Vortex entanglement in Bose-Einstein condensates coupled to Laguerre-Gauss beamsN. Lo Gullo,¹ S. McEndoo,¹ T. Busch,¹ and M. Paternostro²¹*Department of Physics, University College Cork, Cork, Ireland*²*School of Mathematics and Physics, Queen's University, Belfast BT7 1NN, United Kingdom*

(Received 12 December 2009; published 24 May 2010)

We study the establishment of vortex entanglement in remote Bose-Einstein condensates (BECs). We consider a two-mode photonic resource entangled in its orbital angular momentum (OAM) degree of freedom and, by exploiting the process of light-to-BEC OAM transfer, demonstrate that such entanglement can be efficiently passed to the matterlike systems. Our proposal thus represents a building block for novel dissipation-free and long-memory communication channels based on OAM. We discuss issues of practical realizability, stressing the feasibility of our scheme, and present an operative technique for the indirect inference of the set vortex entanglement.

I. INTRODUCTION

The rich variety of coherently exploitable degrees of freedom with which a photonic system is endowed has been extensively used in recent years in order to demonstrate the building blocks of quantum technology protocols, including quantum cryptography [1], quantum repeaters [2], teleportation, and quantum computing [3]. In this context, the exploitation of orbital angular momentum (OAM) carried by light is settling as a new and exciting opportunity for coherent manipulation at the classical and quantum levels [4]. High-density data transmission [5], activation of micromachines, and optical tweezers [6] are among the most prominent applications of optical OAM so far.

In addition, the field of quantum information processing has now started exploiting the additional opportunities offered by this photonic degree of freedom for communication and manipulation purposes. It has been shown that it is possible to create OAM-entangled photons by means of a routinely used setup such as spontaneous parametric down-conversion (SPDC) [7]. This has triggered a plethora of studies on how to generate, manipulate, and detect nonclassical states of OAM [8], culminating in the demonstration of Bell's inequality violation by OAM-entangled two-photon states [9], the introduction of so-called hyperentangled states [10], the design of quantum cryptographic schemes based on higher-dimensional systems [11], and the transfer of OAM states from light to matterlike systems [12].

In particular, the latter scenario holds the potential for the realization of experimentally feasible longtime quantum memories embodied by superfluid rotational states of Bose-Einstein condensates (BECs) [12–16]. The spatial coherence intrinsic in a BEC allows for a superfluid vortex state in which the bosons in the condensate have a well-defined and quantized OAM, which offers a perfect match with rotating photon carriers. Along the seminal lines traced by the experiments in [12], a few theoretical proposals for the light-to-vortex state transfer have been presented [13–16]. Here we close the circle of these proposals and show that it is possible to create entanglement between two spatially separated BECs by transferring OAM from entangled photon resources to the condensates. We propose a simple and efficient scheme to achieve this goal using experimentally achievable parameters and routinely produced

OAM-entangled light resources. On a different level, our study proposes a scheme that is able to transfer (with, in principle, 100% efficiency) higher dimensional entanglement between two independent systems by means of bilocal interactions, thus contributing to an area that is witnessing theoretical and experimental interest (see Choi *et al.* [2] and Ref. [17]).

The article is organized as follows. In Sec. II, we introduce the idea behind our proposal and address the Hamiltonian for the OAM entanglement transfer. The key part will be the introduction of an adiabatic Hamiltonian involving Raman processes where photonic OAM quanta are used in order to put a single BEC into a vortex state with nonzero winding number. Section III represents the core of our proposal by providing a clear physical picture of the process discussed previously and assessing the quantitative performance of the light-to-BEC entanglement transfer. By starting from an OAM-carrying photonic state, we show that significant vortex-vortex entanglement is established by our scheme for experimentally realistic parameters. Section IV describes realistic techniques for the inference of such quantum correlations based on the reverse of the map addressed here. Finally, in Sec. V, we summarize our findings and open up perspectives for further development. A few technical steps that complement the quantitative analysis presented in the body of the article are contained in the appendix.

II. THE MODEL

Let us start by presenting the model used in order to describe the light-to-BEC transfer of entanglement. We shall see that a key point in this mechanism resides in the collective coupling of the atoms belonging to one of the BECs to the respective light field. Together with the indistinguishability of the resource photons, this permits us to entangle the two BECs. We consider two spatially separated and trapped BECs, each with N_0^I ($I = A, B$) ^{87}Rb atoms and let each of them interact with one of the field modes of an OAM-entangled two-photon state (see the sketch in Fig. 1). Such a photonic resource can be produced, for instance, by type I parametric down-conversion of a Gaussian laser beam, which is an OAM-preserving process: The sum of the OAM carried by the entangled signal and idler mode produced by a laser-pumped nonlinear crystal

FIG. 1. (Color online) Sketch of the proposed setup. An OAM-entangled two-photon state is produced by SPDC of a Gaussian pump. Each output mode interacts with a respective trapped BEC, which is also pumped by an intense field with no OAM. The local matter-light interaction transfers the OAM entanglement from the field modes to the condensates' rotational degree of freedom.

equals the OAM initially carried by the pump [7]. In this article, we shall consider a two-photon state produced by SPDC of a laser beam with no-OAM (i.e., prepared in a Gaussian spatial mode). This implies that the output modes, here labeled as α and β , carry opposite OAM and enter the state

$$|\Phi\rangle_{\alpha\beta} \simeq C_0|1_0\rangle_\alpha|1_0\rangle_\beta + C_{1,-1}|1_1\rangle_\alpha|1_{-1}\rangle_\beta + C_{-1,1}|1_{-1}\rangle_\alpha|1_1\rangle_\beta. \quad (1)$$

Here $|n_k\rangle_\alpha$ indicates an n -photon state populating mode α and carrying OAM equal to $\hbar k$. Moreover, the presence of $|1_0\rangle_\alpha|1_0\rangle_\beta$ in $|\Phi\rangle_{\alpha\beta}$ accounts for a residual component with no OAM and $|C_0|^2 + |C_{1,-1}|^2 + |C_{-1,1}|^2 \simeq 1$ (having neglected components with higher OAM, which are very weakly populated at moderate pump intensities). The main idea behind our proposal is that the arrangement of a locally assisted OAM transfer from a light mode to the respective BEC would also allow for the transfer of quantum correlations, therefore constructing an effective entangled channel involving remote matter systems.

The basic building block for the transfer is an off-resonant double Raman scattering process. We consider each individual atom as a six-level system, shown in Fig. 2. The energy scheme comprises a ground-state triplet made out of a nonrotating state $|0\rangle$ and two other states, indicated as $|\pm 1\rangle$, having angular momentum $\pm\hbar$. The elements of excited-state triplet $|e\rangle$ and $|e'\rangle$ are linked to $|\pm 1\rangle$ by two classical pumps, while the field modes in $|\Phi\rangle_{\alpha\beta}$ drive the $|0\rangle \leftrightarrow |E, e, e'\rangle$ transitions. In what follows, Δ and Δ_0 indicate the one-photon Raman detunings, which are set by appropriately choosing the frequencies of the driving fields. The classical pumps are taken to have a Gaussian spatial profile so that photons scattered in the $|e\rangle \leftrightarrow |1\rangle$ and $|e'\rangle \leftrightarrow |-1\rangle$ transitions carry no OAM. Together with the conditions on the OAM properties of Eq. (1), this ensures

FIG. 2. (Color online) Six-level configuration for OAM transfer. We show a schematic of the relevant energy levels of a single ^{87}Rb atom interacting with Laguerre-Gauss driving fields and classical Gaussian pumps with frequency ω_p . The ground-state triplet comprises states having angular momentum 0 and $\pm\hbar$. The excited-state triplet is adiabatically eliminated from the dynamics by a double off-resonant Raman transition with the one-photon detunings Δ and Δ_0 . Two-photon detunings $\delta_{\pm 1}$ are also introduced for the stabilization of the entanglement-transfer process. The component in Eq. (1) carrying zero OAM (being in a Hermite-Gauss spatial mode) drives off-resonantly the $|0\rangle \leftrightarrow |E\rangle$ transition.

that an atom undergoing the two-photon Raman transition from state $|0\rangle$ to $|\pm 1\rangle$ (as shown in Fig. 2) acquires an OAM exactly equal to $\pm\hbar$.

We now introduce the second-quantized matter field operators $\hat{\psi}_{I,j}(\mathbf{r})$, obeying the bosonic commutation rules $[\hat{\psi}_{I,i}(\mathbf{r}), \hat{\psi}_{J,j}^\dagger(\mathbf{r}')] = \delta_{I,J} \delta_{i,j} \delta(\mathbf{r} - \mathbf{r}')$. Here $I, J = A, B$ are labels for the BECs, while $i, j = 0, \pm 1, E, e, e'$ refer to the atomic states. As for the photonic part of our system, standard commutation relations $[\hat{c}_{n_i,k}, \hat{c}_{n_j,k'}^\dagger] = \delta_{n_i,n_j} \delta_{k,k'}$ involving the creation (annihilation) operator $\hat{c}_{n_i,k}$ ($\hat{c}_{n_i,k}^\dagger$) hold. Here $n_A = \alpha$ ($n_B = \beta$) refers to the photonic mode α (β) that interacts with condensate A (B). Finally, $k, k' = \pm 1, 0$ refers to the OAM degree of freedom of the photon.

Besides the term describing the energy of the free photonic fields, the Hamiltonian of the system consists of the following four terms:

$$\hat{H} = \hat{H}_a + \hat{H}_{aa} + \hat{H}_{ad} + \hat{H}_{ap}, \quad (2)$$

which we now address in detail. The first two terms describe the properties of the trapped BECs and are given by

$$\begin{aligned} \hat{H}_a &= \sum_{I,j} \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,j}^\dagger(\mathbf{r}) \left(-\frac{\hbar^2}{2m} \nabla_I^2 + V_{I,j}(\mathbf{r}) \right) \hat{\psi}_{I,j}(\mathbf{r}), \quad (3) \\ \hat{H}_{aa} &= \frac{1}{2} \sum_{I,j,j'} \eta_{j,j'}^I \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,j}^\dagger(\mathbf{r}) \hat{\psi}_{I,j'}^\dagger(\mathbf{r}) \hat{\psi}_{I,j'}(\mathbf{r}) \hat{\psi}_{I,j}(\mathbf{r}). \end{aligned} \quad (4)$$

In all the preceding, \mathcal{V}_I is the quantization volume for the light-matter interaction involving condensate I . The $V_{I,j}(\mathbf{r})$ s are the state-dependent atomic trapping potentials, $\eta_{j,j'}^I = (4\pi\hbar^2/m)a_{j,j'}^I$ accounts for the collisional energy between two atoms (of mass m) in states j and j' , and $a_{j,j'}^I$ is the corresponding s -wave scattering length. As will be clarified later on, the excited triplet $\{E, e, e'\}$ can be adiabatically eliminated from the dynamics of the atomic system. Therefore, by assuming no initial population of these states, we can

simplify our treatment and take $a_{j,E}^I = a_{j,e}^I = a_{j,e'}^I = 0$ for $j = 0, \pm 1$. The third term in Eq. (2) describes the interaction between BEC I and the quantized field mode n_I and can be written as

$$\begin{aligned} \hat{H}_{ad} = & \sum_{I=A,B} \left[\chi_{I,0} \hat{c}_{n_I,0} \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,E}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}) \mathcal{A}_{n_I,0}(\mathbf{r}) \right. \\ & + \chi_{I,1} \hat{c}_{n_I,1} \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,e}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}) \mathcal{A}_{I,1}(\mathbf{r}) \\ & \left. + \chi_{I,-1} \hat{c}_{n_I,-1} \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,e'}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}) \mathcal{A}_{I,-1}(\mathbf{r}) \right] + \text{H.c.} \end{aligned} \quad (5)$$

The coefficients $\chi_{I,k}$ ($k = 0, \pm 1$) are the effective dipole moments associated with the transitions depicted in Fig. 2. The functions $\mathcal{A}_{n_I,k}(\mathbf{r})$ describe the spatial shape of the states entering $|\Phi\rangle_{\alpha\beta}$, and we choose them to be

$$\begin{aligned} \mathcal{A}_{n_I,0}(\mathbf{r}) &= i \sqrt{\frac{\hbar\omega_0}{2\epsilon_0\mathcal{V}_I}} e^{ik_z z} e^{-\frac{r^2}{\mathcal{W}^2}}, \\ \mathcal{A}_{n_I,\pm 1}(\mathbf{r}) &= i \sqrt{\frac{\hbar\omega_{\pm 1}}{2\epsilon_0\mathcal{V}_I}} \left(\frac{\sqrt{2}r}{\mathcal{W}} \right)^{|\pm 1|} e^{\pm i\phi} e^{ik_z z} e^{-\frac{r^2}{\mathcal{W}^2}}. \end{aligned} \quad (6)$$

Here ϵ_0 is the vacuum permeability. While the first of these equations refers to a field mode having a Gaussian spatial profile, the second describes OAM-carrying Laguerre-Gauss beams. We assume that the beam-waist \mathcal{W} is larger than any linear dimension of the BECs so that the Gaussian part of the function reduces to a constant. This approximation also ensures the collective nature of the interaction between the fields and the atoms belonging to a given BEC. The last term in \hat{H} describes the coupling between the classical pumps and the BECs:

$$\begin{aligned} \hat{H}_{ap} = & \sum_{I=A,B} \left[\hbar\Omega_I e^{-i\omega_I t} \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,e}^\dagger(\mathbf{r}) \hat{\psi}_{I,1}(\mathbf{r}) e^{i\mathbf{k}_I \cdot \mathbf{r}} \right. \\ & \left. + \hbar\Omega_I e^{-i\omega_I t} \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,e'}^\dagger(\mathbf{r}) \hat{\psi}_{I,-1}(\mathbf{r}) e^{i\mathbf{k}_I \cdot \mathbf{r}} \right] + \text{H.c.} \end{aligned} \quad (7)$$

The coefficients Ω_I are the Rabi frequencies for the matter-pump interactions. Moreover, we initially prepare each condensate in the atomic state $|0\rangle$ by means of optical pumping techniques, for instance, in such a way that the excited triplet can be considered as empty. We now proceed with the adiabatic elimination of the excited states under the assumption of large single-photon detunings Δ and Δ_0 (with respect to the typical coupling rates entering \hat{H}_{aa} , \hat{H}_{ad} , and \hat{H}_{ap}). We take the time evolution due to the fields to be faster than the center-of-mass motion of the atom when in one of the excited levels so that we can neglect the free atomic Hamiltonian for these states. We move to a proper rotating frame where we redefine the excited-state (ground-state) matter field operators as $\hat{\psi}_{I,e} = \hat{\psi}_{I,e} e^{-i\omega_I t}$, $\hat{\psi}_{I,e'} = \hat{\psi}_{I,e'} e^{-i\omega_{-1} t}$, and $\hat{\psi}_{I,0} = \hat{\psi}_{I,0} e^{-i\omega_0 t}$ ($\hat{\psi}_{I,k} = e^{-i\omega_I t} \hat{\psi}_{I,k}$) and the photonic operators as $\hat{c}_{I,k}(t) = e^{i\omega_I t} \hat{c}_{I,k}$ (with $k = 0, \pm 1$). Following the work of Marzlin *et al.* [13] and Kapale and Dowling [15], we

explicitly allow for two-photon Raman detunings $\delta_{\pm 1}(t) = \omega_l - \omega_p(t) - \tilde{\omega}_{\pm 1}$ (see Fig. 2), which help in the stabilization of the transfer process (see also Ref. [14]). Here $\hbar\tilde{\omega}_{\pm 1}$ are the actual energies of the rotating atomic states. In fact, one can intuitively understand the necessity for a time-dependent two-photon detuning as a result of the adiabatic elimination of the excited triplet and the existence of interatomic collisions, which change the energies of the atom in time. Therefore, in order to achieve efficient transfer of OAM entanglement, we need a ‘‘chirped’’ frequency of the pump fields that allows us to track and compensate for the change in energy levels. The technical details behind the adiabatic elimination sketched here are presented in the appendix.

We thus arrive at the effective Hamiltonian $\hat{H}_{\text{eff}} = \hat{H}_a + \hat{H}_{aa} + \hat{H}_{\text{int}}$ for the description of the adiabatic interaction between light and BECs, where

$$\hat{H}_a = \sum_{I,j} \int_{\mathcal{V}_I} d\mathbf{r} \hat{\psi}_{I,j}^\dagger(\mathbf{r}) \left[-\frac{\hbar^2}{2m} \nabla_I^2 + V_{I,j}(\mathbf{r}) + \epsilon_j(t) \right] \hat{\psi}_{I,j}(\mathbf{r}), \quad (8)$$

$$\begin{aligned} \hat{H}_{\text{int}} = & \sum_{I,k} \left[\hat{c}_{n_I,k} \int_{\mathcal{V}_I} d\mathbf{r} \mathcal{C}_{n_I,k}(\mathbf{r}) \hat{\psi}_{I,k}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}) + \text{H.c.} \right. \\ & \left. + \hat{c}_{n_I,k}^\dagger \hat{c}_{n_I,k} \int_{\mathcal{V}_I} d\mathbf{r} \frac{\chi_{I,l}^2 |\mathcal{A}_{n_I,k}(\mathbf{r})|^2}{\Delta_I} \hat{\psi}_{I,0}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}) \right] \\ & + \sum_I \hat{c}_{n_I,0}^\dagger \hat{c}_{n_I,0} \int_{\mathcal{V}_I} d\mathbf{r} \frac{\chi_{I,0}^2 |\mathcal{A}_{n_I,0}(\mathbf{r})|^2}{\Delta_{I,0}} \hat{\psi}_{I,0}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}). \end{aligned} \quad (9)$$

In Eq. (8), $j = 0, \pm 1$ should be taken, while in Eq. (9), it is $k = \pm 1$. Moreover, we have introduced the coupling coefficient $\mathcal{C}_{n_I,k}(\mathbf{r}) = (\hbar\Omega_I^* \chi_{I,k} / \Delta_I) \mathcal{A}_{n_I,k}(\mathbf{r}) e^{-i\mathbf{k}_I \cdot \mathbf{r}}$ and the energies $\epsilon_j(t)$ such that $\epsilon_0(t) = \hbar\omega_I$ and $\epsilon_{\pm 1}(t) = \hbar[\omega_{\pm 1} - \delta_{\pm 1}(t) - \tilde{\omega}_{\pm 1}]$. The term describing interparticle collisions \hat{H}_{aa} remains identical to Eq. (4). The interpretation of the form taken by \hat{H}_{eff} is straightforward. While Eq. (8) describes the energy of the noninteracting matter part of the system, modified by the introduction of δ_{\pm} -related terms, Eq. (9) accounts for the light-matter interaction and includes the dynamical ac Stark shift effect arising from the adiabatic elimination. In particular, the first term in \hat{H}_{int} describes a three-mode interaction where photonic excitations are used in order to perform an atomic transition between ground-triplet states. This is the key to our analysis on OAM entanglement transfer and the starting point of our quantitative study.

III. THREE-MODE EXPANSION AND LIGHT-INDUCED TRANSFER OF OAM ENTANGLEMENT

A. Bosonic-mode expansion

In order to fix the ideas and discuss an experimentally relevant case, we consider the anisotropic harmonic trap potential $V_I(r, z) = (m/2)(\omega_r^2 r^2 + \omega_z^2 z^2)$ for each of the BECs used in our proposal. Here $\omega_z(\omega_r)$ is the frequency of the trap along the longitudinal (radial) direction. In order to be able to neglect any longitudinal excitations, we assume $\omega_z \gg \omega_r$ so that each BEC is confined in a pancakelike structure. In

the limit where the interatomic collisions are very small, the cylindrical symmetry of the problem allows us to describe the center of mass of one atom in a BEC by means of the set of eigenstates (θ is the angular coordinate of a cylindrical reference frame)

$$\begin{aligned}\phi_{l,0}(r,z) &= \frac{1}{\pi^{\frac{3}{4}} a_r \sqrt{a_z}} e^{-\frac{1}{2}\left(\frac{r^2}{a_r^2} + \frac{z^2}{a_z^2}\right)}, \\ \phi_{l,\pm 1}(r,z,\theta) &= \frac{1}{a_r} r e^{\pm i\theta} \phi_{l,0}(r,z),\end{aligned}\quad (10)$$

with associated eigenvalues $E_l = \hbar\omega_z/2 + \hbar(|l| + 1)\omega_r$. Here $a_{z,r}$ are the characteristic lengths of the harmonic motion along the longitudinal and radial directions. The description provided by the eigenfunctions [Eqs. (10)] remains valid under the assumption of dilute BECs so that their ground states result from the simple tensor product of the single-particle states $\phi_{l,0}(r,z)$. This is a good approximation as long as $N^l a_{r,j}^l \ll a_z$ [18], implying that the scattered part of the single-particle wave function contributes with only a small correction to the wave function of the noninteracting case. In order to provide a better picture of the anticipated three-mode interaction depicted in Eq. (9), we now define new bosonic operators $\hat{b}_{l,j}$ and $\hat{b}_{l,j}^\dagger$ for the matterlike part of our system as (omitting the tilde from now on for readability) $\hat{\psi}_{l,j}(\mathbf{r}) = \phi_{l,j}(\mathbf{r})\hat{b}_{l,j}$. By using the orthogonality of the $\phi_{l,j}(\mathbf{r})$ and the commutation relations valid for $\hat{\psi}(\mathbf{r})$ s, it is straightforward to find that $[\hat{b}_{l,i}, \hat{b}_{l,j}^\dagger] = \delta_{i,j}$. Inserting these definitions into the effective Hamiltonian, we obtain a much simplified and self-evident picture of the process through

$$\begin{aligned}\hat{H}_a &= \sum_{l,k} [E_{l,0} + |k|\hbar\omega_r + \epsilon_k(t)] \hat{b}_{l,k}^\dagger \hat{b}_{l,k}, \\ \hat{H}_{aa} &= \frac{1}{2} \sum_{l,j,j'} \xi_{j,j'}^l \hat{b}_{l,j}^\dagger \hat{b}_{l,j}^\dagger \hat{b}_{l,j'} \hat{b}_{l,j}, \\ \hat{H}_{\text{int}} &= \sum_{l,k=l,-1} (g_{l,k} \hat{b}_{l,k}^\dagger \hat{b}_{l,0} \hat{c}_{n_l,k} + \text{H.c.}) \\ &\quad + \hat{b}_{l,0}^\dagger \hat{b}_{l,0} \sum_{l,k} \rho_{l,k} \hat{c}_{n_l,k}^\dagger \hat{c}_{n_l,k},\end{aligned}\quad (11)$$

where each coefficient can be expressed in terms of the noninteracting wave functions, as shown in Table I.

TABLE I. Coupling rates in the effective Hamiltonian after the introduction of the effective matterlike bosonic operators [see Eqs. (11)] and their expressions in terms of the noninteracting atomic wave function for a pancakelike potential.

Coefficient	Corresponding expression
$E_{l,0}$	$\int_{V_l} d\mathbf{r} \phi_{l,0}^*(\mathbf{r}) [-\frac{\hbar^2}{2m} \nabla_l^2 + V_{l,j}(\mathbf{r})] \phi_{l,0}(\mathbf{r})$
$g_{l,k}$	$\int_{V_l} d\mathbf{r} \mathcal{E}_{n_l,k}(\mathbf{r}) \phi_{l,0}^*(\mathbf{r}) \phi_{l,0}(\mathbf{r})$
$\rho_{l,0}$	$\int_{V_l} d\mathbf{r} \frac{\chi_{l,0}^2 \mathcal{A}_{n_l,0}(\mathbf{r}) ^2}{\Delta_{l,0}} \phi_{l,0}(\mathbf{r}) ^2$
$\rho_{l,1}$	$\int_{V_l} d\mathbf{r} \frac{\chi_{l,1}^2 \mathcal{A}_{n_l,1}(\mathbf{r}) ^2}{\Delta_l} \phi_{l,0}(\mathbf{r}) ^2$
$\xi_{j,j'}^l$	$\eta_{j,j'}^l \int_{V_l} d\mathbf{r} \phi_{l,j}(\mathbf{r}) ^2 \phi_{l,j'}(\mathbf{r}) ^2$

The effect of the light-matter coupling is now manifest: besides the ac Stark shifts proportional to $\rho_{l,j}$, \hat{H}_{int} consists of a scattering process at a rate $g_{l,k}$ where the annihilation (creation) of a photon of angular momentum k is accompanied by the Raman transition $|0\rangle_l \rightarrow |k\rangle_l$ ($|k\rangle_l \rightarrow |0\rangle_l$). Such a mechanism, which would determine a perfect transfer of OAM from the light resource to the BECs, is disturbed by the interatomic collisions in \hat{H}_{aa} and should also take into account the modifications induced by the dynamical shifts in $\hat{H}_{a,\text{int}}$. The creation of inter-BEC OAM entanglement is thus a trade-off between these various processes. The task of Sec. III B is precisely the quantitative assessment of such a trade-off. It is worth remarking here that in virtue of the definitions of $\epsilon_k(t)$, the term $|k|\hbar\omega_r + \epsilon_k(t)$ appearing in the energy of the rotating states with $j = \pm 1$ is explicitly dependent on the two-photon Raman detunings $\delta_k(t)$ and takes the form $\hbar(\omega_k - \delta_k - \tilde{\omega}_k + |k|\omega_r)$. When the interactions considered in our scheme are included, the energy levels are shifted so that the shift $\tilde{\omega}_k - |k|\omega_r \neq 0$ is in general nonzero and, possibly, time-dependent. In what follows, we shall assume that such a shift occurs linearly in time.

B. Entanglement transfer process

As discussed in Sec. II, we assume an initial preparation where the atomic excited triplet is empty and all the atoms in each BEC populate $|0\rangle_l$. We indicate such a collective atomic state as $|N_0^l\rangle_l$, which condenses information on the population of level $|0\rangle_l$ and $|\pm 1\rangle_l$. On the other hand, the OAM-entangled photonic resource is taken as prepared in the experimentally realistic state $|\Phi_Z\rangle_{\alpha\beta} = (1/\sqrt{3})(|1_0, 1_0\rangle_{\alpha\beta} + |1_1, 1_{-1}\rangle_{\alpha\beta} + |1_{-1}, 1_1\rangle_{\alpha\beta})$. (Here we put the label Z, which refers to the state obtained by Zeilinger and coworkers.) In Refs. [7,9], it was shown that two-photon multidimensional OAM-entangled states generated by means of SPDC can be effectively distilled into states very close to $|\Phi_Z\rangle_{\alpha\beta}$, thus making the contributions coming from states having higher OAM negligible.¹ This effectively makes the Hilbert space spanned by photonic OAM states isomorphic to that of a spin-1 particle, or *qutrit*, so that $|\Phi_Z\rangle_{\alpha\beta}$ describes a maximally entangled two-qutrit state. The initial state is thus taken to be $|\Psi(0)\rangle_{AB\alpha\beta} = |N_0^A, N_0^B\rangle_{AB} |\Phi_Z\rangle_{\alpha\beta}$, whose dynamics under Eqs. (11) are now evaluated in a rotating frame defined according to Eq. (A2) (see the appendix).

It is straightforward to verify that when starting from $|\Psi(0)\rangle_{AB\alpha\beta}$ as given earlier, the evolved state $|\Psi(t)\rangle_{AB\alpha\beta}$ obtained on use of the effective Hamiltonian in Eqs. (11)

¹By means of continuously pumped cavity-enhanced SPDC, which is a customary method for the generation of photonic resources for atomic memories and quantum repeaters, one can have highly monochromatic twin-beam states in spatially very spread single-photon wave packets carrying the desired value of angular momentum. Such states can be treated, for all practical purposes, as plane waves in our calculations. However, it is straightforward to adapt our formalism to the case of pulsed SPDC by making the Rabi frequencies appearing in \hat{H}_{eff} explicitly time-dependent to incorporate the form of the photonic wave packet.

lies entirely in a nine-dimensional sector of the Hilbert space spanned by the states

$$\begin{aligned}
 |\Psi\rangle_0 &= |N_0^A\rangle_A |N_0^B\rangle_B |1_0\rangle_\alpha |1_0\rangle_\beta, \\
 |\Psi\rangle_1 &= |N_0^A\rangle_A |N_0^B\rangle_B |1_1\rangle_\alpha |1_{-1}\rangle_\beta, \\
 |\Psi\rangle_2 &= |N_0^A\rangle_A |N_0^B\rangle_B |1_{-1}\rangle_\alpha |1_1\rangle_\beta, \\
 |\Psi\rangle_3 &= |N_0^A - 1, 1_1\rangle_A |N_0^B\rangle_B |0\rangle_\alpha |1_{-1}\rangle_\beta, \\
 |\Psi\rangle_4 &= |N_0^A - 1, 1_{-1}\rangle_A |N_0^B\rangle_B |0\rangle_\alpha |1_1\rangle_\beta, \\
 |\Psi\rangle_5 &= |N_0^A\rangle_A |N_0^B - 1, 1_1\rangle_B |1_{-1}\rangle_\alpha |0\rangle_\beta, \\
 |\Psi\rangle_6 &= |N_0^A\rangle_A |N_0^B - 1, 1_{-1}\rangle_B |1_1\rangle_\alpha |0\rangle_\beta, \\
 |\Psi\rangle_7 &= |N_0^A - 1, 1_1\rangle_A |N_0^B - 1, 1_{-1}\rangle_B |0\rangle_\alpha |0\rangle_\beta, \\
 |\Psi\rangle_8 &= |N_0^A - 1, 1_{-1}\rangle_A |N_0^B - 1, 1_1\rangle_B |0\rangle_\alpha |0\rangle_\beta.
 \end{aligned} \tag{12}$$

The notation used here is such that $|N_0^I - s, s_k\rangle_I$ indicates a state where s atoms populate an atomic eigenstate of the angular momentum with eigenvalue $k\hbar$, while $N_0^I - s$ atoms populate the state $|0\rangle_I$ having zero OAM. It is worth stressing that the number and structure of the states involved in the evolution of a given initial state are strongly dependent on the total initial angular momentum carried by the latter. In fact, our effective Hamiltonian preserves the total light-matter OAM. This property implies that the dynamically evolved state of the system should be written as

$$|\Psi(t)\rangle_{AB\alpha\beta} = \sum_{i=0}^8 f_i(t) |\Psi_i\rangle, \tag{13}$$

with numerical coefficients $f_i(t)$ such that $\sum_i |f_i(t)|^2 = 1$. The analytic solution of such a dynamics is a formidable problem, and we thus resort to a numerical investigation in order to infer the behavior of $f_i(t)$ s. To find the coefficients $\{f_i(t)\}$, we have numerically solved the Schrödinger equation using the Hamiltonian in Eqs. (11).² We have explored a wide range of parameters, including the case where the system is symmetric under the exchange of the two BECs, finding qualitatively similar results. In the following, we concentrate on the symmetric case and use the parameters listed in the caption of Fig. 3, which shows that a complete transfer of OAM from the photonic state to the BECs is possible, in analogy with the semiclassical case approached in Refs. [13–15]. The (dashed) green curve shows the temporal dynamics of the probabilities $|f_{1,2}(t)|^2$, whereas the (solid) yellow curve depicts $|f_{7,8}(t)|^2$ for a given set of the relevant physical parameters and a specific choice for the functional form of the chirped two-photon detunings. These two sets of probabilities are almost mutually mirror symmetric. Damped oscillations are superimposed to a monotonic behavior induced by the

²We have verified the validity of the description given by the adiabatic Hamiltonian \hat{H}_{eff} by numerically solving the full problem represented by Eq. (2) for the same initial state and using parameters validating the use of the effective coupling model. We have checked that the normalization of the state vector spanned by the states in Eq. (12) is maintained within the time window used for our study, thus showing negligible leakage outside the relevant sector of the Hilbert space.

FIG. 3. (Color online) Evolution of the state probabilities $|f_i(t)|^2$ against the interaction time t (in microseconds) for $N_0^I = 10^5$ atoms per condensate. Here $f_{i,j}^I = 5$ nm, $\Omega_I = 27.5$ kHz, $\chi_{I,\pm 1} = 1.18$ kHz, $\Delta = 90$ kHz, and the two-photon detunings having the functional form $\delta_{\pm 1}(t) = 2\Omega_I(1 - \Omega_I t/2) - \omega_t$. The trap frequencies are $\omega_t = 70$ Hz and $\omega_z = 500$ Hz. The photonic resource is tailored at a wavelength of 702 nm at an angle of 4° off the initial pumping Gaussian beam's axis.

compensation arising from the chirped detunings [in our case, $\delta_{\pm 1}(t) = 2\Omega_I(1 - \Omega_I t/2) - \omega_t$]. The low-lying (dotted) red curve is for $|f_{3,4,5,6}|^2$, whose corresponding states only marginally contribute to the evolution of the system. Finally, the (dash-dotted) horizontal blue line shows the probability $|f_0(t)|^2$, which does not change in time as $|\Psi_0\rangle$ is an eigenstate of the effective Hamiltonian. As we shall see, this gives a lower limit for the population of the ground state of the reduced density matrix for the two BECs.

In fact, a plot of the populations of the BECs' reduced density matrix, $\rho_{AB}(t) = \text{Tr}_{\alpha\beta}(|\Psi(t)\rangle_{AB\alpha\beta}\langle\Psi(t)|)$, shows that the state $|N_0^A\rangle_A |N_0^B\rangle_B$ has always a finite occupation probability. This is due to the unavoidable presence of photons carrying no OAM that continuously project the two BECs onto their ground states.

FIG. 4. (Color online) Time behavior of the populations of the atomic states in $\rho_{AB}(t) = \text{Tr}_{\alpha\beta}(|\Psi(t)\rangle_{AB\alpha\beta}\langle\Psi(t)|)$. The same parameters as in Fig. 3 have been used here. The (dashed) green curve is for $|N_0^A, N_0^B\rangle_{AB}$, and the (solid) yellow curve is for state $|B\rangle$. The low-lying (dotted) red curves represent the probability that the remaining two-BEC basis states are excited. The incomplete population transfer from $|0\rangle_I$ to $|\pm 1\rangle_I$ ($I = A, B$) is due to the zero-OAM terms in $|\Phi_z\rangle_{\alpha\beta}$.

The (solid) yellow curve in Fig. 4 shows the population of the state $|B\rangle = (|N_0^A - 1, 1_1\rangle |N_0^B - 1, 1_{-1}\rangle + |N_0^A - 1, 1_{-1}\rangle |N_0^B - 1, 1_1\rangle) / \sqrt{2}$ (we have omitted the BEC label as no ambiguity exists), which shows OAM entanglement between the BECs. Clearly the OAM entanglement transfer generates quite a large component of $|B\rangle$ in the reduced two-BEC state. This arises from the OAM-carrying components in the photonic resource and the efficiency of the population-transfer process. The introduction of this state allows us to draw a clear and compact picture of the asymptotic form of the map $\hat{\mathcal{M}}_t$ transforming photonic OAM entanglement into matterlike entanglement via bilocal far off-resonant double Raman coupling. By neglecting the very small components associated with the remaining excited two BEC states (dotted red line in Fig. 4) and collecting the remaining terms into a diagonal density matrix, this is approximately given by

$$\begin{aligned} & \lim_{t \rightarrow \infty} \hat{\mathcal{M}}_t(|N_0^A, N_0^B\rangle_{AB} \langle N_0^A, N_0^B|) \\ & \simeq \frac{1}{3} (2|B\rangle_{AB} \langle B| + |N_0^A, N_0^B\rangle_{AB} \langle N_0^A, N_0^B|). \end{aligned} \quad (14)$$

Such a formal asymptotic map also explains that we can formally infer the properties of the reduced two-vortex density matrix by treating it as the state of two (in general entangled) qutrits.

C. Assessment of entanglement

We are now in a position to quantitatively estimate the amount of vortex entanglement set between the BECs. In order to tackle this point, our approach will be twofold. First, we study the time evolution of the linearized entropy $S_L(\rho_{AB}(t)) = (9/8)\{1 - \text{Tr}[\rho_{AB}(t)]\}$ [19] of the BEC density matrix. As S_L is a good measure of the purity of a state (it achieves 0 for perfectly pure states and 1 for statistical mixtures), this will give us an indication of the residual entanglement set between the photonic and matterlike parts of the system: as the dynamics set by \hat{H}_{eff} are unitary, the entanglement initially present in the photonic state has to be conserved when the whole state of the matter-light system is considered. Needless to say, such entanglement can be transferred from the photonic subsystem to the atomic one and/or vice versa, and a transient can well exist where the two are almost separable. Such a situation would be witnessed by a small value of S_L and correspond to either large or small values of BEC entanglement, with minimal photon-atom quantum correlations. We have determined the form of S_L as a function of time, which is shown in Fig. 5. As expected, at exactly the time when the populations of the OAM carrying the atomic system become nonzero, the linear entropy changes its behavior, signaling a maximum of mixedness of the light-matter state. This simply implies that for $t \in [400, 500]$ μs , the two subsystems are correlated in a nonclassical sense. If time increases further, S_L evidently decreases, witnessing a reduction in the light-matter entanglement. Because of the conservation of entanglement discussed earlier, this is the region in which we are interested as it could well be the case that in this long time window, significant intervortex entanglement is set at the expense of the initial all-optical one and the transient matter-light correlations highlighted here.

FIG. 5. (Color online) Linear entropy $S_L(\rho_{AB})$ against time t (in microseconds). The same parameters as in Fig. 3 have been used here.

We quantitatively confirm our expectations by studying the negativity [20,21], an entanglement measure based on the violation of the positivity of partial transposition (PPT) criterion for separability of a state. Negativity is defined as [21]

$$N[\rho_{AB}(t)] = -2 \sum_k \lambda_k^-, \quad (15)$$

where λ_k^- are the negative eigenvalues of the partially transposed density matrix with respect to one of the BEC systems. The results are shown in Fig. 6.

As expected, the region of large intervortex entanglement corresponds to the range of interaction times when the linearized entropy decreases toward a steady-state value. We point out that the wavy behavior of the curve in Fig. 6 as well as in the other figures of this article is due to the interatomic scattering. This is confirmed by the plot shown in the inset of Fig. 6, where an asymmetric case is studied. The comparison between symmetric and asymmetric cases shows that a mismatched number of atoms in the two BECs results in a change in the oscillatory behavior of the curve describing the time evolution of the transferred entanglement. On the other hand, mismatched Rabi frequencies only determine a

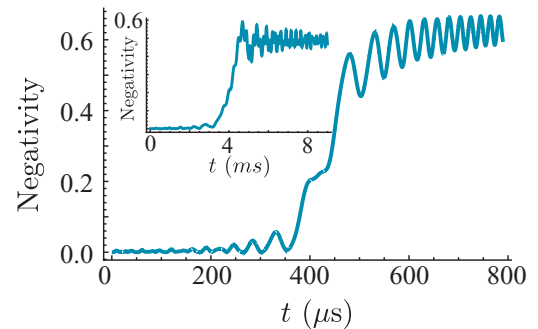

FIG. 6. (Color online) Negativity $N(\rho_{AB})$ against the interaction time t (in microseconds). The same parameters as in Fig. 3 have been used here. We obtain a maximum of entanglement in correspondence of the range of decreasing trend of $S_L(\rho_{AB}(t))$, which witnesses a larger purity of the two-vortex state and smaller quantum correlations between light and matter. Inset shows negativity against t for $N_0^A = 10N_0^B = 10^4$ and $\Omega_B = 10 \Omega_A = 27.5$ kHz. Other parameters are as in Fig. 3.

change in the temporal scale of the entanglement dynamics. The degree of transferred entanglement is only mildly affected, which demonstrates the robustness of our protocol to such effects. The efficiency of our protocol does not depend on the assumption of symmetry under the exchange of the condensates and is retained in a wide range of the relevant parameters. Therefore, for the sake of convenience and without affecting the generality of our results, in what follows, we restrict our attention to the symmetric case.

As discussed earlier, quite a large value of entanglement is set between the vortex states of the two condensates, although a maximally entangled state [achieving $N(\rho_{AB}) = 1$] is not reached. We stress that this is not a limitation of our scheme but, on the contrary, an effect of the zero-OAM component in the photonic resource $|\Phi_{Z\alpha\beta}\rangle$. Such a detrimental contribution can be removed from the BEC's reduced state (and its properties) by resorting to an "active" approach where, instead of discarding the state of light after the interaction with the condensates, we properly postselect its state. On inspection of $|\Psi_{7,8}\rangle$ in Eqs. (12), it is straightforward to see that state $|B\rangle_{AB}$ is associated with modes 1 and 2 in the vacuum state. On the other hand, the entanglement-spoiling component $|n_0^A, n_0^B\rangle_{AB}$ would bring about photons in both the modes. It is therefore sufficient to use a standard Geiger-like avalanche photodetector per mode, which discriminates the vacuum from the presence of any nonzero number of photons in a field, in order to operate the optimal postselection of the BEC state: By registering no click at both the photodetectors, we project the state of A and B onto the maximally entangled state $|B\rangle$. It is in fact worth stressing that by effectively excluding the possibility that the atoms occupy state $|0\rangle_I$, the postselection procedure further reduces the dimension of the relevant Hilbert space spanned by each vortex state to a bidimensional one, thus leaving us with two effective qubits.

IV. DETECTION OF VORTEX ENTANGLEMENT

In this section, we describe a method for the detection of the vortex entanglement created by the preceding process. Given the low excitation level of our protocol, the usual matter-wave interference is not helpful, and we instead propose an approach based on the inversion of the process addressed here for light-to-BEC entanglement transfer. After generation of a two-vortex entangled state (as described in Sec. III), the OAM-transferring interaction should be stopped. We thus assume that the pump fields have been turned off (or set far off-resonant with respect to the frequency of the transitions they guide) so as not to perturb the entangled states of the vortices. The time-reversal nature of our protocol makes it intuitive to understand that if we now reinstate such pumps, photons will be scattered into two Laguerre-Gauss modes at the frequency of the $|0\rangle_I \leftrightarrow |e, e'\rangle$ transition, thus writing back the two-vortex state onto light fields. One can then apply state-property reconstruction techniques, including testing Bell's inequality violation for bipartite states of effective three-level particles [22]. However, the success of such tests is usually very sensitive to the form of the state under scrutiny and the level of nonideality affecting it. We thus resort to a specific and quite promising way to infer the properties of the state we have generated based on Wigner function reconstruction, which is possible by using computer-

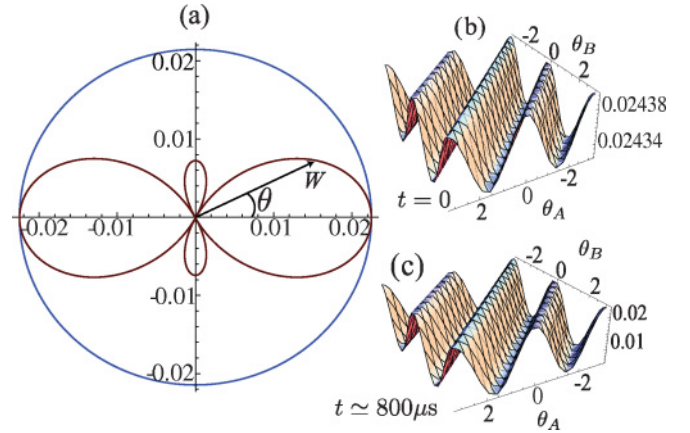

FIG. 7. (Color online) Analysis of the Wigner function for $\rho_{AB}(t)$. (a) The blue circle shows a projection of the Wigner function on the unit circle for $t = 0$, while the red butterfly structure is associated with $t \simeq 800 \mu\text{s}$, where OAM entanglement has been transferred. (b, c) We plot $W(0, \theta_A, 0, \theta_B)$ at the two instants of time considered for (a). Notice the different vertical-axis scales in the two plots. The visibility of the fringes of interference in the Wigner function is an indication of quantum correlations.

generated holograms [7] and homodyne-like measurements [23].

Theoretically, the Wigner function for the OAM state of a photon has been defined in the discrete cylinder $\mathbb{Z} \times C_1$ (C_1 is the unitary circle), representing the phase space for the OAM operator and its canonically conjugate operator $\hat{\theta}$. In Ref. [24], it has been shown that the study of the Wigner function for an OAM state gives information both on the various OAM eigenstates involved in the description of the state and on their relative phases. We define the two-mode Wigner function as

$$W(l_A, \theta_A, l_B, \theta_B) = \text{Tr}[\hat{w}(l_A, \theta_A) \otimes \hat{w}(l_B, \theta_B) \rho_{AB}], \quad (16)$$

where we have introduced the kernel $\hat{w}(l_I, \theta_I)$ ($I = A, B$) mapping quantum states in phase space [24] in a way completely analogous to the continuous position-momentum phase space. In Fig. 7(a), we compare the Wigner function $W(0, \theta, 0, 0)$ associated with $\rho_{AB}(t)$ when the entanglement transfer has not occurred (wide blue circle) to what is achieved at long-enough t , where the map $\hat{\mathcal{M}}_t$ has been implemented [inner (red) butterfly-like structure]. The difference due to the coherence established between two-mode orthogonal eigenstates of the OAM operator in the entangled state ρ_{AB} is striking. Moreover, from Figs. 7(b) and 7(c), we find that $W(0, \theta_A, 0, \theta_B)$ exhibits oscillations whose amplitude depends on the relative phase between the states $|B\rangle$ and $|D\rangle$. The curves shown in Figs. 7(b) and 7(c) are associated with the same interaction time as the circular and butterfly-like structures shown in Fig. 7(a), respectively, which demonstrates that the oscillation amplitudes depend on the populations of these states. Remarkably, the analysis of $W(l_A, \theta_A, l_B, \theta_B)$ for incoherent superpositions of OAM eigenstates results in a flat distribution. Therefore, by experimentally reconstructing the Wigner function, one can determine the inference of entanglement in the associated OAM state. Any deviation from

flat distributions typical of incoherent superpositions implies coherence in the bipartite state, although not entanglement. Methods based on the inverse Radon transform [25] could then be used in order to achieve full information on the state and, eventually, the entanglement set by the transfer mechanism.

V. CONCLUSIONS AND OUTLOOK

We have shown that vortex states of spatially remote, nonisotropically trapped BECs can be entangled by means of bilocal OAM-transfer processes and quantum correlated photonic resources. The amount of vortex entanglement set by our scheme can be quite considerable and appears to be limited only by the zero-OAM carrying component in the photonic resource. While such a bottleneck can be actively bypassed by means of postselection, as described in Sec. III, we are currently working on a modification of our protocol based on the use of other forms of the entangled photon pair [26]. The difference between the two-vortex state achieved by our scheme and a classical admixture of OAM eigenstates (without coherence and thus entanglement) can be revealed by a straightforward state-retrieval process and the reconstruction of the OAM-state Wigner function. We believe that the superfluid phase of a BEC, together with virtually frictionless rotational states of light-induced vortices, can be reliably exploited in order to set a promising scenario for the storage of quantum information and the distribution of quantum-correlated channels for communication.

APPENDIX

In this appendix, we present the calculations which lead to the expression of the effective Hamiltonian in Sec. II. The first step is the adiabatic elimination of the excited triplet $\{|E\rangle, |e\rangle, |e'\rangle\}$, which we perform by defining the rotating-picture new matter field operators $\hat{\psi}_{I,e} = \hat{\psi}_{I,e} e^{-i\omega_I t}$, $\hat{\psi}_{I,e'} = \hat{\psi}_{I,e'} e^{-i\omega_I t}$, $\hat{\psi}_{I,E} = \hat{\psi}_{I,E} e^{-i\omega_I t}$, with $\{\hat{\psi}_{I,E}, \hat{\psi}_{I,e}, \hat{\psi}_{I,e'}\}$ taken as time-independent. Such operators are then used in the Heisenberg equations for the dynamics of the excited-triplet states. One finds

$$\begin{aligned} \hat{\psi}_{I,E}(\mathbf{r}) &= \frac{\chi_{I,0} \mathcal{A}_{n_I,0}(\mathbf{r})}{\hbar \Delta_{I,0}} e^{i\omega_I t} \hat{c}_{n_I,0} \hat{\psi}_{I,0}(\mathbf{r}), \\ \hat{\psi}_{I,e}(\mathbf{r}) &= \frac{\Omega_I}{\Delta_I} e^{i\mathbf{k}_I \cdot \mathbf{r}} e^{-i(\omega_I - \omega_l)t} \hat{\psi}_{I,1}(\mathbf{r}) \\ &+ \frac{\chi_{I,1} \mathcal{A}_{n_I,1}(\mathbf{r})}{\hbar \Delta_I} e^{i\omega_I t} \hat{c}_{n_I,1} \hat{\psi}_{I,0}(\mathbf{r}), \end{aligned} \quad (\text{A1})$$

$$\begin{aligned} \hat{\psi}_{I,e'}(\mathbf{r}) &= \frac{\Omega_I}{\Delta_I} e^{i\mathbf{k}_I \cdot \mathbf{r}} e^{-i(\omega_I - \omega_l)t} \hat{\psi}_{I,-1}(\mathbf{r}) \\ &+ \frac{\chi_{I,-1} \mathcal{A}_{n_I,-1}(\mathbf{r})}{\hbar \Delta_I} e^{i\omega_I t} \hat{c}_{n_I,-1} \hat{\psi}_{I,0}(\mathbf{r}), \end{aligned}$$

where we have defined the single-photon detunings $\Delta_{I,0} = \omega_0 - \omega_{I,E}$, $\Delta_I = \omega_l - \omega_{I,e}$. In order to explicitly include the chirped two-photon Raman detunings, which are crucial in the stabilization of the transfer process, we define new field operators in a rotating frame defined by the Hermitian operator $\hat{O} = \sum_{I,k} \omega_I [\hat{\psi}_{I,k}^\dagger(\mathbf{r}, t) \hat{\psi}_{I,k}(\mathbf{r}, t) - \hat{c}_{n_I,k}^\dagger \hat{c}_{n_I,k}]$. Explicitly, $\hat{\psi}_{I,k}(\mathbf{r}, t) = e^{i\hat{O}t} \hat{\psi}_{I,k}(\mathbf{r}, t) e^{-i\hat{O}t} = e^{-i\omega_I t} \hat{\psi}_{I,k}(\mathbf{r}, t)$, while the photonic operators become $\hat{c}_{n_I,k} = e^{i\hat{O}t} \hat{c}_{n_I,k} e^{-i\hat{O}t} = e^{i\omega_I t} \hat{c}_{n_I,k}$. Defining the free Hamiltonians $H_0^{I,k} = -\hbar^2 \nabla_{\mathbf{r}}^2 / (2m) + V_{I,k}(\mathbf{r})$ and with the help of Eqs. (A1), we finally get

$$\begin{aligned} i\hbar \frac{d}{dt} \hat{\psi}_{I,0}(\mathbf{r}) &= \left[\hat{H}_0^{I,0} + \hbar\omega_I + \sum_j \eta_{j,0}' \hat{\psi}_{I,j}^\dagger(\mathbf{r}) \hat{\psi}_{I,j}(\mathbf{r}) \right. \\ &+ \frac{\chi_{I,0}^2 |\mathcal{A}_{n_I,0}(\mathbf{r})|^2}{\hbar \Delta_{I,0}} \hat{c}_{n_I,0}^\dagger \hat{c}_{n_I,0} + \frac{\chi_{I,1}^2 |\mathcal{A}_{n_I,1}(\mathbf{r})|^2}{\hbar \Delta_I} \hat{c}_{n_I,1}^\dagger \hat{c}_{n_I,1} \\ &+ \left. \frac{\chi_{I,-1}^2 |\mathcal{A}_{n_I,-1}(\mathbf{r})|^2}{\hbar \Delta_I} \hat{c}_{n_I,-1}^\dagger \hat{c}_{n_I,-1} \right] \hat{\psi}_{I,0}(\mathbf{r}) \\ &+ \frac{\Omega_I \chi_{I,0}^*}{\Delta_I} \mathcal{A}_{n_I,1}^*(\mathbf{r}) e^{i\mathbf{k}_I \cdot \mathbf{r}} \hat{c}_{n_I,1}^\dagger \hat{\psi}_{I,1}(\mathbf{r}) \\ &+ \frac{\Omega_I \chi_{I,-1}^*}{\Delta_I} \mathcal{A}_{n_I,-1}^*(\mathbf{r}) e^{i\mathbf{k}_I \cdot \mathbf{r}} \hat{c}_{n_I,-1}^\dagger \hat{\psi}_{I,-1}(\mathbf{r}) \end{aligned} \quad (\text{A2})$$

$$\begin{aligned} i\hbar \frac{d}{dt} \hat{\psi}_{I,1}(\mathbf{r}) &= \left[\hat{H}_0^{I,1} + \hbar(\omega_l - \delta_1 - \tilde{\omega}_1) + \frac{\hbar |\Omega_I|^2}{\Delta_I} \right. \\ &+ \left. \sum_j \eta_{j,1}' \hat{\psi}_{I,j}^\dagger(\mathbf{r}) \hat{\psi}_{I,j}(\mathbf{r}) \right] \hat{\psi}_{I,1}(\mathbf{r}) \\ &+ \frac{\Omega_I^* \chi_{I,1}}{\Delta_I} \mathcal{A}_{n_I,1}(\mathbf{r}) e^{-i\mathbf{k}_I \cdot \mathbf{r}} \hat{c}_{n_I,1} \hat{\psi}_{I,0}(\mathbf{r}), \end{aligned} \quad (\text{A3})$$

$$\begin{aligned} i\hbar \frac{d}{dt} \hat{c}_{n_I,0} &= \left[-\hbar\omega_I + \int_{V_I} d\mathbf{r} \frac{\chi_{I,0}^2 |\mathcal{A}_{n_I,0}(\mathbf{r})|^2}{\hbar \Delta_{I,0}} \hat{\psi}_{I,0}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}) \right] \hat{c}_{n_I,0}, \end{aligned} \quad (\text{A4})$$

$$\begin{aligned} i\hbar \frac{d}{dt} \hat{c}_{n_I,1} &= \left[-\hbar\omega_I + \int_{V_I} d\mathbf{r} \frac{\chi_{I,1}^2 |\mathcal{A}_{n_I,1}(\mathbf{r})|^2}{\hbar \Delta_I} \hat{\psi}_{I,0}^\dagger(\mathbf{r}) \hat{\psi}_{I,0}(\mathbf{r}) \right] \hat{c}_{n_I,1} \\ &+ \int_{V_I} d\mathbf{r} \frac{\Omega_I \chi_{I,1}^*}{\Delta_I} \mathcal{A}_{n_I,1}^*(\mathbf{r}) e^{i\mathbf{k}_I \cdot \mathbf{r}} \hat{\psi}_{I,0}^\dagger(\mathbf{r}) \hat{\psi}_{I,1}(\mathbf{r}). \end{aligned} \quad (\text{A5})$$

From these expressions, it is straightforward to define the effective interaction Hamiltonian \hat{H}_{eff} used throughout the article.
