Abstract—We provide a geometric solution to the problem of optimal relay positioning to maximize the multicast rate for low-SNR networks. The network we consider consists of a single source, multiple receivers and the only intermediate and locatable node as the relay. We construct network the hypergraph of the system nodes from the underlying information theoretic model of low-SNR regime that operates using superposition coding and FDMA in conjunction (which we call the "achievable hypergraph model"). We make the following contributions.

1) **We show that the problem of optimal relay positioning maximizing the multicast rate can be completely decoupled from the flow optimization by noticing and exploiting geometric properties of multicast flow.**

2) **All the flow maximizing the multicast rate is sent over at most two paths, in succession. The relay position depends on only one path (out of the two), irrespective of the number of receiver nodes in the system. Subsequently, we propose simple and efficient geometric algorithms to compute the optimal relay position.**

3) **Finally, we show that in our model at the optimal relay position, the difference between the maximized multicast rate and the cut-set bound is minimum.**

We solve the problem for all (P_s, P_r) pairs of source and relay transmit powers and the path loss exponent $\alpha \geq 2$.

Index Terms—**Low-SNR, broadcast relay channel, geometry.**

I. INTRODUCTION

We primarily consider the problem of optimal relay positioning in order to maximize the multicast rate in low-SNR networks consisting of a single source s, a set of multiple receivers T and an arbitrarily locatable relay r, on a 2-D Euclidean plane. In [1], the authors previously addressed this problem under a heavy and complex network flow optimization framework. They showed that optimizing the relay position can lead to a strong gain in the multicast rate.

In [2] the authors introduced equivalent hypergraph models for the low-SNR Broadcast (BC) and Multiple Access channels (MAC). The authors then derived an achievable hypergraph model for the broadcast relay channel (BRC), obtained by concatenating the equivalent BC and MAC hypergraphs. This concatenated model follows from constraining the source and relay to transmit using the optimal schemes for the low-SNR BC and MAC: superposition coding and frequency division, respectively. In this paper, building on this model, we solve geometrically the problem of optimal relay positioning under

the pretext of multicast rate maximization, which is much simpler and efficient than the solution proposed in [1].

Most importantly, we establish the fact that for a given low-SNR BRC hypergraph $\mathcal{G}(\mathcal{N}, \mathcal{A})$, the multicast rate is maximized by sending all the flow through at most two paths in succession, independently of the number of destination nodes. This is a consequence of simply maximizing the multicast min-cut. The dependency of the multicast min-cut on the relay position is essentially through a single path (out of the two), and this motivates a simple geometric interpretation and formulation of the problem. It should be noted that, the "optimal relay position" refers to the position that maximizes the multicast rate over a given achievable hypergraph, but in general the achievable hypergraph model is not necessarily optimal in terms of meeting the cut-set bound for low-SNR networks. On the other hand, the achievable hypergraph model performs closely to the peaky binning scheme in the case of a single destination [3], and enjoys an important practical advantage of being easily scalable to more complicated topologies. Finally, under our model the difference between the maximum multicast rate and the cut-set bound is minimized at the optimal relay position.

In the proposed geometric approach, we decouple the problem of rate maximization from the problem of computing the optimal relay position. This substantially reduces the complexity (compared to the flow optimization based framework in [1]) and also provides a great deal of insight in understanding the nature of such network planning problems. Finally, we show that at the optimal position the difference between the maximum multicast rate and the cut-set bound is minimized under the achievable hypergraph model.

The paper is organized as follows. We introduce the low-SNR achievable hypergraph model of the BRC in section II. Then we prove certain geometric properties of multicast in section III. The computation of optimal relay position is divided in two parts, section IV for $P_s = P_r$ and section V for $P_s \neq P_r$. Finally, we conclude in section VI.

II. LOW-SNR SYSTEM AND HYPERGRAPH MODEL

A. System model and notations

The network topology is given by a hypergraph $\mathcal{G}(\mathcal{N}, \mathcal{A})$, where $\mathcal{N} = \{s, r, T\}$, and all nodes except r are fixed on the 2-
Fig. 1. Wideband Multiple User Channels. The BC rates: $R_1 = (1-\beta)h_1^2 \frac{P}{N_0}\mathbb{1}_{]h_2^2,+\infty[}(h_1^2)$, $R_2 = (1-\beta)\frac{P}{N_0}\mathbb{1}_{[0,h_2^2[}(h_1^2)$, $R_c = \beta\min\{h_1^2,h_2^2\}\frac{P}{N_0}$. The BRC rates: $r_0 = \frac{\beta_0 P_s}{D_{sr}^2 N_0}$, $r_1 = \frac{\beta_1 P_s}{D_{st_1}^2 N_0}$, $r_2 = \frac{\beta_2 P_s}{D_{st_2}^2 N_0}$, $r_3 = \frac{\mu_1 P_r}{D_{rt_1}^2 N_0}$, $r_4 = \frac{\mu_2 P_r}{D_{rt_2}^2 N_0}$. Here, h gives the path loss and D_{ij} the distance from i to j.

D Euclidean plane. $T = \{t_1,..,t_n\}$ denotes the set of $n = |T|$ receivers ordered in increasing distance from s. $\mathcal{C}$ represents the convex hull of $\{s,T\}$. The multicast rate from s to T is defined as $R_{sT} \triangleq \min_{t\in T}(R_{st})$, where R_{st} is the total rate from s to receiver $t \in T$. P_s and $P_r = \gamma P_s$ are the total transmit powers of s and r, respectively, and $\gamma > 0$ is their ratio. D_{uv} denotes the Euclidean distance between nodes u and v, and $\alpha \geq 2$ the path loss exponent. For a subset $Q \subseteq \mathcal{N}\backslash r$, define $L_Q(\mathcal{C})$ as the point in $\mathcal{C}$, that minimizes the maximum over the distances between itself and each node in Q, i.e.

$$L_Q(\mathcal{C}) \triangleq \arg\min_{r\in\mathcal{C}}\left(\max_{j\in\{Q\}}(D_{rj})\right). \tag{A}$$

The value of objective function of the output of Program (A) is denoted as D_Q.

B. Low-SNR BC, MAC and BRC hypergraph models

In [1], [2], it was shown that concatenating the low-SNR BC (superposition coding) and MAC (FDMA) equivalent hypergraph models results in an achievable hypergraph model for the low-SNR BRC. The rate region of this model is included in the capacity region of the low-SNR broadcast relay channel. In fact, even though superposition coding and FDMA are independently capacity achieving for the low-SNR AWGN BC and MAC channels respectively, their combination in general is not capacity achieving for the low-SNR relay channel, and a fortiori for the low-SNR BRC [3].

In this section, we briefly recall the equivalent hypergraph models for the low-SNR BC and MAC, and the achievable hypergraph model for the BRC [1]. Note that in the low-SNR regime, BC and MAC are *not* limited by interference.

1) Low-SNR BC equivalent hypergraph: Superposition coding is known to achieve the capacity region of the AWGN BC. In the low-SNR regime, the rates achieved by superposition coding boil down to the time-sharing region [4]–[6]. For a given topology with $|T| = n$ receivers, the hypergraph will contain at most n hyperarcs with non-zero capacities [1]. Figures 1(a) and 1(b) illustrate the two-destination case.

2) Low-SNR MAC equivalent hypergraph: In the low-SNR regime, interference becomes negligible with respect to the noise [1], [2], and all sources can achieve their point-to-point capacity to the common destination, like with frequency division multiple access (FDMA). In the general wideband MAC with n sources, the hypergraph model consists of n hyperarcs of size 1 from each source s_i, $i \in \{1,..,n\}$ to

the destination with non-zero capacity. Figures 1(c) and 1(d) illustrate the two-source case.

3) Low-SNR BRC achievable hypergraph: We can obtain an achievable hypergraph model of the low-SNR BRC by simply concatenating the BC and MAC equivalent hypergraphs, as shown in Figures 1(e) and 1(f) for the two-destination case. As mentioned before, this achievable hypergraph model is suboptimal in general for the BRC, but the ability to scale easily to larger and complex networks is one of its biggest strength.

III. GEOMETRIC PROPERTIES OF MULTICAST

In this section, we derive the geometric properties of the optimal relay position maximizing the multicast rate for the BRC. We first focus on the single destination case of the BRC: the relay channel, in Section III-A. Then, these preliminary observations and properties are extended for the general problem with an arbitrary number of destinations, in Section III-B.

A. Single destination: low-SNR relay channel

Consider the simple network in Figure 2 (a), with a fixed source s, a fixed receiver t and an arbitrarily positionable relay r, where the multicast rate R_{st} from s to t is to be maximized. Naturally, R_{st} depends on the position of r. The achievable hypergraph in Figure 2 (a) can be broken into two subgraphs, shown in Figures 2 (b) and (c), which are essentially the two disjoint paths from s to t.

Our claim is that the optimal position of the relay maximizing the multicast rate from s to t lies on the line segment $s-t$ joining s and t, and at this optimal position all the flow R_{st} is sent through a single path consisting of two hyperarcs, namely $\{(s,r),(r,t)\}$ shown in Figure 2 (c). This holds true for any given pair of power constraints $(P_s,P_r) \succ 0$ and for any path loss exponent $\alpha \geq 2$. We prove this claim in Lemmas 1 and 2 hereafter.

We first recall the following lemma from [1].

Lemma 1 (Lemma 1 [1]): The optimal position of r maximizing R_{sT} lies inside the convex hull $\mathcal{C}$.

Here, Lemma 1 simply implies that the optimal position of r lies on the segment $s-t$.

The rates over the three hyperarcs $\{(s,r),(r,t),(s,rt)\} = \mathcal{A}$ are given by,

$$R_{sr} = \frac{P_{sr}}{D_{sr}^\alpha N_0}, \quad R_{rt} = \frac{P_{rt}}{D_{rt}^\alpha N_0}, \quad R_{srt} = \frac{P_{srt}}{D_{st}^\alpha N_0}, \tag{1}$$

$$P_{sr} + P_{srt} \leq P_s, \quad P_{rt} \leq P_r, \tag{2}$$

Fig. 2. (a): One receiver case decomposed into two subgraphs from s to t, (b) and (c), respectively. (d): Optimal position of r for $P_s = P_r$ and $\alpha = 2$, which is at the perpendicular bisector (red) of line segment $s - t$. (e): Left bias for $P_s < P_r$. (f): Right bias for $P_s > P_r$.

where N_0 is the noise power spectral density. Note that the multicast rate is given by $R_{st} = R_{srt} + \min(R_{sr}, R_{rt})$.

Lemma 2: The optimal location of r on the segment $s - t$ for a simple BRC with $\gamma \in (0, \infty)$ and $\alpha \geq 2$ that maximizes the multicast rate R_{st} satisfies,

$$D_{sr}^* = \frac{D_{st}}{1 + \sqrt[\alpha]{\gamma}} \; , \quad D_{rt}^* = \frac{\sqrt[\alpha]{\gamma} D_{st}}{1 + \sqrt[\alpha]{\gamma}} \; , \quad (3)$$

and the optimal (maximized) multicast rate is given by,

$$R_{st}^* = \frac{P_s}{(D_{sr}^*)^\alpha N_0} = \frac{\gamma P_s}{(D_{rt}^*)^\alpha N_0} \quad (4)$$

where all the flow R_{st}^* is sent over the path $\{(s,r),(r,t)\}$.

In Lemma 2 the starred entities refer the optimal values and for the proof the reader is referred to Appendix A.

Lemma 2 essentially gives the position of r in terms of how far it is from s and r on the segment $s - t$. Also, it provides the maximized multicast rate R_{st}^* that is achieved at this position. It can be easily seen that the relay position only affects the rate over the path $\{(s,r),(r,t)\}$. Since the min-cut of the path $\{(s,r),(r,t)\}$ is strictly larger than the min-cut of the path $\{(s,rt)\}$, i.e. the rate that can be sent for a unit power over the former path is strictly larger than the latter path ($R_{srt} < \min(R_{sr}, R_{rt})$), the rate over the path $\{(s,r),(r,t)\}$ should be maximized first by simply maximizing its min-cut $\min(R_{sr}, R_{rt})$ before allocating any power to the path $\{(s,rt)\}$. The min-cut $\min(R_{sr}, R_{rt})$ is maximized at the position on the segment $s - t$ such that rates over the two hyperarcs of the path $\{(s,r),(r,t)\}$ become equal, and all the flow from s to t is transmitted over this path only. The maximized multicast flow R_{st}^* is then simply given by the rates of either of the two hyperarcs.

Several important conclusions can be drawn from Lemma 2. The multicast flow optimization can be separated from the determination of the optimal relay position that maximizes the multicast flow. Even if the aim is not to maximize the multicast flow (for instance by simply choosing not to use all the source and relay powers), Lemma 2 still gives the most suitable relay position for any feasible multicast rate $R_{st} \leq R_{st}^*$. At the same time, the algorithmic style intuitive proof arguments in the previous paragraph indicate that upon computing the optimal relay position, the multicast rate maximization problem could be casted as a straightforward linear program resulting in a

simple power allocation scheme maximizing the multicast rate. This fact will prove handy for the general case with arbitrary number of destinations. On the other hand, we observe the dependency of the optimal relay position on the constants α and γ. If $\gamma = 1$ i.e. $P_s = P_r$, the optimal relay position is always at the mid-point of the segment $s - t$ for any value of $\alpha \geq 2$. When $\gamma \neq 1$, there will be a natural bias on the optimal position of r either towards s or t, depending on the value of γ. This bias will also depend on the value of α. Figure 2(e) and 2(f) show the bias effect.

B. Multiple destinations

In this subsection, we extend the simple geometric insights developed in Section III-A for a single destination to the general case of an arbitrary number of destinations $|T| = n$.

Let us first note the following. For a given hypergraph $\mathcal{G}(\mathcal{N}, \mathcal{A})$, and a fixed position of r, we have at most $(n+1) + (n)$ hyperarcs in the system, i.e. $|\mathcal{A}| = 2n + 1$. The former $(n + 1)$ are source hyperarcs, emanating from s to the nodes in $\mathcal{N} \backslash s$ and the latter n are the relay hyperarcs, emanating from r to all T. Also, for any given position of r there always exist at least two paths that will span all the receiver set T, namely $\{(s, T)\}$ (or $\{s, t_1..t_n\}$) and $\{(s, T_1), (r, T_2)\}$ (where $r \in T_1$ and $T_1 \cup T_2 = \{r, T\}$).

Now, consider that each hyperarc $(i, J) \in \mathcal{A}$ is associated with a continuous function $f_{iJ}(P_i^+, D_{iJ}^-) : \mathbb{R}^2 \longrightarrow \mathbb{R}$, that is a monotonically increasing in the transmit node's power P_i and monotonically decreasing in the distance D_{iJ}, where D_{iJ} is the Euclidean distance between the transmit node i and the farthest receiver node $j \in J$ (from i) spanned by the hyperarc. Then the following theorem holds true.

Theorem 1: Given a hypergraph $\mathcal{G}(\mathcal{N}, \mathcal{A})$ and the associated rate functions $f_{iJ}(P_i^+, D_{iJ}^-) : \mathbb{R}^2 \longrightarrow \mathbb{R}$ for each hyperarc in $\mathcal{A}$, at the optimal position maximizing the multicast rate R_{sT} one of the two multicast flow characteristics holds:

(i) all the optimal flow R_{sT}^* goes through at most two paths $\{(s, T_1), (r, T_2)\}$ and $\{(s, T)\}$, in succession.

(ii) all the optimal flow R_{sT}^* can be arbitrarily split between the two paths $\{(s, T)\}$ and $\{(s, T_1), (r, T_2)\}$.

For the proof of Theorem 1, refer to Appendix B.

Theorem 1 partially generalizes Lemma 2. We say partially, because on one hand, Theorem 1 establishes the important multicast flow characteristics at the optimal relay position, but it does not provide a simple numerical result that determines the optimal relay location (like Lemma 2). Note that, for a given relay position there could be multiple paths from s, through r, to all T, but in the Theorem 1 by path $\{(s, T_1), (r, T_2)\}$ we mean the path from s, through r, to all T that has the highest min-cut among all the paths from s, through r, to all T. Intuitively, Theorem 1 states that only those paths will contain the multicast flow from s to the receiver set T that serve all T, namely $\{(s, T)\}$ and $\{(s, T_1), (r, T_2)\}$. All other path that serve proper subsets of T will carry no flow as they do not contribute to the multicast flow and among all the paths serving all T through r, only the path with the highest

min-cut will carry the multicast flow. This fact is a simple yet fundamental consequence of the definition of multicast.

Theorem 1 reveals a lot about the nature of multicast flow over a hypergraph. The dependence of relay position on the rate of only a single path $\{(s, T_1), (r, T_2)\}$ reduces the problem to its core by removing the clutter away. In other words, now we only need to worry about the maximization of the flow over this single path and the relay position that maximizes the flow over this path also maximizes the multicast flow R_{sT}. This result of Theorem 1 motivates a pure geometric interpretation of the problem. If we imagine the two hyperarcs (s, T_1) and (r, T_2) to be two circles C_s and C_r centered at s and r with radii π_s and π_r, respectively, then the optimal relay positioning problem could be stated as: *For a given $\mathcal{G}(\mathcal{N}, \mathcal{A})$, find the point in $\mathcal{C}$ such that when r is positioned at this point, $\max(\sqrt[\alpha]{\gamma}\pi_s, \pi_r)$ is minimized while $r \in C_s$ and the region of union of two circles $C_\cup = C_s \cup C_r$ encompasses all T.*

At first, it seems plausible to try a simple (preferably convex) optimization framework to compute such a point, but the condition that the two circles must encompass all $\mathcal{N}$ brings in discreteness, which we avoid for obvious reasons. In contrast, we propose a simple (polynomial time) algorithm to compute such point in the next sections. Once the optimal relay position is obtained, obtaining optimal power allocations (for s and r) maximizing the multicast rate boils down to solving a simple linear program involving only two paths. We divide the development of this algorithm into two cases of $\gamma = 1$ and $\gamma \in (0, \infty)$. The case of $\gamma = 1$ is easy to understand and holds importance in its own right. In addition it develops the basic intuition for the proposed algorithm and leaves the extension to the case of all values of $\gamma \in (0, \infty)$, as straightforward.

IV. $(P_s = P_r)$ - CASE AND ALGORITHM

In this section, we have $\gamma = 1$ and $\alpha \geq 2$ for a given $\mathcal{G}(\mathcal{N}, \mathcal{A})$ on the 2-D Euclidean plane. The optimal relay positioning problem stated geometrically in the previous section simply boils down to finding the point in $\mathcal{C}$ such that $\max(\pi_s, \pi_r)$ is minimized while $r \in C_s$ and $C_\cup$ encompasses all T. We divide the problem in the following two cases based on the topology of the given $\mathcal{G}(\mathcal{N}, \mathcal{A})$.

A. $s - t_n$ mid-point case

Lemma 3: If r is placed at the mid-point of $s - t_n$ such that the hyperarcs C_s and C_r each with radii $\frac{D_{st_n}}{2}$ span all T, then it is the optimal relay position maximizing R_{sT}.

The proof of Lemma 3 is a straightforward generalization of Lemma 2 and therefore is omitted. Intuitively, Lemma 3 simply states that since the farthest node (from s) t_n is also the limiting node for maximizing R_{sT}, if the rate is maximized only to t_n while guaranteeing it to all other nodes in T, then this maximizes R_{sT} as well. This means that if r is placed at the mid-point of the segment $s - t_n$ (as this position maximizes the rate to t_n only) and if the two hyperarcs of the path $\{(s, r), (r, t_n)\}$ ($\{C_s, C_r\}$) span all T, then clearly this is the relay position that maximizes R_{sT}.

B. General Case

In this case we tackle all topologies and case A becomes a special case of it. Recall that, the entity $L_Q(\mathcal{C})$ represents the coordinates of the point which is the argument of the objective function of the output of program (A), and D_Q is the value of the objective function of the output of program (A).

Optimal relay positioning Algorithm (ORP)
Given: $\mathcal{G}(\mathcal{N}, \mathcal{A})$.

1) Compute $l_0 = L_{\{\mathcal{N}\setminus r\}}(\mathcal{C})$ and build the set $\mathbf{N_0} = \{t \in T | D_{st} < D_{l_0 t} \& D_{l_0 t} > D_{s l_0}\} = \{t'_1, .., t'_m\}$ in increasing order of distance from s. If $\mathbf{N_0} = \{\emptyset\}$, declare l_0 as the optimal relay position and quit, else go to step 2.
2) Build the set $\mathbf{N_1} = \{\mathcal{N}\setminus(r, \mathbf{N_0})\}$ and compute the point $l_1 = L_{\mathbf{N_1}}(\mathcal{C})$. Form the hyperarcs C_s and C_{l_1} of radii $D_{s l_1}$ and $D_{\mathbf{N_1}}$, respectively. If $C_\cup = C_s \cup C_{l_1}$ encompasses all T, output l_1 as the optimal relay position and quit, else go to step 3.
3) Reform the hyperarc C_s of radius $D_{st'_m}$ and build the set $\mathbf{N_2} = \{t \in T | D_{st} > D_{st'_m}\}$ and compute $l_2 = L_{\mathbf{N_2}}(\mathcal{C})$. Declare l_2 as the optimal relay position and quit.

Algorithm ORP is a straightforward set of basic and intuitive computational steps based on the properties of the point $l_0 = L_{\mathcal{N}\setminus r}(\mathcal{C})$. If there exist no node $t' \in T$ such that $t' \notin C_s$ and $D_{st'} < D_{l_0 t'}$ (i.e. set $\mathbf{N_0}$ is empty), that can be directly reached by s rather than by a path through r, then l_0 is certainly the optimal relay position. In contrast, if the set $\mathbf{N_0}$ is not empty, then there exist at least one receiver node in the system that influences the computation of the optimal relay position but can be served directly by C_s. Therefore, either the nodes in $\mathbf{N_0}$ can be removed from the computation of the optimal relay position (l_1 in Step 2) and $\max(\pi_s, \pi_r)$ can be further reduced or we could reform the hyperarc C_s with radius $D_{st'_m}$ (where, t'_m is the farthest node in $\mathbf{N_0}$ from s) and then computing the point l_2 for the nodes that were not covered by C_s and thus reducing the value of $\max(\pi_s, \pi_r)$. Note that, Algorithm ORP categorizes all possible topologies of the given $\mathcal{G}(\mathcal{N}, \mathcal{A})$ in three steps and there is no underlying iterative process. This makes algorithm ORP behave like a numerical formula, which we originally wanted from Theorem 1.

We leave the formal proof that ORP always outputs the optimal relay position maximizing R_{sT} to Appendix C and extend this simple approach in a straightforward manner to the case of all values of $\gamma \in (0, \infty)$ in the next section.

V. $P_s \neq P_r$ - CASE AND ALGORITHM

In this section, we consider $\gamma \in (0, \infty)$ for a given $\mathcal{G}(\mathcal{N}, \mathcal{A})$ and $\alpha \geq 2$. Almost all the theory developed in Section IV simply transcends to this section, with certain notable differences. Mainly, that when $\gamma \neq 1$ it gives rise to a bias in the positioning of r (ref. Figure 2(e) and 2(f)). Taking into account the bias while computing the optimal relay position will be the main enhancement in this section. Likewise previously, we first consider the $s - t_n$ case.

A. $s - t_n$ case

Lemma 4: Given $\mathcal{G}(\mathcal{N}, \mathcal{A})$, if r is placed on $s - t_n$ at a distance of $D_{sr} = \frac{D_{st_n}}{1 + \sqrt[\alpha]{\gamma}}$ from s, such that $r \in C_s$ and $C_\cup = C_s \cup C_r$ spans all T, then it is optimal relay position that maximizes R_{sT}.

The line of argument for the proof of Lemma 3 (using Lemma 2) could be simply generalized for Lemma 4.

B. General Case

In this case, like in Section IV, we generalize to all topologies. As we know, that the values of γ (when not equal to 1) and α inflict the bias on the relay position. The main difference in case of $P_s \neq P_r$ is the computation of the point $l_i = L_Q(\mathcal{C})$ $(i = \{0, 1\})$, given by,

$$l_i = L_Q(\mathcal{C}) \triangleq \arg\min_{i \in \mathcal{C}} \left(\max_{(j \in Q \backslash s)} \left(\sqrt[\alpha]{\gamma} D_{si}, D_{ij} \right) \right). \quad \text{(B)}$$

and the computation of the set $\mathbf{N_0} = \{t \in T | \sqrt[\alpha]{\gamma} D_{sl_0} > D_{l_0 t}\} = \{t'_1, .., t'_m\}$, in the Algorithm ORP. Program (B) and the set $\mathbf{N_0}$ takes into account the bias induced by the differences in the transmit power of the source and relay and the value of α. The rest of the algorithm remains the same.

Now that we have an efficient algorithm for computing the optimal relay position, we can be more ambitious to assess the standing of our work in a more theoretical sense. One of the important consequences of this work that signifies its theoretical importance is shown in Figure 3. We computed the difference between the optimal multicast rate R_{sT}^* (for a given position of r) and the cut set bound for $|T| = 9$ receiver nodes network at 21 interesting positions, including the optimal relay position computed by the Algorithm ORP. At the optimal relay position (blue point), this difference is minimized, confirming the fact that the optimal relay position not only results in gains but the maximized multicast rate is theoretically closest to the cut-set bound at the optimal relay position in our framework.

It is worth mentioning that the theory developed in this paper well transcends to the low-SNR fading channels, which we do not discuss here but can be easily generalized from the results of [2] and [3].

VI. CONCLUSION

We list the important deductions from our work in the following points.

1) The problem of optimal relay positioning to maximize the multicast rate for the achievable hypergraph model of low-SNR networks using superposition coding and FDMA, can be decoupled from flow optimization and casted as a simpler geometric problem, as opposed to a complex network optimization approach of [1].

2) The geometric properties of multicast are innately simple and provide interesting insights for relay positioning problem. This is largely due to the fact that all the multicast flow is pushed over at most two paths which is a direct consequence of the definition of the multicast flow, and this results in simple geometric interpretation.

Fig. 3. $|T| = 9$ case with green receivers, red source and blue as the optimal relay position. The optimal R_{sT} and cut set bound difference (in nats/sec) is calculated for 21 positions and is the lowest at the optimal relay position (blue). We assume $\frac{P_s}{N_0} = \frac{P_r}{N_0} = 1$ (normalized) and $\alpha = 4$.

3) Importantly, the benefits of determining the optimal relay position are substantiated by the fact that the difference between the maximized multicast rate and the cut-set bound at the optimal position is minimized.

We now outline, what we think are certain important future directions our work could take. The geometric properties of multicast give great insights and are surprisingly easy to work with. This motivates us to ask further, whether is it possible to apply the simple techniques of our work for the optimal relay positioning problem to moderate and high-SNR regimes that are interference limited. Another natural and interesting dimension is to look at the possibility of extending this work to multicommodity flows.

APPENDIX A
PROOF OF *Lemma 2*

Proof: We only consider the positions in the interior of the segment $s - t$. Then, the multicast rate is given by

$$R_{st} = R_{srt} + \min(R_{sr}, R_{rt})$$
$$= \frac{\lambda P_s}{D_{st}^{\alpha/2} N_0} + \min\left(\frac{(1-\lambda)P_s}{D_{sr}^\alpha N_0}, \frac{\gamma P_s}{D_{rt}^\alpha N_0}\right) \quad (5)$$
$$= \frac{P_s}{N_0} \min\left(\lambda\left(\frac{1}{D_{st}^\alpha} - \frac{1}{D_{sr}^\alpha}\right) + \frac{1}{D_{sr}^\alpha}, \lambda\frac{1}{D_{st}^\alpha} + \frac{\gamma}{D_{rt}^\alpha}\right).$$

By assumption, we have $D_{st} > \max(D_{sr}, D_{rt})$. Thus, in the minimization of (5), the first and the second term are respectively decreasing and increasing affine functions of λ. Two cases can occur. If $\sqrt[\alpha]{\gamma}D_{sr} \geq D_{rt}$, then the second term is always larger than the first term, which consequently is the minimum of the two. The first term decreases in λ, thus R_{st} is maximized for $\lambda = 0$. Else, if $\sqrt[\alpha]{\gamma}D_{sr} \leq D_{rt}$, the two affine functions intersect in the interval $[0, 1]$ at $\lambda = 1 - \frac{\gamma D_{sr}^\alpha}{D_{rt}^\alpha}$. The multicast rate R_{st} is maximized at this intersection. Note that for the position of r satisfying $\sqrt[\alpha]{\gamma}D_{sr} = D_{rt}$, both solutions match: $\lambda = 1 - \frac{\gamma D_{sr}^\alpha}{D_{rt}^\alpha} = 0$.

By Lemma 1, the relay position maximizing the multicast rate lies on segment $s - t$. Then, we can write

$$D_{st} = D_{sr} + D_{rt}, \quad (6)$$

and the relay position is simply determined by the distance D_{sr}. Using (6), the conditions $\sqrt[\alpha/2]{\gamma}D_{sr} \lessgtr D_{rt}$ in Lemma 2 can be rewritten in function of D_{sr} as

$$D_{sr} \lessgtr \frac{D_{st}}{1 + \sqrt[\alpha]{\gamma}}. \quad (7)$$

Given the optimal power allocation λ^*, and using (7), the multicast rate R_{st} can be rewritten as the following function of D_{sr}

$$R_{st} = \begin{cases} \frac{P_s}{D_{st}^\alpha N_0}\left(1 + \gamma\frac{D_{st}^\alpha - D_{sr}^\alpha}{(D_{st} - D_{sr})^\alpha}\right), & \text{if } D_{sr} \leq \frac{D_{st}}{1 + \sqrt[\alpha]{\gamma}}; \\ \frac{P_s}{D_{sr}^\alpha N_0}, & \text{if } D_{sr} \geq \frac{D_{st}}{1 + \sqrt[\alpha]{\gamma}}. \end{cases} \quad (8)$$

From (8), it can be seen that R_{st} is an increasing function of D_{sr} over $(0, \frac{D_{st}}{1 + \sqrt[\alpha]{\gamma}}]$, and then a decreasing function of D_{sr} over $[\frac{D_{st}}{1 + \sqrt[\alpha]{\gamma}}, D_{st})$. Therefore, the multicast rate is maximized at the border between these two intervals: $D_{sr}^* = \frac{D_{st}}{1 + \sqrt[\alpha]{\gamma}}$. Substituting D_{sr}^* in (8) yields R_{st}^*. This completes the proof of the Lemma. ∎

APPENDIX B
PROOF OF *Theorem 1*

A simple assimilation of the basic graph theoretic and Euclidean geometric concepts helps form the fundamental reasoning for the proof. Let's assume that the hypergraph $\mathcal{G}(\mathcal{N}, \mathcal{A})$ is given with the constant $\gamma \in (0, \infty)$ (where, $P_r = \gamma P_s$) and each hyperarc $(i, J) \in \mathcal{A}$ is associated with any continuous rate function $f_{iJ}(P_i^+, D_{iJ}^-) : \mathbb{R}^2 \longrightarrow \mathbb{R}$, that is monotonically increasing in the transmit power of the emanating node i of the hyperarc and is monotonically decreasing in the distance D_{iJ} (between the transmit node i and the farthest node $j \in J$ from i). We notice that there are only two transmitters in the system s and r and the multicast rate from s to the receiver set T is defined as $R_{sT} = \min_{(t \in T)}(R_{st})$, where R_{st} is the total rate received by the receiver $t \in T$.

Proof: To prove the theorem, we first notice that for a given position of r there are at least two paths, namely certain paths of the type $\{(s, T_1), (r, T_2)\}$ (where, $T_1 \cup T_2 = T$) and the path $\{(s, T)\}$, that span the whole receiver set T. Any other path, that only serves the proper subsets of T does not count in contribution to the multicast rate R_{sT}.

Among all the paths from s to T, that go through r (i.e. of the type $\{(s, T_1), (r, T_2)\}$, where, $T_1 \cup T_2 = T$), only the path with highest min-cut contributes to the multicast flow R_{sT}. Let us denote this path as $\{(s, T_1'), (r, T_2')\}$, where $T_1' \cup T_2' = T$. Once the min-cut of the path $\{(s, T_1'), (r, T_2')\}$ is reached, considering it has the highest min-cut among the paths that span all T through r, no flow can be sent over any other path of the type $\{(s, T_1), (r, T_2)\}$. This is true because when the min-cut of the path $\{(s, T_1'), (r, T_2')\}$ is achieved (for a fixed position of r) either P_s is consumed or P_r is consumed. If P_s is consumed, no more multicast flow can be pushed, and if P_r is consumed before P_s then rest of the flow have to be pushed over the path $\{(s, T)\}$ (not involving r). On the other hand for a given position of r, if the min-cut of the path $\{(s, T_1'), (r, T_2')\}$ is strictly less than of $\{(s, T)\}$, then all the multicast flow must be sent over the path $\{(s, T)\}$.

This implies that for any given position of r, all the multicast flow must be sent over at most these two paths. Now, we can write down the min-cut of the multicast flow as

$$R_{sT} = f_{sT}(P_s^+, D_{sT}^-) + \min(f_{sT_1'}(P_s^+, D_{sT_1'}^-), f_{rT_2'}(P_r^+, D_{rT_2'}^-)).$$

Now, consider the region $C_\cap = C_s \cap C_{t_n}$, which is the intersection of the two circles centered at s and r with radii $\pi_s = \min(D_{st_n}, \frac{2D_{st_n}}{1 + \sqrt[\alpha]{\gamma}})$ and $\pi_r = \min(D_{st_n}, \frac{2\sqrt[\alpha]{\gamma}D_{st_n}}{1 + \sqrt[\alpha]{\gamma}})$, respectively. The radii π_s and π_r takes the bias due to α and γ into account. Simply stated, if $\gamma > 1$ then $\pi_s < \pi_r$, and if $\gamma < 1$ then $\pi_s > \pi_r$, and finally if $\gamma = 1$ then the two circles have equal radii. It is clear that if $\gamma \in (0, \infty)$ then the area of $C_\cap > 0$.

If the relay is positioned outside $C_\cap$, then

$$\max\left(\frac{2D_{sr}}{1 + \sqrt[\alpha]{\gamma}}, \frac{2\sqrt[\alpha]{\gamma}D_{rt_n}}{1 + \sqrt[\alpha]{\gamma}}\right) > D_{st_n},$$

implying,

$$f_{sT}(P_s^+, D_{sT}^-) > \min\left(f_{sT_1}(P_s^+, D_{sT_1}^-), f_{rT_2}(P_r^+, D_{rT_2}^-)\right).$$

This means that the min-cut of the path $\{(s, T)\}$ is strictly larger than the min-cut of the path $\{(s, T_1'), (r, T_2')\}$, implying that all the multicast flow must be sent over the path $\{(s, T)\}$, rendering relay useless. Hence, the optimal relay position must lie inside $C_\cap$.
Fig. 4. $T = \{t_1, t_2, t_3\}$ case illustrating step 3 of the algorithm ORP. (a): The relay r is placed at the point $l_0 = L_{\mathcal{N}\backslash r}(\mathcal{C})$ with $\mathbf{N_0} = \{t_1\}$. $D_{st_1} < D_{rt_1}$ and $D_{st_1} > D_{sr}$ (b): Reforming the hyperarc C_s and r is placed at $l_2 = L_{\mathbf{N_2}}(\mathcal{C})$ (where, $\mathbf{N_2} = \{t_2, t_3\}$), thus reducing $\max(\pi_s, \pi_r)$.

From here, it is straightforward to see that if the optimal relay position lies in the interior of $C_{\cap}$, rendering the min-cut of the path $\{(s, T_1'), (r, T_2')\}$ strictly larger than the path $\{(s, T)\}$; then flow over the path $\{(s, T_1'), (r, T_2')\}$ must be maximized first and then the flow over the path $\{(s, T)\}$, in order to maximize R_{sT}. This proves the first point of the theorem.

Similarly, if the optimal relay position lies on the boundary of the region $C_{\cap}$, then

$$f_{sT}(P_s^+, D_{sT}^-) = \min\left(f_{sT_1}(P_s^+, D_{sT_1}^-), f_{rT_2}(P_r^+, D_{rT_2}^-)\right),$$

rendering the min-cut of the two paths equal. In this case, all the flow can be sent over the path $\{(s, T)\}$, $\{(s, T_1), (r, T_2)\}$ by arbitrarily sharing the flow between them. This case is reminiscent to the case when relay is placed outside $C_{\cap}$, but for completeness we count it as an individual case, and moreover in this case relay is not really useless. This proves the second part and hence completes the proof of Theorem 3. ∎

APPENDIX C
PROOF OF OPTIMALITY OF ALGORITHM ORP

Assume a given $\mathcal{G}(\mathcal{N}, \mathcal{A})$ and $\gamma = 1$. The argument of the output of Program (A) is a point l and the objective function value of the output of Program (A) is distance denoted by D_Q (where, Q is the set of points of input to Program (A)).

Proof: In order to prove that Algorithm ORP always outputs optimal relay position, we need to prove that the three steps suffice to tackle all the topologies of a given $\mathcal{G}(\mathcal{N}, \mathcal{A})$ (namely, the distribution of the points $\mathcal{N}\backslash r$ on the 2-D Euclidean plane).

First, we divide all the topologies in two classes. In the first, the point l is the optimal relay position (which corresponds to the step 1 of the algorithm ORP), and the second class in which the point l is not the optimal relay position (this class corresponds to the Step 2 and 3 of the algorithm ORP). The only complicated case (if at all) is the Step 3, so we will go about proving the optimality of the output of algorithm ORP backwards in the order Step 3, then Step 2 and finally Step 1.

For a given $\mathcal{G}(\mathcal{N}, \mathcal{A})$, compute the point l_0 defined as,

$$l_0 = \arg\min_{j \in \mathcal{N}\backslash r} \left(\max(D_{ij})\right)$$

$$\text{subject to:} \quad i \in \mathcal{C}. \tag{9}$$

Form the hyperarcs C_s of radius D_{sl_0} and C_r of radius $D_{\mathcal{N}\backslash r}$. Denote the value of the quantity $\max(\pi_s, \pi_r) = \zeta$. Construct the set $\mathbf{N_0} = \{t \in T | D_{st} < D_{l_0 t} \,\&\, D_{l_0 t} > D_{sl_0}\} = \{t_1', .., t_m'\}$, in the increasing order of distance from s. Considering the set $\mathbf{N_0}$ is not empty, take the farthest node t_m' from s. If $D_{st_m'} > D_{sl_0}$, then it is clear that t_m' should be approached directly from s and not through r, because $D_{l_0 t_m'} > D_{sl_0}$ and $\max(D_{sl_0}, D_{l_0 t_m'}) < D_{st_m'}$. Reforming a source hyperarc C_s of radius $D_{st_m'}$ (where, $D_{st_m'} < \zeta$), the set $\mathbf{N_2} = \{t \in T | D_{st} > D_{st_m'}\}$ can be constructed consisting of all the nodes not lying in the area C_s. Now, computing the point $l_2 = L_{\mathbf{N_2}}(\mathcal{C})$ we could form the second hyperarc C_r of radius $D_{\mathbf{N_2}}$. Note that $D_{\mathbf{N_2}} < \zeta$ because the set $\mathbf{N_2}$ consists only the nodes in T that are not in the hyperarc C_s and $D_{st_m'} > D_{sl_0}$. Denoting $\max(\pi_s, \pi_r) = \zeta''$ (with respect to point l_2), we now have $\zeta'' < \zeta$. We cannot further reduce $\max(\pi_s, \pi_r)$ as t_m' is the farthest node in $\mathbf{N_0}$ that satisfies this property. Thus l_2 is the optimal relay position. Figure 4 illustrates this step for $|T| = 3$ case.

On the other hand, if the node t_m' satisfies the relation $D_{st_m'} \leq D_{sl_0}$, it is clear that all the nodes in $\mathbf{N_0}$ could be dropped from the computation of the point l and the set $\mathbf{N_1} = \{\mathcal{N}\backslash(r, \mathbf{N_0})\}$ can be constructed. Therefore, computing the point $l_1 = L_{\mathbf{N_1}}(\mathcal{C})$, gives the optimal relay position as there is no node in the set $\mathbf{N_1}$ that influences the computation of the optimal relay position unnecessarily. Again, reforming the hyperarcs and denoting $\max(\pi_s, \pi_r) = \zeta'$ (with respect to point l_1), we can easily see that $\zeta' < \zeta$. The value of $\max(\pi_s, \pi_r)$ cannot be reduced further because there is no receiver node in T that is in the set $\mathbf{N_0}$ that cannot be encompassed by the area of union of the two hyperarcs C_s and C_r (constructed with respect to the point l_1). Thus, in this case l_1 is the optimal relay position.

Finally, if the set $\mathbf{N_0} = \{\emptyset\}$, the point l_0 is clearly the optimal relay position as there is no receiver node in the system that is affecting the computation of the relay position and can be dropped off simultaneously. Hence, the three steps of algorithm ORP always outputs the optimal relay position for a given $\mathcal{G}(\mathcal{N}, \mathcal{A})$. ∎

The case when $\gamma \neq 1$ is a straightforward generalization and line of argument for the proof of optimality remains the same for the case of $\gamma = 1$.
