#### Abstract

A total of twelve water samples which include those from two hand dug wells, five bore holes and five streams as well as twenty soil samples were collected around the West African Portland Cement (WAPCO) factory in Shagamu, Southwestern Nigeria. The water samples were analysed for physical, chemical and biological parameters while the concentrations of cations and anions in soil samples were also determined. There is a general trend of dominance of Ca<sup>2+</sup> over Na<sup>+</sup> over Mg<sup>2+</sup> over K<sup>+</sup> and HCO<sub>3</sub><sup>-</sup> over SO<sub>4</sub><sup>2-</sup> over Cl<sup>-</sup> over NO<sub>3</sub><sup>-</sup> among cations and anions respectively in water samples while that of soil samples show trend of dominance of Ca<sup>2+</sup> over Mg<sup>2+</sup> over Na<sup>+</sup> over K<sup>+</sup> and HCO<sub>3</sub><sup>-</sup> over SO<sub>4</sub><sup>2-</sup> over Cl<sup>-</sup> over NO<sub>3</sub><sup>-</sup> among cations and anions respectively. The underlying rocks have a significant effect on the geochemistry of water and soil as indicated by the dominant ions and the boomerang diagram. The study has shown that the soil samples especially within 500m radius of the limestone activities are contaminated as revealed by the concentrations of Ca<sup>2+</sup> and Mg<sup>2+</sup> that exceed normal background values for soil, while the composition of water samples are within the maximum permissible levels of World Health Organization (WHO) standard for drinking water. However, some water samples have concentration of ions in excess of the highest desirable levels.

#### Introduction

Limestone (Industrial mineral) production has been on the increase since its inception in 1957 because of the high demand for cement in the Nigerian market. This activity after a long time may cause environmental damage, widespread pollution and disruption of ecosystem.

In Shagamu, where the underlying geology is of uncompact and high permeability alluvial sands, the polluting effluent as a result of limestone mining are capable of escaping into the subsurface to contaminate the surface and groundwater in the aquifer as well as the soil. This can form a pollution plume that can extend for several hundreds of meters (Keswick et al, 1982, Okufirasin, 1991 and Asiwaju- Bello et al, 2001). The aim of this study is thus to access the effect of Limestone mining activities in Shagamu on soil, surface and groundwater.

The study area, Shagamu, lies within longitude 3° 3' E and 3° 45' E and 6° 30' N and 7° North (fig 2). It occupies a low lying marshy depression about 200m above the sea level (Ewekoro depression) within the Dahomey basin (Jones and Hockey, 1964) bounded by highland to the north and south.

The area falls within the tropical rainforest zone of Nigeria with annual rainfall ranging between 1500mm and mean annual temperature distribution of 27° C with two distinct seasons, the dry and wet seasons (Ilcoje, 1981).

#### Geology and Hydrogeology

Shagamu lies within the Dahomey basin, which is one of the sedimentary basins on the continental margin of the Gulf of Guinea extending from southwestern Ghana in the West to Western flank of the Niger Delta (Jones and Hockey, 1964). The stratigraphic units include; Ise, Afowo, Araromi, Ewekoro, Akinbo, Oshosun and Ilaro formations (fig 1) as studied by various authors like Jones and Hockey, (1964), Adegoke and Omatsola, (1981), Agagu, (1985). The sediments exposed at the Shagamu quarry belong to the paleocene-Eocene age. In contrast to the homogeneous Ewekoro exposure, the formation in this area is heterogeneous varying appreciably in color, texture and fossil contents. The local stratigraphy comprises sequence of sediments (in order of increasing age).

Fig. 1: Stratigraphy of Dahomey Basin after Omatsola and Adegoke (1981)

- Brown alluvium (top soil)
- Red alluvium (laterite)
- Shale (Akinbo formation)
- Limestone (Ewekoro formation)

The drainage is dendritic and the major rivers include Odari and Bere (fig 2). The area is water logged for most part of the year due to low relief, high water table and impervious nature of underlying rocks.

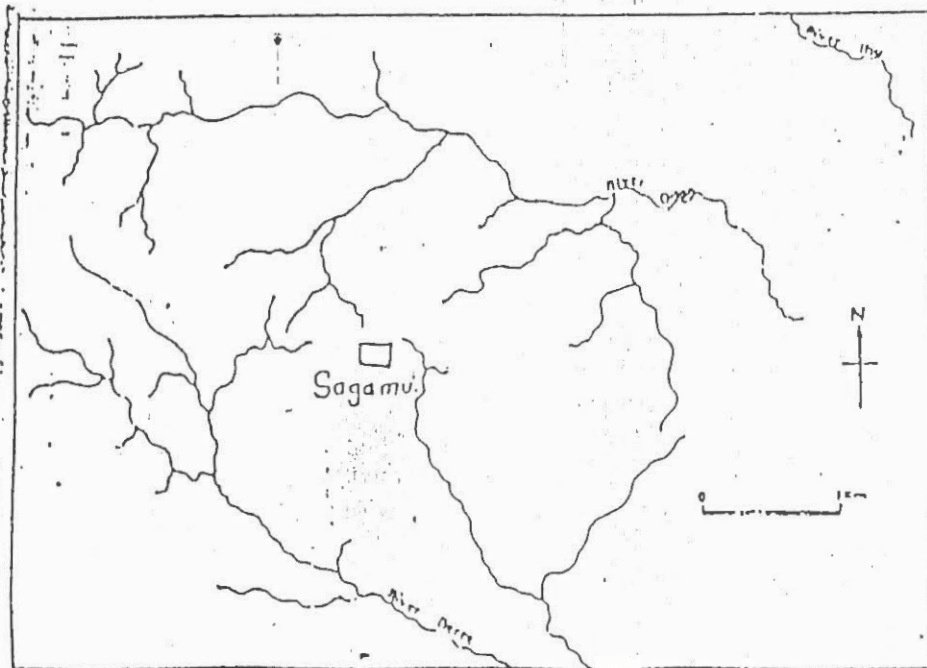

Fig. 2: Map showing the Dendritic drainage pattern of the study area, (Sagamu)

Methodology

Of twelve water samples which include two from hand dug wells, five from bore holes and five streams as well as twenty soil samples were collected around the premises of the West African Portland Cement Company (WAPCO) in Sagamu, Southwestern Nigeria.

Water samples were collected with 1 litre white kegs and spread across the study area for the purpose of determining water quality. Physical properties of water such as color, odor, taste and pH were determined on the field by visual inspection and the use of pH meter.

Other parameters such as  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ ,  $Mg^{2+}$ ,  $Cl^-$ ,  $HNO_3$ ,  $NO_3^-$ ,  $SO_4^{2-}$ , Total hardness, TDS, were analysed in the laboratory using atomic Absorption Spectrophotometer and titration methods. Uniform counts were also determined.

Top soil samples were collected at depth of 0-5cm and at interval of 50m into clean polythene bags and air dried for 24 hours before they were taken to the laboratory where pH, major cations and anions were analysed using Atomic absorption Spectrophotometer after the soil samples have been digested appropriately.

Results and Discussion

The results of physical, chemical and bacteriological analyses of water samples are presented in Tables 1 to 5 and illustrated in Figs 3-20. There is general trend of dominance among cations of  $Ca^{2+}$  over  $Mg^{2+}$  over  $Na^+$  over  $K^+$  (Figs 5) in the water samples while soil samples show general trend of dominance of  $Ca^{2+}$  over  $Mg^{2+}$  over  $Na^+$  over  $K^+$  among cations (Fig 3).

The concentrations of anions on the other hand show that HCO<sub>3</sub><sup>-</sup> > Cl<sup>-</sup> > SO<sub>4</sub><sup>2-</sup> > Cl<sup>-</sup> > NO<sub>3</sub><sup>-</sup> in soil (Fig 4) and HCO<sub>3</sub><sup>-</sup> > Cl<sup>-</sup> > SO<sub>4</sub><sup>2-</sup> > NO<sub>3</sub><sup>-</sup> (Fig 6). Elevated values of all the ions are recorded within 500m radius for water samples while control samples were taken as far as 15,000m away from the quarry. However, it is noted that Ca<sup>2+</sup>, Mg<sup>2+</sup> and HCO<sub>3</sub><sup>-</sup> constitute the major contaminant in both soils and water. Their mean values are 52.67 mg/l, 17.67ppm, and 46.43mg/l respectively in water and 196.94ppm, 25.48ppm and 198.10ppm in soil (Tables 3 and 4).

Fig. 5: Concentrations of Cations In Water Samples

Fig. 6: Concentrations of Anions in Water Samples

Also, the concentration of some major ions like Ca<sup>2+</sup>, Mg<sup>2+</sup> and Hco<sub>3</sub><sup>-</sup> as well as pH were seen to be higher for samples taken very close to the quarry site than those far away from it (Fig 7-14).

Various rock types, their weathered products and precipitation from rainfall contributed greatly to the chemical composition of water and soil in the study area. This has gone a long way to impair their quality. This is confirmed in fig 15, where log TDS against  $\frac{Na^+}{Na^+ + Ca^{++}}$  ratio were used to plot boomer

Fig. 15: Classification of surface water according to GIBBS (1970)

Diagram shows that water samples in the study area are influenced by the chemical weathering of underlying bedrock which is limestone ( $\text{CaCO}_3$ ) in this case. Also, the high concentration of calcium as the dominant cation and  $\text{HCO}_3^-$  as the dominant anion in both soil and water confirms this (Ajani, 1994). The high concentration of  $\text{Mg}^{2+}$  also indicates alteration of some limestone ( $\text{CaCO}_3 - \text{Mg}(\text{CO}_3)$ ) while  $\text{SO}_4^{2-}$  is produced primarily from the oxidation of sulphate minerals and dissolution of gypsum or other sulphate minerals. Most of the water samples very close to the quarry site have their chemical parameters especially  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  above the highest desirable level (Table 6).

Correlation coefficient established between  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  is + 0.80 (direct and very good) which shows that the water samples are generally related while that between  $\text{NO}_3^-$  and  $\text{Cl}^-$  is 0.64 (Indirect and good) and shows that there is no trace of faecal pollution in the water samples. This is also confirmed by the absence of coliform bacteria as revealed by the bacteriological analysis of water samples (Table 6).

It was also observed that the water sampled close to the quarry site are very hard according to Todd (1980) and alkaline in nature. This can be linked with high concentration of  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$  and pH in water.

The results of chemical analysis of soil samples were compared with the normal background values for soil (Table 6) and it was noticed that the concentrations of all the cations except that of Na and pH exceeded the normal background values for soil (Figs 10-20). Hence, the soil is contaminated especially those within 500m radius of the quarry site.

Temperature of water is between  $27^\circ\text{C}$  and  $28.5^\circ\text{C}$  with average of  $27.8^\circ\text{C}$ . TDS values range between 60ppm and 329.96ppm with an average value of 104.95ppm and this confirms the fresh nature of water while total Alkalinity ranges between 33.3 mg/l and 132.2mg/l with an average of 65.49mg/l. The water samples are classified as Excellent based on the Sodium Absorption Ratio ( $\text{SAR} = \text{Na}^+ / (\text{Ca}^{2+} + \text{Mg}^{2+} / 2)$ ) which means that they are perfect for irrigation purposes. The values of total hardness which range from 20mg/l to 152mg/l with average of 65.49mg/l show that the water fall between soft to moderately hard category.

Calcium has a concentration of 7.82ppm to 60.00ppm with an average of 16.72 ppm while the concentration of magnesium ranges from 2.50ppm to 10.75ppm with an average of 5.38ppm. The concentrations of potassium and sulphate are 10.56ppm and 4.56ppm respectively. Bicarbonate has average of 0.87ppm.  $\text{Fe}^{2+}$  was present in only one sample with value of 0.02ppm. Chemical analysis shows that all the water samples have properties that fall within the WHO standard for drinking water (Table 5).

#### Bacteriological Analysis

It was used to detect the presence and density of organisms in the water as indices of faecal and bacteria pollution. The results (Table 1) show that the coliform count ranges from 0cfu/m to 18cfu/ml. None of these values is above WHO standard recommended value for potable water. Appropriate treatment measure must be applied before its suitability for domestic purposes.

#### Conclusions

The study focused on the effects of limestone ( $\text{CaCO}_3$ ) on the geochemistry of water and soil in Omu, Southwestern Nigeria. The sources of the water include surface and groundwater which developed through the weathering and fracture of the rocks. This water percolates through fractures and pore spaces between the underlying bedrock which is limestone. Also, the soil in the study area has high permeability and porosity which comprises brown alluvial sands as top soil and this enables easy access of ions into the soil.

was observed that the closer the soil and water samples are to the quarry site, the higher are the concentrations of ions such as  $\text{HCO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ , while TDS and Total hardness are similar to water samples only.

However, Proximity to the quarry site does not show any significant effect on the concentration of  $\text{K}^+$ ,  $\text{Cl}^-$ ,  $\text{NO}_3^-$  and coliform count but has a pronounced effect on the pH as indicated in the alkaline nature of water and soil in the study area.

Thus, it can be concluded that the underlying rocks which are predominantly Limestone have a significant effect on the geochemistry of water and soil in the study area as indicated by the boomerang diagram after Gibbs (1970). Although the concentration of water samples for now are still within the maximum permissible level of WHO standard, some parameters already have values higher than the highest desirable level in the WHO standard which means that with time there is possibility that water within the study area will be contaminated.

The study has also shown that soil samples especially within 500m radius of the limestone quarry site are contaminated as revealed by the concentrations of  $\text{Cu}^{2+}$ ,  $\text{Mg}^{2+}$  and  $\text{HCO}_3^-$ , which exceeded the normal background value for soil.

It is recommended that Government should put in place stiff environmental protection laws that will force industries to operate a standard waste disposal method that is free of Environmental hazards
