The only points not yet completely certain in the balance-sheet are the waste items. A.b.d. and the connected loss items 1.c. and B.C. Although great care was taken when sampling the powder, a certain possibility of error in determining the plutonium content cannot be excluded. It will be possible to obtain completely reliable results only when the waste is dissolved into a solution for reprocessing and this solution accurately analyzed.

The amounts of plutonium given as losses were calculated as the difference between the remaining amounts determined by chemical analysis and the amount of plutonium contained. This amount of loss will change somewhat when, as mentioned above, the waste is reprocessed. Even the losses occurring in this process, which run to about 1% of the treating quantity, must be added to the total loss if a genuine total balance-sheet is required.

There are two groups of material losses in fabrication with plutonium. Materials whose presence can no longer be detected come under the first group. When plutonium accosting is carried out satisfactorily, there can be only three reasons for this disappearance :

- the original amount was incorrect;
- small but systematic faults in analyses and weight determinations have all added up and simulate the disappearance of a certain amount (this effect, as well as the first one, can also be positive and lead to a production of plutonium);
 - part of the Pu-241 has changed into Am-241 and must be regarded as a genuine loss.

In practice, all three causes are important. A final dealer de gen With the case in hand, the following should also be noted :

化试验 建氯化酸盐 化达尔加油 计分数分子 机机械 建筑运输 法认

- Before being dispatched from Hanford, the plutonium ingots and the were weighed very accurately in the present of a Transuranium Institute employee. For the most part, there was good agreement between the analyses carried out separately by the USAEC and Euratom.
- Any possible systematic fault occurring in plutonium determinations of the individual charges during fabrication can only be extremely small since the analyzing process was, at all times, under very strict control. The fact that the calculated values of 25.00 or 23.80% Pu which were aimed at when the individual charges were made up agree well with the averages of all the analyses, 24.984 and 23.763, can be taken as proof of the quality of the analyses.
- A total of about 56 g Pu-241 decomposes annually in the amount of plutonium used for fabrication.

The losses involved in the second main group are with respect to the direct re-use of the material. This plutonium was mainly in a form which could not be economically recovered, for example, as finely distributed oxide dust on filters, gloves, plastic and paper waste, or, more generally, in weak concentrations on all inner surfaces of the glove boxes or greatly diluted in waste water. Traces were always present and often even semi-quantitatively assayable, but in many cases, reprocessing was not worth the trouble and was written off as a loss.

During MASURCA fabrication, great importance was attached to keeping this lost amount to a minimum. One principal advantage was that the glove boxes used were new and easy to clean.

As shown in Table 23, the present total loss that could be determined in the fabrication at hand was 0.08% of the original amount of plutonium. Even after waste reprocessing, this value was not

higher than 0.2%. This can be noted as a very good result.

It must be taken into account when comparing with other fabrications that :

•

1. 1

:

.

and the second second second second

- metallic elements can be made in a smaller number of operations than oxide elements, and that
- ceramic powders and pellets give off considerably more dust than metal rods.

In the production of oxide elements, therefore, somewhat greater losses may be justified.

7. PROBLEMS OF WORK ORGANIZATION

空空中 人名布尔奥 1 IFA CIDEC Great efforts were made when fabricating the MASURCA always to observe the principles of rational, industrial fabrication. These were not only for reasons of a purely technical nature, relating to staffing and equipment, but also because our knowledge and experience of the European fuel element industry should serve as a good basis for the preparation of similar fabrications. Some significant problems arising from work organization will thus be dealt within this chapter. プライト・シューアのとうとう 「唯一」に対応する

Materials and Plutonium Accounting 7.1

Exact knowledge at all times of the amounts and types of material in circulation and their whereabouts had a special importance in e en ale en comparação quês passes a fabrications using plutonium. nde gebeelde het die keel de neer verde die Alexander de gebeelde die die die die het die die die die die die

The most important reasons for this were : (All the set of the se

- criticality danger; a second of the second state of the second sta
- value of the material:
- and the second - shortage of plutonium;
- requirements concerning physical properties and chemical como mail a como si à dicaj succionação position of the final product. A R L A 445 <u>e</u>n 1997 - 1997 and a second second

A total of 16 different plutonium zones were established and accurately demarcated in Wing G of the Transuranium Institute because of the criticality danger (see Fig. 6). The maximum allowed for each zone was 2.5 kg Pu. Exceptions were zone A. 😔 in which the plutonium ingots were crushed, and main storage the point L, where all the plutonium was in birdcages.

There was a log-book in each zone to control the amounts of plutonium by entering all material arriving and leaving. A 🛸 copy of each day's entries was sent straight away to the central E. S. Martin, C. S. S. Martin, M. S. S. Martin, J. Phys. Rev. Lett. 71, 164 (1996).

ag contractor de la contractor de la contractor

· 注意意义,就是这个人的意义,你是不是没有。" "这个人

plutonium accounting office of the Institute where the amendments were entered into a bank book after examination of the numerical values.

Only one engineer in Wing G was authorized to sanction material transport. He first of all checked whether the new zone was sufficiently free of plutonium, made an entry in the log-book of the former zone, accompanied the movement of material and made an entry in the log-book of the new zone. During the MASURCA fabrication, a total of 3192 transport operations were carried out, making an average of almost 30 per charge or almost 19 per working day.

However, plutonium accounting only satisfied the requirements concerning criticality and, by supervision of plutonium movements, that concerning the control of amounts and losses, but it was difficult to use it for the complete characterization of the individual plutonium-containing entries. For this reason, an independent material card index was prepared from which the origin, charge number, place, weight and whereabouts of each single amount of material could be determined at any time. One such card is shown in Fig. 41. At the outset, this card index system used cards for the single plutonium ingots but finished with 12 cards corresponding to the entries for individual materials in the total balance-sheet given in Table 23.

A part of the plutonium movements scheme, greatly simplified, is shown in Fig. 42. Each square represents one single amount of material, these being entered separately on a card. In order for all fabrication processes to be properly recorded, a total of 2260 cards were necessary.

The constant booking of small losses and disparities was a special, complex problem during fabrication. The following, for instance, could have occurred during centrifugal casting :

- some plutonium could have vaporized and only be recovered later when the furnace was cleaned;
- the plutonium content of the four different material items may not have been exactly as calculated - 25.00 or 23.80%; the plutonium content of the slag may have been somewhat higher and that of the rods somewhat lower;
- rounding off the calculated plutonium amounts of the individual items to the nearest gram could have resulted in the total amount appearing to be larger than the original amount.

The method adopted in practice was to use the calculated values for all alloy residue until the elements were completed, and to collect all losses and inaccuracies in the waste that were metallurgically reprocessed. The material balance-sheet for casting Ma-53, taken from Section 4.3.3 but added to, is given in Table 24 as an example.

Table 24	:	Complete material	balance-sheet	fo r	the	casting	of
		charge Ma-53					

22 rods	9489 g alloy	= 2372	g Pu	ан. Сталта с
alloy residue	461 g alloy	= 115	g Pu	1 1 1
slag	285 g	= 71	g Pu	н
waste	2 g	= 2	g Pu	
starting quantity :	10238 g alloy	= 2560	g Pu	

The two grams of waste here bear no real relation to the two grams of Pu logged. Should it become clear after completion of a charge that the actual amount, determined from the total weight of the cores and the plutonium analysis, differed from the amount assumed at the time, then a correction was made in the accounts and the difference on paper either subtracted or added (see Fig. 41).

Waste which occurred from time to time, e.q., during thorough furnace cleaning, was dealt with differently. This was treated as waste but was not logged, i.e. was entered as zero grams. In actual fact it increased the amount of plutonium in the waste.

These examples only deal with some of the problems that arose. In each operation, the basic principle of accounting was thus :

- to ensure that the single amounts of plutonium agree with the final amounts;
- to ensure that all losses and inaccuracies are concentrated in the relatively small amounts of waste.

In this way, the plutonium accounting system used by us, although fairly simple, varied only slightly from the actual situation and gave at all times a clear picture of the total amounts of materials used in fabrication.

The total plutonium losses could have been easily determined at the end of fabrication by exact chemical analysis of the waste collected.

7.2 Time and Personnel Requirements

Fabrication started at the beginning of January 1966 and ended on 18 October of the same year - a total of 172 working days. No work took place during the whole of August. Details of monthly output figures are given in Fig. 43. Only 3% of the total number of elements were fabricated during the first month and 17% in the best month. This slow initial rate was partly due to technical problems : the main cause was a lack of knowledge of working with plutonium on the part of most of those involved. Only three of the people directly concerned with fabrication had previous experience of working with plutonium.

Table 25 gives details of the breakdown of the personnel directly engaged in the fabrication.

물건 가지 않는 것 같아요. 그는 것 같은 것 같아. 말했는 것

Table 25 : Personnel breakdown

Category A	
Head of Metallurgy Section (Head of	
MASURCA project)	80%
Assistant Head of Metallurgy Section	100%
Head of Analytical Chemistry Section	10%
Head of Radiation Protection Section	10%
<u>Category B</u>	
Four members of Metallurgy Section	100%
One member of Analytical Chemistry Section	50%
One member of Radiation Protection Section	100%

	4	11

Decontamination work was confined to the mornings so that some of the people employed on this could do other work in the afternoons, testing and preparing rods for welding, for instance.

The working day of the 2.5 members of the Analytical Chemistry Section (see Table 25) engaged in practical work analysis, was divided as follows : 50% plutonium and iron determination, 10% carbon analysis and 40% spectrometry. This comprised all the work.

8.5 hours were worked daily between Monday and Thursday and 7.5 hours on Fridays. The weekly work schedule was : one finished charge

daily between Monday and Thursday, clearing up, cleaning, control and preparatory work on Fridays such as removing slag from crucibles, furnace clearing, glove changing, spraying of new crucibles, etc., 172 working days made up 34.4 weeks giving an average charge output of 3.1 per week. Once initial difficulties had been surmounted, higher output figures of 4.5 were obtained over longer periods, meaning that it was only on every other Friday that a charge was not handled.

At this rate, the physical and psychological capacities of those involved in the work had almost reached its limits and the risk of contamination accidents became greater. Apart from any damage to health, a contamination accident could have lead to a fairly long stoppage of the whole fabrication process since decontamination of plant and apparatus can be very time consuming. The problem of the capacity of individual workers was, therefore, constantly kept in mind since a whole day spent working in or on glove boxes required constant close attention and concentration on the part of those involved.

The daily work plan was always adhered to. The need for a rational division of time was already imposed by the criticality danger. As has already been described (Section 7.1), the old charge had to be removed from each plutonium zone before a new one could be taken to it. Transport operations were carried out as given in the timetable in Fig. 44. The first of these operations took place in the morning from zone D (welding unit) to zone E (grinding machine), the last in the evening from zone F (ultrasonic bath) to the helium testing plant (zone G), where the elements remained overnight under helium pressure. Each specific charge did not remain long in the ultrasonic bath and was moved along on the same day. Each charge remained in the other zones for one day with the result that at any one time a total of nine charges were being handled.

Should a delay have arisen for any reason during an operation, the charge in question was removed from the fabrication process and, if need, be stored until Friday when it was completed.

The only entries in Fig. 44 are the transporting of the main amounts of plutonium, i.e., the charges. Allowance must be made for the fact that there were a considerable number of other transport operations (samples for analysis, slag, waste, turnings, alloy residue, etc.) and these had to be carried out at intervals.

A total of 172 working days were necessary for the whole fabrication process, including Fridays. A total of 22 people were involved in fabrication, making a total of 3784 man/days or an average of 1.79 man/days for each element. This figure was only 1.25 man/days during the period of faster fabrication (nine charges each with 19.6 elements in 10 working days).

8. RADIATION PROTECTION

「「「「」」、「」」「「「」」の「」、電気機の「「品の電灯」構築性性の

Besides the hazards connected with the use of conventional machinery and instruments and the handling of radioactive material, a number of special risks exist when fissile material is being handled in large quantities. Proper knowledge of the rules, a good set of working rules and safety regulations, well applied by experienced personnel able to recognize dangerous situations, may be regarded as the basis for safety. Further, an independent control on safe conduct of the personnel is needed. This control must include the measurement of those parameters which indicate potential hazards.

8.1 The Special Hazards of Plutonium

Even when applying the special methods for safe handling of plutonium in glove boxes, which will not be discussed here in detail, experience in every nuclear centre has shown that a certain risk remains of small particles being released into the laboratory air.

To demonstrate this, the maximum permissible quantity in certain organs of the body (Ref. 14) is shown in Table 27 for 3 nuclides, together with the diameter of the particle which contains this quantity.

<u>Table 27</u> : Maximum permissible body burden and corresponding particle size of different isotopes

Nuclide	MPBB (Ci)	diameter of particle (um)
Pu-239	0.04×10^{-6}	1.5
Am-241	0.05×10^{-6}	0.07
Cm-242	0.05×10^{-6}	0.012

From these MPBB values the maximum permissible concentration in air (MPC) for each of these elements has been derived; for Pu-239, 1 MPC is formed by one particle of 1.6 μ um per m³ of air. Even a small

error made when changing a glove or when bagging out material from a box is sufficient for these quantities to be released into the air.

The handling of kilogram amounts of plutonium metal and compounds containing considerable percentages of Pu-240 and Am-241 necessitates special shielding provisions or restrictions in handling time to prevent the personnel from absorbing external radiation doses above the maximum permissible level. External dose rates from a 1 kg sphere of plutonium metal have been calculated (Ref. 15). Table 28 gives a summary of these values.

_

The composition of the plutonium used in the MASURCA process is the same as given in Table 28.

As regards the handling and transporting of single quantities of plutonium of up to 4 kg, well-defined working conditions must be

provided to avoid assembling amounts of plutonium which might compose a critical mass.

The essential conditions for safety in this respect are and

- limitation of quantities, where possible;
- safe design of machinery and transport containers;
- well-defined responsibility for each part of the process and good accounting laid down in safety reports before the production is started;
- the existence of a nuclear safety committee of specialists of different disciplines to provide an independent check on planned processes.

The spontaneous ignition temperature of plutonium metal (and some of its alloys) is very low, especially when finely divided, as in processes like turning and milling.

In general, compounds of plutonium and alloys should be regarded as pyrophoric, and in most cases the work should be carried out in an inert atmosphere.

The fact that plutonium metal oxidizes readily, thereby causing the formation of very fine dust particles, creates a serious inhalation hazard when no precautions are taken for good containment.

8.2 Responsibilities

The individual worker is ultimately made responsible for carrying out his work in a safe manner, safe for himself as well as for his environment. The general responsibility for the safety during the different parts of the production process has been laid in the hands of those directly responsible for these processes. The final responsibility goes via the section leader to the director of the Institute.

The radiation protection service is made responsible for ensuring the observance of safety rules and regulations, for supervising the measurement of radiation doses (external, air control, surface contamination) and for giving advice in questions of safety. It also intervenes in cases of accidents.

Two radiation protection technicians occupying a laboratory in the wing itself, supported by a central radiation control laboratory, a central control room for alarm purposes and an instrument maintenance group, are charged with this surveillance work.

8.3 Safety Regulations and Working Methods

The most efficient protection against inhalation hazard is obtained when the individual worker follows the procedures for work on glove boxes, as laid down in the safety regulations of the Institute.

Particular attention must be paid to :

- control of airtightness of the glove boxes and safe installation of equipment in the boxes before use; constant control of the underpressure in the glove box and warning when the pressure system fails;
- using the right procedure for glove changing and introducing material into and taking material out of glove boxes; the technique of sealing the plastic bags, in particular can be a source of any small releases of radioactive dust into the laboratory air;
- regular control of gloves and plastic bags;

- controlling contamination of personal gloves on completion of a particular operation in a glove box:
- application of the rules governing transportation of fissile
 material.

Fig. 6 shows a plan of the wing in which the process was carried out. The glove boxes containing the machinery are placed in a number of caissons and laboratories called plutonium zones and indicated by the capitals A, B ... The borderline between the zones was marked with red lines on the floor with special chains.

Zones A - E each contain a number of connected glove boxes. Glove boxes positioned in different zones in the same caisson are not connected, so as to avoid mistakes being made when transfering material from one zone into another.

There is a distance of at least 1 meter between any two zones. The work in zone F is carried out in open air hoods, while in zones G, H and K the elements are simply handled on tables.

Zones I and M - Q consist of safes (for temporary storage); zone L is the main plutonium store.

The maximum allowed quantities of plutonium in the various zones were :

W. C. Harrison M.

· · · · · ·

 Zone A
 4 kg

 Zone B - K and M - Q
 2.5 kg

 Zone L
 200 kg

Four kg are allowed in zone A because the initial material consists of 4 kg ingots. Transportation between zones takes place in special containers. The 4 kg ingot is crushed in zone A and the 2.5 kg needed for one fabrication process weighed out and left in the zone. The remaining 1.5 kg are temporarily stored in one of the zones M - Q. same the second state of the second sta

A time schedule exists for the entire process (Fig. 44) and one engineer is made responsible for the authorization of transport operations and for the administration of plutonium in each zone. The transportation routes are carefully laid down so as to avoid exceeding the maximum allowed quantity at any point.

Some special safety provisions had to be taken because the induction furnaces in zone A and B have a water cooling system.

They are provided with the usual safety devices should the cooling system fail. As a precaution against the possibility of these devices not working, the cooling water is distributed over a number of separate closed circuits. The quantity of water in each of these circuits is too small to form a critical mass with the plutonium in the furnace. Should this subcircuit be emptied into the furnace.

In addition to these precautions a very powerful pump with a capacity of 2000 m^3/hr is provided for each furnace as well as the normal vacuum pumps.

8.4 Air Sampling

During the entire fabrication process the air was controlled by air sampling on glass fibre filters (ID 18 cm, sampling rate $20-25 \text{ m}^3/\text{hr}$) in the ventilation exhaust duct of each caisson or laboratory and at those places where a risk of air contamination exists, such as :

- the special ventilated box for unpacking the 4 kg ingot in zone A (Fig. 45);
 - the place near the glove box bag where this ingot is introduced in the line of boxes in zone A.

These filters are changed daily, and the alpha-contamination is measured directly after changing, using a special method to subtract the natural radioactivity from the total radioactivity on the filter (beta-alpha pseudo coincidence method)(Ref. 16).

Each of these filters is controlled again eight days later. The sensitivity of these measurements is :

- direct control : 3 - 6 MPC/hr (1 MPC = 1.8 • 10⁻¹² Ci/m⁻³ inside controlled zones)

이 전화 이 관련 관련 관련 관련

- second control : 0.03 MPC/hr

During the last few months of the process a continuous air contamination monitor built on the same principle (Ref. 16) was installed, controlling the air in the combined ventilation exhaust duct of the caisson. This monitor gives the alarm when contamination exceeds a value of 6 MPC/hr (same MPC value as above).

A continuous monitor was installed, controlling the air leaving the building at the point where it enters the stack. The sensivity of this measurement is approximatively 100 MPC/hr (1 MPC = 6×10^{-14} Ci/m⁻³ for air leaving controlled zones). Since the air has passed the ventilation filter a few seconds before sampling, it contains practically no natural radioactivity, and a simple measurement of total alpha radioactivity on the filter was sufficient.

During the last few months of the process a personal air sampler was worn during the process of unpacking the ingot from the birdcage and inserting it in the first glove box chain. The sensitivity of this measurement is approximately 150 MPC/hr (MPC = $18 \cdot 10^{-12}$ Ci/m⁻³).

After an incident involving a possibility of an air contamination, a large volume air sampler (up to $60 \text{ m}^3/\text{hr}$) is used to obtain a quick result on which further decisions can be based.

IOI

Before starting the fabrication, these measurements were carried out on a 2 kg plutonium ingot of approximately the same composition as the plutonium to be used in the process, in order to determine the permitted handling period and to compare the results with those calculated.

Table 29 gives the results of these measurements. As reliable measurements of the surface dose are rather elaborate, calculated values were used to decide upon direct handling times.

<u>Table 29</u>: Dose rates at 45 cm from 2 kg metal Pu-ingot, measured behind 8 mm perspex

Type of radiation	Dose rate (mrem/hr)
Gamma	3
Neutron	2.6

The gamma radiation was measured with a rem-equivalent proportional counter, having a linear sensitivity ranging from 40 keV to a few MeV. The neutron radiation was measured with an Anderson & Brown remcounter. The neutron dose rate agrees fairly well with the calculated values given in Table 29 for 1 kg. The discrepancy between the calculated and the measured values in the case of gamma radiations is undoubtedly due to absorption in the metal, which is much larger for this 2 kg ingot than for the 1 kg used for the calculations.

Every person working regularly in the production building wore a film dosimeter of the conventional type for measuring the gamma and neutron dose as prescribed, issued and evaluated by the German authorities. The evaluation of these doses takes place at monthly periods.

A pocket dosimeter (electrometer type, directly readable, the dose of which is recorded daily) was also used.

As part of an experiment, a glass dosimeter (silver activated metaphosphate) (Ref. 17) has been used by a number of persons to compare with the film badge results. Those who regularly handle large quantities of plutonium use a wrist dosimeter (same glass as c). The end of the second state of the end of the second state of the end of the e

Table 30 shows the properties of these dosimeters.

<u>Table 30</u> : Properties of personal dosimeters used

Туре	Radiation detected	Energy range	Dose range

	neutrons	thermal	40 mrem - 100 rem
Pocket dosimeter	gamma	100 KeV	200 mrem
Spherical (glass) dosimeter	gamma) X-radiation) neutron)	40 KeV	50 mrem - 3000 rem

8.6 Alarm System

A centralized alarm system was installed. The radiation protection team is informed of every alarm that is detected in the central control room and the appropriate action taken.

and the state of the second

The following alarm signals are installed :

- criticality alarm (automatic)
- fire alarm (automatic and hand)
- "call for help" alarm, installed in every box and at other strategic locations
- water flooding alarm in box (automatic)
- pressure failure alarm in box (automatic)
- a number of warning signals to indicate faults in auxiliary equipment.

I03 -

An intercom system between the laboratories and the control room and a loudspeaker system are installed to provide the necessary communications.

8.7 Doses absorbed by the Personnel

8.7.1 External dose

Table 31 shows the doses received by 17 persons during the period from 1 January 1966 to 1 November 1966. These persons worked regularly in the production building, most of them handling large quantities of fissile material. The important differences between film badges and glass dosimeter results can be explained as follows :

- In the cases of M1, 2 and 3 large unshielded quantities were handled (2.5 to 4 kg in the furnace glove boxes). This causes a relatively large X-ray dose. The film badge is more sensitive to this type of radiation than the glass dosimeter.
- Numbers M5 17 were mainly handling canned plutonium. The cans absorb a good deal of the less energetic radiation; the radiation transmitted is therefore mainly the energetic gamma radiation. Here the differences in doses between glass dosimeters and films may be caused by the better directional sensitivity dependance of the spherical glass dosimeter, resulting in better detection of reflected gamma radiation by this dosimeter.

The difference between results measured by the pocket dosimeters and the two other types may be due to the insensivity of the pocket dosimeter for radiation below 100 keV. Some differences remain unexplained.

No fast neutron doses could be detected on the film badge because of shadowing of the nuclear tracks on the film by the gamma radiation, although the results of our previous neutron measurements expected a neutron dose to be shown. This makes the neutron badges of little value and reliable measurements of the neutron radiation field are preferred for our protection.
<u>Table 31</u> : Gamma dose (in mrem) absorbed by 17 members of the subproduction group, received over a 10 month period

8,7.2 Air sampling results

a a state de la seconda

The results of the routine air sampling programme for 1966 are shown in Table 32. These are given in MPC/hr (48 \cdot 10⁻¹² Ci/hr/m⁻³).

As was expected, caissons 1 and 2 show the largest number of contaminations. Comparison with results of air sampling after incidents shows that the number of contaminations discovered by routine control is small. This also applies to those laboratories in which no continuous air monitor is installed. From these facts it may be concluded

I05

and the state of the second second

that incidents are detected in most cases by the usual contamination control of gloves and hand & shoe control rather than by continuous air control. However, a small number of incidents has definitely shown the value of continuous monitoring, especially in locations where a large number of people carry out different operations. The number of contaminations shows a general tendency to decrease towards the end of the process.

.

and a state of the state of the

8.8 Incidents

In Table 34 the reported number of incidental contaminations over a period of 10 months is shown, together with their causes, locations, activity release and the result of the air samples taken directly after the incident.

** A the state of the state

The total amount of activity detected in these 27 incidents on bags, gloves, floor and shoes is 0.5 µCi, i.e., 12 times the maximum permissible body burden of 0.04 µCi. Of this quantity 0.05 MPBB was deposited on the filters, which were in most cases placed in their normal routine position. This means that only about 0.5% of the released activity has been found on the air sample.

The causes of these 27 cases are distributed as follows :

- damaged box gloves	11 cases
- change of bags	10 cases
- change of gloves	2 cases
- unknown	 4 cases

Further facts are :

- 30% of the incidents resulted in air contaminations.

- All the air contaminations but one coincide with contaminations of bag and/or box gloves greater than 10^{-4} µCi.
- On the other hand, from eight cases of contaminated gloves and/ or bags under 10^{-4} µCi, no detected air contamination resulted.
- 70% of the air contaminations coincide with floor and/or shoe contamination.

- In 20 cases (75%) the floor and/or shoes were contaminated.

Although from a statistical viewpoint only a small number of cases has been examined, the following tentative conclusions may be drawn :

- The fairly marked correlation found between air and floor contamination in well ventilated rooms such as those concerned here is by no means self-evident. One would expect the small particles, having deposition velocities of the order of 1 cm/min⁻¹, to be caught in the ventilation stream rather than deposited on the floor.

I08

The correlation between incidents with contamination and floor/shoe contamination is even greater.

- This means that great stress must be placed on regular floor contamination control in these plutonium handling areas as a control on the "contamination checking discipline" of the workers.
- Secondly, since contamination of the glove or bag must be of a certain minimum value to cause serious air contamination, regular control of personal gloves after every interruption of the work in the box is important, especially when handling metallic plutonium, to avoid the danger of inhaling plutonium particles.
- It is important to use a sensitive, reliable alpha monitor for this purpose.

8.9 Determination of Particle Sizes of Active Dust in Air

The final hazard of working in contaminated air depends on the retention of the inhaled particles in the pulmonary tract. To estimate this, it is necessary to know the size distribution of the particles.

For radioactive particles such a study can be carried out by preparing autoradiographs of the active filters. This is carried out as follows :

- A special X-ray film is laid on the filter for a period depending on the activity on the filter. After development the picture shows a number of spots localizing the radioactive particles and showing the distribution of the particles on the filter (Fig. 46).
- From those parts of the filter showing these active particles, a second autoradiograph is made with the so-called stripping film method. A very thin layer of nuclear track film is put on the part of the filter containing the active spots using a

special technique (Ref. 18).

Fig. 47 shows the tracks of a plutonium particle obtained by the stripping film technique.

Fig. 48 shows the particle itself. This picture could be made by focussing deeper into the centre of the star formed by the nuclear tracks in Fig. 47.

Finally Fig. 49 shows the size and activity distribution of 82 particles which were detected on filters during the MASURCA production. These 82 particles come from a total quantity of 8 \cdot 10⁻⁹ grams of plutonium and a total activity of 0.5 \cdot 10⁻⁹ Ci (approx. 1% of the maximum permissible body burden).

From Fig. 49 it can be seen that most of the particles fall in the size range which is easily inhaled and retained $(0.1 - 1 \mu m)$; these particles, however, contain together only 1.3% of the total activity.

ANNEX V

APPENDIX V

Potentiometric determination of plutonium in plutonium - uranium - iron alloys

Dissolve 500 (p) mg of shavings in 50 ml of a mixture which is 11 N in nitric acid and 0.05 N in hydrofluoric acid. Dilute to 100 ml (solution A) and pipette 20 ml of this solution into a. 100 ml beaker. Add 5 ml of 2 N nitric acid and 100 mg of silver (II) oxide and stir the solution occasionally. After 15 minutes heat to boiling, keep the solution at a temperature near the boiling point for 5 minutes, and cool. Add 1 ml of a sulphamic acid solution (97 g/L) and 2 ml of an aluminium nitrate solution $(37.5 \text{ g of Al}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}/\text{L})$. Add 10 ml of an iron (II) sulphate solution (7 g of FeSO₄ . 7 $H_{2}O$ and 13,5 ml of concentrated sulphuric acid made up with water to 1 L). After 5 minutes titrate the excess of iron (II) with 0,01 (T/N) cerium (IV) sulphate solution (4.04 g of $Ce(SO_4)_2$. 4 H_2O and 27 ml of concentrated sulphuric acid made up with water to 1 L). During the titration maintain a constant polarisation current of 3 uA in a double platinum electrode and measure the potential as a function of the amount of cerium (IV) solution added (a ml consumed). Carry out a blank starting from 10 ml of the iron (II) solution (b ml consumed).

The sample contains :
$$\frac{(b-a)t \cdot 59775}{p}$$
 % of pluto-
nium

Spectrophotometric determination of iron in plutonium - plutonium uranium - iron alloys

Pipette 10 ml of solution A (see instruction 1, appendix V) into a 100 ml volumetric flask and make up to volume with water. Pipette 10 ml of this solution into a 25 ml volumetric flask and add 2 ml of a formate-formic acid buffer solution (204 g of sodium formate and 368 g of formic acid per litre), 2 ml of hydroxylamine hydrochloride solution (50 g per litre; to be prepared freshly every day) and 1 ml of a 0.5 % orthophenthroline solution. Make up to volume with water, wait 45 minutes and measure the absorbance at 508 nm in a 1-cm cell against a blank. Prepare the blank by carrying 10 ml of water instead of 10 ml of solution A through the procedure. Calculate the amount of iron with the aid of a calibration graph (a jug found).

Prepare the calibration graph by carrying through the procedure 0, 2, 4, 6, 8 and 10 ml of an iron solution which contains 10/ug per ml.

The sample contains $\frac{10 \text{ a}}{\text{p}}$ % of iron.

3. <u>Conductometric determination of traces of carbon in plutonium -</u> <u>uranium - iron alloys</u>

Weigh out 1 (p) g of degreased shavings and transfer to a degassed ceramic crucible on the bottom of which has been put a copper disk and transfer the crucible to an induction furnace which is connected on one side to a supply of purified oxygen or purified air and on the other side to a gaz absorption apparatus containing 0.05 N sodium hydroxide solution (conductivity R_1). Pass a stream of air through the whole system and heat up to 600°C during 1 minute. Close the stream of air and connect to oxygen. Heat until the anode current has decreased to the value which is reached when the furnace is switched on under unloaded conditions. Measure the conductivity of the sodium hydroxide solution with a Wheatstone bridge which has been modified in such a way that the resistance is linearly proportional to the concentration of the absorbed carbon dioxide (conductivity R_2). Carry out a blank and apply the procedure to a crucible which only contains two copper disks (conductivity R_b). Calculate the amount of carbon using for calibration the results obtained by application of the procedure to steel standards, furnished by the "Bundesanstalt für Materialprüfung", Berlin-Dahlem, Germany. The measured conductivities in this case be R_{χ} and R_{μ} . The standard sample contains a ug of carbon.

The analyzed sample contains : $\frac{(R_1 - R_2 - R_b)a}{(R_3 - R_4)p}$ ppm of carbon.

4. Emission spectrographic determination of traces of silicon, magnesium, chromium, nickel, manganese and molybdenum in plutonium - uranium - iron alloys

4.1. Apparatus

- a) Spectrograph 3.4 m Ebert; grating 15,000 grooves/inch, linear dispersion 2.5 Å/mm in the second order,
- b) source 0 40 Amp.,
- c) comparator microphotometer,
- d) spectroprojector, magnification 20 times,
- e) photographic emulsion : Kodak SA 1.

4.2. Sample preparation

Weigh out 2 g of sample in a platinum crucible and calcine in a furnace at 900° C for 1 hour. Cool, homogenize in an agate mortar and recalcine at 900° C for 1 hour. Cool, weigh out 980 mg of the oxides and add 20 mg of gallium oxide. Homogenize in an agate mortar and then in a mixer for 3 minutes. Transfer 100 mg of the oxide mixture to the electrode. Shake carefully and make a vent hole in the powder for the vapours to escape. Prepare three electrodes.

4.3. Electrodes

- a) Graphite anode of height 15.9 mm with two cylindrical holes. One hole with depth 3.97 mm and diameter 3.18 mm allows the electrode to be placed on a support. The other hole with diameter 3,97 mm and depth 7,14 mm contains the sample.
- b) Graphite cathode, diameter 3,05 mm, height 38,1 mm.
- c) Electrode gap is kept at 4 mm and centered in the optical path by projection.

4.4. Excitation

D.C. arc 15 A.

4.5. Exposure conditions

spectral region	:	2400 - 3700 Å
slid width	:	15 ₁ u
filters	:	100 % and 40.9 % transmission
preburn period	:	5 sec.
exposure period	:	40 sec.

4.6. Photographic processing

development	:	Kodak T 19
stop bath	:	5 % acetic acid
fixing	:	Kodak special
washing	:	running water for 30 min.
drying	:	air current at 40 ⁰ C.

4.7. Interpretation of spectra

Check the spectra with the aid of the spectroprojector. Carry out the densitometric measurements using the following lines:

	Element	Reference
Si	2506 9 Å	
Mg	2776 2	
	2779 8	
Mn	28 01	Ga 2665 🖁
Cr	2835	
Ni	3002	
Mo	31 32	

Calculate the amounts of the elements to be determined with the aid of calibration graph. Construct these graphs using $U_{3}O_{8}$ certified standard samples of the National Bureau of Standards, Washington, USA, to which known amounts of the elements are added.

NOTICE TO THE READER

All Euratom reports are announced, as and when they are issued, in the monthly periodical EURATOM INFORMATION, edited by the Centre for Information and Documentation (CID). For subscription (1 year: US 15, £ 6.5) or free specimen copies please write to:

Handelsblatt GmbH "Euratom Information" Postfach 1102 D-4 Düsseldorf (Germany)

or

Office central de vente des publications des Communautés européennes 2, Place de Metz Luxembourg

To disseminate knowledge is to disseminate prosperity — I mean general prosperity and not individual riches — and with prosperity disappears the greater part of the evil which is our heritage from darker times.

Alfred Nobel

SALES OFFICES

All Euratom reports are on sale at the offices listed below, at the prices given on the back of the front cover (when ordering, specify clearly the EUR number and the title of the report, which are shown on the front cover).
