### Appendix D

### Digital Console Scheduler

In order to compare the performance of scheduling strategies to DMCs, the author has developed a scheduler specifically targetted at the DMC problem domain. This application is coded in the strongly-typed compiled Prolog implementation available from Borland.

### D.1 Overview

This appendix lists the definition and source files required to re-build DCS — the Digital Console Scheduler. Table D-1, below, illustrates the various options supported by the DCS scheduling engine for static-level (CPM), dynamic-level (DYN) and A* algorithms (AST).

Algorithm ^a	IPC Mechanism	Static Labelling	Dynamic Labelling	Heuristic Underestimate
СРМ	FWE (d) NSL NML	HLN HLE (d) LCN LCE RND		
DYN	FWE (d) NSL NML	HLN HLE (d) LCN LCE RND	NON PRO TSK (d) ALL	
AST	FWE (d) NSL NML			NON MPC MIA MRC ALL (d)

Table D-1: Options supported by the DCS scheduling engine.

a. (d) indicates that this is the default value for the given option.

#### **ABSTRACT**

In this paper we address the problems associated with the implementation of large-scale digital audio signal processing systems. For example, the audio mixing console requires the realisation of an architecture comprising in the order of 100 digital signal processors (DSPs). A hybrid multiprocessor, offering efficient computation with minimal communication overhead, is described and its suitability to the real-time environment discussed. Task allocation has a substantial impact on the efficient utilisation of such a DSP-engine. We are interested in algorithms that can produce optimal schedules in reasonable time and fast sub-optimal algorithms. An integrated software environment allows graphical input of DSP taskforces and hardware resource schematics, and the assessment of preferred scheduling strategies. We summarise the theoretical background, discuss the results obtained, and assess the implications of this research to the real-time audio processing environment.

#### 1 Introduction

A number of multiprocessor architectures have been proposed in response to an ever-growing need for speeding up DSP-intensive applications. With the widespread availability of programmable DSP devices, a single scalable multiprocessor exhibits the ability to provide good performance for a range of real-time digital audio applications. One such application is the audio mixing console which, when implemented digitally, demands a computation engine rated in thousands of MIPS. With current technology, a topology comprising in the order of a 100 devices must be realised.

In order to efficiently develop such a system and allow unused processing power to be reallocated by the user in the operating environment, task scheduling strategies are necessary to efficiently distribute the set of processing algorithms required — termed the taskforce — across the architecture. A good scheduling algorithm will maximise and balance the utilisation of processing resources, and minimise the communication between processors. In addition any strategy must observe all precedence relations, must be non-preemptive, and must not allow distributed execution of any task.

Sections 1 and 2 describe the preferred approaches to this problem, and their relative performance is discussed in Section 3. In Section 4 the architecture of the hybrid multiprocessor is detailed, with Sections 5 and 6 reviewing the data transfer techniques used. Finally, the current state of this research project and proposed further work is summarised.

#### 2 Dynamic Programming

Dynamic Programming is employed in problems where finding a solution can be reduced to a sequence of interrelated decisions forming a path in a state-space. Scheduling taskforces on a multiprocessor architecture can be cast in these terms, as shown in Fig. 1. Each alternative decision from a node corresponds to scheduling a different task, or idle period, on a processor. At each step the non-intuitive option of scheduling an idle period, lasting until the next processor has completed its currently assigned task, must be allowed to guarantee optimality. Here the search is termed informed, as a set of alternative candidate nodes at each decision is kept, corresponding to the whole growing edge of the search tree.

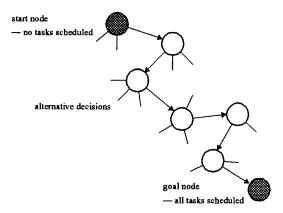

Fig. 1: Task scheduling in terms of state-space searching.

The A* algorithm employs the best-first principle at each decision point, combined with problem-specific heuristics to draw the search process quickly towards a goal node, thereby avoiding aimless paths. Our implementation uses the minimum processor cost underestimate [1]. This corresponds to the optimistic estimate of the finishing time of the partial schedule, completed with all currently unassigned tasks. It is computed under the assumption that both the precedence relations, and the non-preemption and distributed execution constraints are relaxed.

#### 3 Critical Path Method

In list scheduling strategies the tasks are first ordered according to some external priority scheme, and then scheduled according to this regime. One technique used to form such a priority list is the Critical Path Method, originally investigated by Hu [2]. 2

Although only optimal for taskforces consisting of equal duration tasks and exhibiting in-tree precedence constraints, the concept of Hu-level is widely applicable. A task  $t_i$  is given the label  $x_i$ , where  $x_i$  is the length of the longest path from  $t_i$  to the root task, which is given the label '0'. Tasks that are one unit removed from the root task are given the label '1', and so on as Fig. 2. The priority list is then ordered by non-increasing Hu-level, and the taskforce scheduled according to this regime.

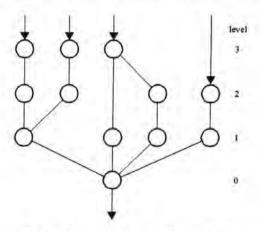

Fig. 2: Hu-level labelling of a console taskforce.

Typically several root tasks are present, corresponding to a console taskforce with multiple outputs. In these cases, an artificial or "dummy" root task can be added to the taskforce. Tasks with execution times greater than one are represented by an indivisible chain of unit-weight tasks whose sum equals the weight of the original task. It can be shown that the level of the chain-task furthest from the root is the same as the level of the multi-unit task.

#### 4 Scheduling Results

As a simple example, the 4:1 console taskforce of Fig. 3 requires 136 cycles of sequential processing, has an ideal schedule length of 62 cycles, and (ignoring bus delays) can be allocated optimally onto 4 processors as Fig. 4 and Table 1. Investigations with full channel strip processing enabled show that the A* strategy results in considerable scheduling overhead when compared to the CPM approach. Furthermore, such large problem instances can result in extremely large search trees as the A* policy may degenerate towards an exhaustive search [3].

The level of performance achieved by the Hu-level Critical Path algorithm is typically well inside the theoretical performance bound of a factor of 2 from optimal. Results indicate that this approach produces such schedules in relatively short execution times. This can be attributed to the fact that in most cases console taskforces are configured as trees, or a forest of trees. In particular, the reader's attention is drawn to the allocation of a 16:8 console onto a eight processor architecture. Dynamics processing functionality was removed from four of the sixteen channels, allowing this 16:8 taskforce to be squeezed within the constraints imposed by the professional sampling rate [4].

In such large taskforces replacing the 2-input mix tasks with 8-input primitives, requiring 10 instruction cycles, can greatly

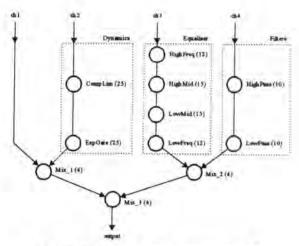

Fig. 3: Example 4-input: 1-output console taskforce.

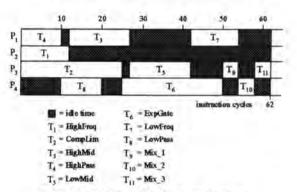

Fig. 4: Optimal allocation of example taskforce

Algorithm	Sequen- tial Schod- ale	Parallel Schedule	Algo- rithm Runtime	Speed-up	Processor Efficiencies
Α*	136	62	4:73	219.4%	59,7% 19,4% 77,4% 62,9%
Harleyd	136	62	1:93	219,4%	39.7% 19.4% 77.4% 62.9%

Table 1: Performance assessments for above schedule.

reduce the scheduling overhead. This is due to two reasons: firstly, the number of tasks is considerably reduced, thereby significantly reducing the run-time of the A* and, to a lesser degree, CPM algorithm; secondly, the range of task size ratio is reduced by a factor of 2.6, so reducing the number of A* search-space nodes. However, this loss of relatively small tasks, and the tight packing previously available, means that high processor efficiencies are not as readily achieved.

#### 5 Hybrid Hardware Module

The Inmos transputer is capable of parallel communication and computation, providing an ideal building block for the construction of scalable concurrent systems. However, the transputer is not effective at executing the data flow algorithms

required in real-time multi-channel digital audio applications [5]. In contrast, DSPs such as the Motorola DSP56001 are specifically designed to efficiently implement such algorithms [6]. Due to inherent communication overheads, scalable architectures are not easily implemented with these devices alone. A hybrid multiprocessor assembled from nodes consisting of several Motorola DSP56001s hosted by a single transputer offers efficient computation with minimal communication overhead.

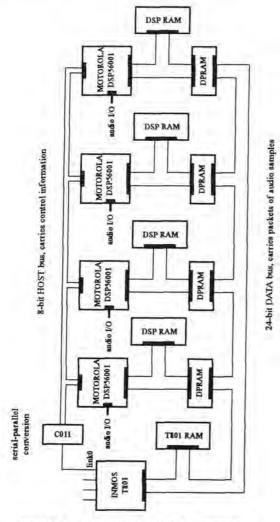

Fig. 5: Schematic diagram of hybrid processing node.

Inter-node communication is carried out using the transputer serial links, with one link reserved for broadcasting low bandwidth control data to the DSPs via a IMSC011 link adapter. Assuming a sampling frequency of 48kHz and that block moves are used for data transfer, then each transputer is capable of supporting up to 34 audio paths in this trivalent configuration, Fig. 6. Intra-node communication is achieved through the non-multiplexed external memory interface (EMI) of the IMST801 part. Each DSP possess an exclusive block of dual-ported RAM (DPR): the other port of the DPR is mapped into the transputer's EMI via appropriate decode logic.

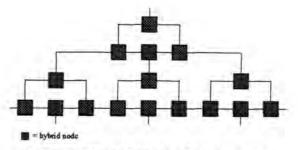

Fig. 6: Temary tree configuration with hanging pipeline.

#### 6 Intra-Node Communication

3

The transputer controls data transfer within the processing node. Data vectors pertaining to a particular DSP are externally placed by the transputer into the appropriate DPR. An arbitrary, and time varying, soft configuration of the processors may be defined in software and mapped onto the hard configuration imposed by the hardware. Thus complex configurations, such as a hypercube or any random topology, may be realised with this system. Data integrity and synchronisation is assured by the use of semaphores [7]. The DPR is divided into domains which contain both input and output vectors, and an associated Boolean semaphore as Fig. 7. A processor will only effect a data transfer if the semaphore is in the correct state.

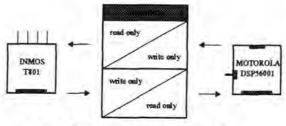

Fig. 7: Single domain DPR partitioning scheme.

Two of the major problems that arise in multi-processor systems are bus bottlenecking and spin-locking [8]. Bus bottlenecking is considerably reduced in this architecture as each DSPs bus is processor exclusive. Spin-locking occurs when a processor repeatedly tests and fails a semaphore, resulting in increased processor idle time. Although appropriate scheduling strategies can minimise spin-locking, a proposed extension to the single domain scheme promises to reduce the effects further. Here the DPR is partitioned into two domains, each of which is accessed in a cyclic manner by both the transputer and the DSPs.

#### 7 Semaphore Management

It is important to reduce the overhead associated with accessing and testing semaphores as much as possible. The DSP sees the semaphore as occupying a single word in external memory space and it is a simple matter to read a semaphore and to act upon its state. The approach taken with the transputer is somewhat different, however. Time critical sections of code are written in transputer assembly for optimum performance and embedded in an Occam2 harness, as Fig. 8. The transputer uses a byte-oriented addressing scheme, beginning at the most negative address and working upwards. Instructions may be

stripped, and execution time minimised, by treating the semaphore as boolean values occupying contiguous byte locations in external memory space. This requires that two address decode schemes be implemented for the transputer.

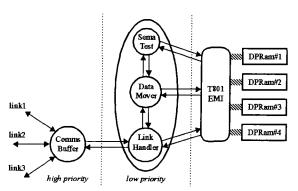

Fig. 8: Occam2 harness for dependent data paths.

The first, mapping contiguous blocks of DPR into contiguous words of transputer memory, is used for data areas. The second, mapping non-contiguous bytes contained in different DPR domains into contiguous bytes of transputer memory, for the semaphores. Due to the prefixing nature of transputer code, the semaphores may only occupy the sixteen locations beginning at byte location 0 to ensure zero prefixing. A restriction with this approach is that a maximum of sixteen semaphores may be used for maximum performance, and that additional address decoding needs to be utilised. It follows that a maximum of eight DSPs, using the twin domain approach, may be supported by a single transputer at full semaphore access speed.

#### 8 Conclusions

These encouraging results indicate that the sub-optimal strategy, based on the Hu-level Critical Path Method, consistently produces good-quality schedules with minimum overhead. Correspondingly this approach has direct application for the reallocation of unused processing resources by the engineer in the operating environment. In contrast, the optimal A* Dynamic Programming implementation may be utilised in the development cycle when assessing alternative multiprocessor designs, or in the production of pre-defined allocations yielding maximum system performance for a given architecture. Further results extend this concept by sacrificing channel processing to provide reverberation and other time-domain effects processing on a given hardware resource.

A target hybrid multiprocessor architecture has been described. The multiprocessor combines the efficiency of communication exhibited by the Inmos IMST801 transputer, and the computational power of the Motorola DSP56001. This novel architecture is fully scalable and capable of supporting additional processing elements whilst incurring negligible communications overhead. Further research will investigate the application of these strategies to architectures configured from the revolutionary Texas Instruments TMS320C40 part, and techniques for embedding resource re-allocation methods on such platforms [9].

## ARCHITECTURAL ISSUES FOR PARALLEL DSP AUDIO SYSTEMS

#### KEN N LINTON

University of Durham South Road, Durham, DH1 3LE, UK

The design and implementation of audio systems through analogue technology is a well understood art. With the success of both professional and consumer digital formats, the audio industry is moving quickly towards an entirely digital signal path. In this paper, the principle architectural issues of implementing digital audio systems with general purpose digital signal processors are discussed. Particular attention is given to the design and performance aspects appropriate to professional audio products.

#### INTRODUCTION

Digital signal processing (DSP) devices are inherently programmable. Instead of using different types of hardware to accomplish different processing functions, DSPs just perform different sets of summations, delays and multiplies grouped together as processing algorithms. With a DSP-based audio system, the limiting factor is the total amount of processing power available rather than the quantity and type of processing hardware provided. The modularity, flexibility, and reliability of DSP makes it attractive for all manner of applications, including those traditionally implemented by analogue technology.

The advent of relatively low cost DSPs has made multi-DSP processing an economic reality in today's digital audio environment. As the audio community becomes accustomed to buying more technology with less money, design engineers face increasingly difficult design problems. In most cases, this requires that the designer opt for a software-based multiprocessor (M-P) system built from freely available off-the-shelf components from a range of manufacturers. This strategy allows a quicker design cycle and a flexible approach to the design of professional audio products.

#### 1 DESIGN CONSTRAINTS

In the design of parallel DSP audio systems, the first three constraints are those inherent in conventional uni-processor designs: processor speed, memory resource and input/output (I/O)

bandwidth. Since most applications require more processing power than is provided by a single DSP device, a multi-DSP architecture must be created. Memory capacity is not usually of concern since DSPs can address much more memory than can be accessed in a sample period. As most DSPs offer independent I/O, supporting ADC/DACs and AES-EBU/SPDIF interfaces, multi-DSP M-Ps offer excellent I/O bandwidth which scales with the number of processors.

#### 1.1 Initial Decisions

The two most fundamental decisions which must be taken very early on in the design process are, firstly, how powerful each DSP should be, and, secondly, how many processors should be supported. For a system of required performance P, and an ideal architecture containing nprocessors, each with an individual processing capability of p, the hyperbolic relationship between n and p, as Figure 1, defines a span of possible architectures satisfying [1]. Therefore, one could use a small number of very powerful (and expensive) processors, or a large number of relatively slow (and cheap) processors. The use of large numbers of DSPs is made attractive by the development of relatively cheap DSP devices suitable for professional audio applications.

The cost advantage of using low-speed technology is balanced by the degradation in efficiency that inevitably occurs as the number of processors in a system increases. Moreover, the complexity of programming a M-P with many DSPs far exceeds the complexity of programming an architecture

consisting of just a few processors. Consequently, although economics might enhance the attractiveness of a system with many low-speed DSPs, the advantages disappear if efficiency is not held high. When the parallelism cannot be tapped effectively, it simply adds to system cost and complexity. This demands that multi-DSP systems are assembled in such a way that the performance of each DSP is effectively harnessed.

#### 1.2 Implementing Parallelism

There are two fundamental ways in which DSPs can be composed to create parallel architectures. Perhaps the simplest way to introduce parallelism is to replicate a component n times, as shown in Figure 2a. To exploit this form of parallelism, the digital audio streams processed must be separated in space into individual channels. For this reason this form of parallelism is known as spatial parallelism. A typical example from everyday life is the familiar row of checkout desks in a supermarket.

The other fundamental way of introducing parallelism is to partition the audio processing into a number of steps, as shown in Figure 2b, which when applied sequentially to each sample perform the original processing desired. In other words, the task is partitioned in time, with each step of the application being applied to a separate sample. For this reason this form of parallelism is known as temporal parallelism. The application of temporal parallelism in digital audio produces pipelined structures.

#### 1.3 Processor Pipelining

Pipelining is an implementation technique whereby multiple tasks are simultaneously overlapped in time [2]. In fact, pipelining is the key implementation technique used to make fast DSP devices. In a processor pipeline, as in an assembly line, the work required to complete a processing application is broken into smaller pieces or stages. The stages are then connected one to the next to form a pipe, as Figure 3a. Samples enter at one end, are processed through the stages, and exit at the other end, as detailed in Figure 3b.

In digital audio systems response is perceived as intimate if the system operates with a latency, or accumulated processing delay, of less than one millisecond. To meet the necessary frequency response requirements, each DSP in the audio system must take a new set of input samples every 20.8µs, given the professional sampling rate of 48kHz. This corresponds to a maximum processor

pipeline of 48 stages between any input and any output.

#### 1.4 Additional Constraints

Three additional design constraints, which are not usually associated with uni-processor systems, stem from the need for parallel architectures. Firstly, with multiple DSPs it becomes necessary to exchange audio samples and control parameters so some type of interprocessor communications (IPC) network is required. Novel techniques are required to tie together conventional DSPs in large digital audio systems. Secondly, because the processors must work together they are required to synchronize to coordinate such activities as access cost-effective shared data. Finally, programmable DSP systems necessitate M-P architectures which incorporate sufficient flexibility in their design to support several different audio processing applications.

#### 2 M-P CONFIGURATIONS

Most professional audio applications require a processing rate much higher than can be provided by any single DSP device. For example, a 2-channel third-octave graphic equaliser operating at the professional sample rate (48kHz) requires about three 10.25 MIPS DSPs. A zero chip interface may be implemented by connecting the serial links of two or more DSPs. Unfortunately, the relative slowness of this technique restricts this approach to a limited number of applications. For faster data transfer, the parallel data bus must be used to connect multiple DSPs in tightly coupled M-P architectures.

Conceptually, the simplest way to interconnect multiple DSPs is to provide full connectivity between processors. However, due to the sheer hardware costs involved, designers must forgo this luxury. Shared-memory architectures are probably the most common form of M-P, since they are the natural extension of conventional uni-processor systems. A radically different communication mechanism is message-passing. In message-passing architectures DSPs communicate by sending and receiving messages via dedicated communication channels [1].

#### 2.1 Shared-Memory Design

The simplest way to construct an audio M-P is to connect the DSPs on a shared bus, providing shared common memory to all processors, as shown in Figure 4. In order to isolate the processors from each other so that they can

simultaneously access their local memories, bidirectional bus transceivers are required. The bus is then active only when data is transferred between DSPs, allowing the bus to remain free during processing which does not demand IPC. If the local DSP RAMs were not present, there would be severe contention on the bus, causing arbitration delays to reduce performance.

Unfortunately, in the case of processors such as the DSP56001 there is no provision to force the external memory port to quickly tri-state (isolate) in a deterministic manner. Since the address bus is always driven (except by granting the bus), one DSP's local RAM cannot be directly accessed by another DSP while the first accesses its internal RAM. Additional bus transceivers would be required to allow one DSP to quickly access another DSP's local RAM without shorting its main bus, increasing board real-estate and power consumption [3].

#### 2.2 Arbitration Schemes

Arbitration schemes are necessary to resolve the situation when multiple processors need to access the same piece of data at the same time. Most DSP devices have provision for asynchronous sharing of their external memory port, with the use of busrequest (BR) and bus-grant (BG) signals. M-P architectures which use BR and BG signals to directly share a common bus typically require a hardwired master-slave relationship between the interconnected DSPs. This situation is certainly suitable for many product designs. However, software control is to be preferred, as this provides an equal relationship between the processors.

A second disadvantage of this technique is that the process of granting the bus is too time consuming for most real-time audio applications, as there is little time in one 48kHz sample period for arbitration of the bus. In synchronous designs, the most serious problem with this technique is the indeterminate timing of the bus-granting process. For example, the BR to BG delay for a 20.5 MHz (10.25 MIPS) DSP56001 is specified to take between 73 to 240ns for zero-wait states [4]. Since this delay may be more than one instruction cycle, synchronous DSPs cannot be kept in step when sharing a common bus via the BR/BG arbitration technique.

#### 2.3 Summary

An *n*-processor system requires a bus whose bandwidth is of the order of *n*-times that of a uniprocessor bus. Consequently, the major

shortcoming of shared-memory M-Ps is self-evident: the data transfer capacity between processors is determined by the bandwidth of the bus and is therefore constant. As the number of DSPs grows, the shared bus between DSP modules becomes a serious bottle-neck to IPC. This factor limits the number of processors that can be usefully incorporated into such a system, and hence fixes an upper limit on extensibility.

Typically, bus-oriented systems can support 10 DSPs efficiently and possibly stretch to 20 or 30. Beyond this range, bus contention leads to degraded performance to the extent that such systems are unlikely to support large audio systems unless a technological breakthrough provides a very high bandwidth bus at relatively low cost. A possibility for the future is to implement large digital audio systems with optic fibre links. However, the low cost and simplicity of bus-structured M-Ps has proved to be advantageous for a number of small-scale parallel DSP systems, yielding high performance/cost ratios without any pretensions of scalability.

#### 3 SYNCHRONIZATION MECHANISMS

Multiple DSPs can be synchronized at the instruction cycle level through the use of a common clock. However, clock skew can be a considerable problem especially at high clock rates in large M-P architectures. Alternatively, synchronization mechanisms are used to ensure that shared data is always valid in asynchronous designs. This is one of the most difficult and errorprone types of DSP programming that exists, because it involves the understanding of the potential simultaneous actions of multiple DSPs.

#### 3.1 Semaphores

The dictionary defines semaphore as "signalling by flags". Semaphore flags are used like locks to shared resources, such as hard disk buffers and interprocessor message queues, and so permit only one DSP at a time to gain access. Two different operations are performed on the semaphore: the request operation which attempts to gain access and the release operation which signals the termination of the access. These operations are used to guarantee mutual exclusion, meaning that only one processor is able to access shared data at any given time, locking out all other processors. This occurs from the time a request is granted until the time that the semaphore is released.

At one extreme a whole shared memory can be controlled by a single semaphore, whereas at the

other extreme every data item could be individually locked. The former precludes any parallel operations on the shared data, of course, while in the latter case the overhead of performing the locking operations would be prohibitive. Typically, this overhead is distributed across several data values, with one semaphore locking the corresponding data structure.

#### 3.2 Test-and-Set

One of the most basic synchronizing techniques is the *test-and-set* primitive [5]. Firstly, the DSP desiring to obtain exclusive access to the shared data, reads the corresponding semaphore flag. It then tests this prior semaphore value to determine if it was successful (i.e. a  $\theta$ ) and, finally, writes a I to the semaphore location. As a result, the test-and-set operation forces the semaphore flag to be set to I, whether or not it was set beforehand. If the semaphore was not already set, then this DSP can access the shared resource. All other DSPs are blocked because the semaphore is now set. As a result, only one DSP at a time has permission via the semaphore.

To ensure that it can be used successfully, the testand-set operation must be uninterruptible. That is, once it is initiated and the read access is completed, no other access can be made to the semaphore until the semaphore is rewritten during the second step of the test-and-set. If an intervening access were permitted, synchronization could fail. This is because one DSP may test the semaphore and, before it can set it, another DSP might test it. In this case, both processors believe they have the semaphore. Most DSPs support an indivisible READ/MODIFY/WRITE instruction. which ensures that the address bus remains active throughout the entire operation.

If several DSPs execute a test-and-set on a semaphore concurrently, the requests will be serialised and executed one by one due to the indivisible nature of the READ/MODIFY/WRITE operation. Given serial execution, no more than one DSP from a set of concurrent requesters can observe a  $\theta$  semaphore value and thereby gain access to the shared resource. When it has finished with the resource the processor must release the semaphore. To achieve this, the owner DSP does no more than clear the flag by writing a  $\theta$  into the semaphore location. Note, it is not necessary to perform a READ/MODIFY/WRITE instruction to unlock the semaphore.

#### 3.3 Spin-Lock

The test-and-set is only half of the synchronisation mechanism: the other is the action taken depending on whether the semaphore has been granted or not. A question which immediately arises is what to do with a DSP which is waiting to access a shared resource. One mechanism which gives fast entry to a shared resource is the *spin-lock*. Thus, if the lock has been granted, the processor continues on to use the shared resource. If not, then a spin-lock occurs, and the DSP must *spin* backwards and re-execute the test-and-set, repeating the process until the lock is granted, as Figure 5. There are two major drawbacks to using spin-locks [6].

Firstly, a DSP which is polling a semaphore is not doing any useful work. Secondly, it is consuming memory cycles in the bank containing the semaphore value and, if several processors are waiting at the same semaphore, memory bandwidth is rapidly consumed. This contention causes additional cycles of delay while a DSP is attempting to release a lock, which magnifies the effect of the bottle-neck at the semaphore. As a result, spin-locks waste valuable MIPS by dedicating potentially useful DSP instruction cycles to the effort of repeatedly testing semaphores.

#### 4 PERFORMANCE ISSUES

Characterising the performance of DSP engines is an important exercise if designs are to be compared, particularly with respect to scalability. A realistic assessment must take into account both the architecture and the applications for which it is intended. Characterising a particular audio application includes considering processing, memory, I/O, and IPC resources required. Similarly, proposed architectures should be considered in terms of the hardware resources available to the range of applications being considered [7].

#### 4.1 MIPS

A number of popular measures have been adopted in the quest for a standard measure of M-P performance. Small, key pieces extracted from real applications, such as biquad audio algorithms, can provide useful processing kernels for performance evaluation. One alternative to time is the parameter MIPS million instructions per For second. example, Table 1 details hypothetical processing budget for a comprehensive digital mixing console [8]. Since

MIPS is the rate of operations per unit time, faster architectures have a higher MIPS rating.

Although MIPS is easy to understand, the problems with using MIPS as a measure for comparison are two-fold. Firstly, MIPS is dependent on instruction set, making it difficult to compare M-P systems based on DSPs with different instruction sets. Secondly, MIPS can vary widely between different processing applications on the same audio system. As a result, the only consistent and reliable measure of the performance of M-P systems for a particular audio product is the actual execution time of the required processing algorithms.

#### 4.2 Efficiency

In M-P systems efficiency is defined in terms of the ratio of time spent executing useful DSP routines compared to that consumed by synchronisation and other overheads. When a M-P is operating at peak performance, all processors are engaged in useful work. Moreover, no processor is executing an instruction that would not be executed if the same application was executing on a single DSP. In this state, all n processors are contributing to effective performance, and the MIPS is increased by a factor of n — linear speedup. Unfortunately, this is rarely achieved due to the overheads incurred as a direct result of the use of parallelism.

In one case, designers started out with the knowledge that in previous M-Ps each additional DSP contributed only 0.8 times the actual performance of each processor already in the system [1]. Hence, points on the speed-up curve for such a system would typically be 1, 1.8, 2.5, ..., as shown in the 'actual' curve of Figure 6. Such diminishing returns make each successive processor less and less cost effective. Efficiency is clearly a major concern in the design of digital audio products based on M-P architectures: a design that uses 2n DSPs inefficiently cannot compete on a cost basis with a design that uses n identical processors twice as efficiently.

#### 4.3 Load Balancing

There are various options when executing an audio processing application consisting of *m* processing algorithms on an *n* processor multi-DSP system. If all the work is allocated to one DSP and the remaining processors ignored, the IPC overhead is minimised but the system will perform no better than a single DSP. Conversely, if the work is split between the *n* processors, considerable overhead is

incurred. Here, performance could be up to *n*-times that of a single DSP device, as shown in the ideal curve of Figure 6. Experiments with M-P architectures, however, have demonstrated behaviour in operational systems is more like the 'actual' curve.

In practice, the speed-up increases significantly only for the first few additional processors. At some point the speed-up may actually begin to decrease with each additional DSP this can be as few as 10 depending on the architecture. This decrease in expected speed-up is due to excessive IPC and synchronization overheads, incurred when processing algorithms resident on different DSPs must communicate with each other. The resultant degradation in performance for incremental increase in hardware resources is known as the saturation effect. Consequently, the efficiency of a system depends critically on how the workload is balanced between the processors.

#### 5 FURTHER CONSIDERATIONS

There are many ways to express the performance of a DSP system. For example, the metric of performance commonly assumed is MIPS, but cost, reliability and extensibility are just as important.

#### **5.1** Cost

An understanding of cost is essential for designers to be able to make intelligent decisions about whether or not a particular processor, I/O or interconnection component should be incorporated in design. The cost of DSP components is changing so fast that good designers are basing design decisions not on today's costs, but on projected costs at the time the product is shipped. Although they are far from representing what the customer must pay, cost of components confine a designer's desires. In digital audio systems, component costs typically make up 15-33% of the final list price.

Many engineers are surprised to find that most companies spend only 8-15% of their income on R&D. This information suggests that a company uniformly applies fixed-overhead percentages to turn cost into price. Another point of view is that R&D should be considered an investment, and so an investment of 8% to 15% of income means that every pound spent on R&D must generate £7 to £13 in sales. This alternative point of view then suggests different gross margins for each product depending on the number sold and the size of the investment [2].

Large expensive DSP systems generally cost more to develop — a product costing 10 times as much to manufacture may cost many times as much to develop. Since large audio systems generally do not sell as well as small ones, the gross margin must be greater on big machines for the company to maintain a profitable return on R&D investment. This places large DSP systems in double jeopardy, since there are fewer sold and they require larger R&D costs.

Few customers can afford the initial cost of a large multi-DSP system. However, many can afford to grow a large system in increments as they discover the need for more processing power and as their budgets permit. There is also a great risk in designing a multi-DSP architecture welded to a particular audio processing application. By incorporating sufficient flexibility into a design to cover several applications, the R&D investment can be amortised over a range of end-products constructed from affordable DSP modules.

#### 5.2 Reliability

The reliability of M-P systems is often considered to be an issue which is of secondary importance to the task of designing for maximum throughput. It is a commonly held belief that M-P architectures are inherently tolerant of faults since the replication of processing elements leads to the natural availability of spares. Designing machines which are fault-tolerant (and hence reliable) involves a great deal more that simply providing spares, however. Each fault must be located before any hardware re-configuration can be performed.

As in any electronic system, the most unreliable elements in a multi-DSP architecture are the electrical connections between physically distinct component parts. Since interconnection networks normally contain large numbers of wires and connectors, intermittent faults caused by momentary interruptions are not uncommon. Therefore the protocol for data-movement through the network should be robust and capable of detecting errors. More permanent faults can result in one or more DSPs being unable to communicate with the rest of the M-P.

Since faults cannot be avoided, the only alternative is to design multi-DSP systems for maximum resilience and fault-tolerance. Designing for maximum resilience means discovering which components are least reliable, and either minimising their use or making them more reliable. Designing for fault-tolerance means two things: firstly, designing systems with the ability to

detect the occurrence of an error, and secondly imbuing those systems with the ability to correct and recover from an error.

#### 5.3 Extensibility

It is important to leave room for future expansion of an audio M-P as one runs out of processing power. For example, a shared bus would typically experience heavy traffic with only 10 DSP modules. Many professional audio applications require much more processing power than this. Therefore, a fundamental consideration is the effect on the system of altering the degree of replication, usually upward. When assessing the extensibility of a particular M-P machine, a designer must consider several aspects of the design.

Firstly, as the number of DSP modules is increased the total cost of the system must also increase. It is obviously desirable to minimise this increase in cost to that of linear growth. Secondly, the designer must assess how the basic architecture parameters, such as IPC capacity, vary with replication. A further important practical consideration, especially for very large scale M-Ps, is the space occupied by the system as a whole and, more particularly, by the interprocessor wiring.

If the degree of replication is to be very large then a careful analysis of the rate of growth in hardware complexity must be performed. However, the ability to extend a particular multi-DSP architecture is clearly only important within a given range, since commercial systems have a finite lifetime and end-users have finite budgets. In the longer term, as configurations become larger, the effects of scaling will become more important. The extensibility of M-P architectures is still a subject which is of much research interest.

#### 6 MESSAGE-PASSING DESIGN

Various interconnection schemes have been suggested for message-passing between conventional DSP processors. Here, some of the approaches which utilise widely available integrated devices are considered.

#### 6.1 First-In First-Out Buffers

One technique is to employ first-in first-out (FIFO) buffers. It is important to monitor the boundary conditions (FULL or EMPTY) of these devices, as failure to act on their occurrence will result in data overflow or underflow. The current FIFO generation signals the EMPTY, HALF-FULL and FULL conditions by asserting corresponding

external pins. The EMPTY and FULL flags are also fed back internally and inhibit further read and write until the FIFO is no longer empty or full.

The increasing use of high-speed applications has created a demand for a faster and smarter generation of FIFOs. Flagged FIFOs offer the basic features discussed above while providing two additional programmable flags: ALMOST-EMPTY and ALMOST-FULL. These flags can be used as early warning flags in critical real-time applications such as pipeline DSP for digital audio applications. Current devices provide for unlimited expansion while maintaining a 50ns fall-through time [9].

#### 6.2 Dual-Ported RAM

Due to their high bandwidth and message passing flexibility, dual-ported RAMs (DPRs) can be used to link multiple high-performance DSPs. Several manufacturers produce DPRs in many configurations, all of which operate at static RAM speeds (50-150ns) and have two independent external memory ports [9]. This allows two processors to share the same block of physical memory in their respective address spaces. The two DSPs can access data in two memory locations simultaneously and asynchronously.

This approach clearly out-performs a discrete parts design where two processors must synchronize through arbitration for access to a bus which is used to access one location at a time in a standard single-port RAM. In this way, the integrated DPR approach removes synchronization requirements at the memory's bus access level. Nevertheless, synchronization must be performed at other levels to ensure data integrity and thus proper system operation.

#### 6.2.1 Busy Logic

A problem can occur with DPR memories when both ports attempt to access the same address at the same time. There are two significant cases: when one port is trying to read the same data that the other port is writing and, when both ports attempt to write to the same word at the same time. If one port is reading while the other port is writing, the data on the read side will be changing during the read and a read error can result. If both ports attempt to write at the same time, the memory cell is being driven by both sides and the result can be a random combination of both data words.

Busy logic solves this problem by detecting when both sides are using the same location at the same time. The BUSY output pins are suitable for attachment to the WAIT inputs of most DSPs. This approach is very straightforward and flexible, and has the benefit that a processor cannot be locked out of the RAM longer than the access period of the other processor. Note that although one or the other processor may have to wait occasionally, the throughput loss is minimal since the probability of both DSPs using the same location at the same time is very small.

#### 6.2.2 Semaphore Support

Software constraints may require mutual exclusion at the data structure level rather than at the memory location level. Instead of comparing addresses on every cycle and occasionally asserting BUSY, other DPR devices employ additional circuitry to support semaphores, thus ensuring that only one side has permission to use a block of memory. The conventional test-and-set semaphore operation requires that the two memory accesses are indivisible: some DPR devices employ a twist by using set-and-test.

The set corresponds to a request and the test checks to see if the request was granted. The indivisible double access requirement is avoided because, as soon as the request is made by one DSP, the grant is blocked on the other side. As a result, semaphores can be supported for DSPs which do not provide an indivisible READ/MODIFY/WRITE instruction. Since there is no hardware relationship between semaphores and DPR locations, the block sizes and locations, and semaphore association can be defined in software. This offers the system designer considerable flexibility.

#### 6.2.3 DPR Memory Expansion

DPR chips can be combined to form large dual-port memories. Expansion in memory depth with DPRs is similar to that used for conventional RAMs, where the top address bits enable individual memory blocks. DPRs can also be expanded in width. However, in this case, we have a subtle problem. If the addresses for both ports arrive simultaneously at both RAMs, it is possible for both sides to simultaneously assert BUSY, causing both DSPs to wait indefinitely for their ports to become free. The solution to this BUSY lock-up problem is to use the arbitration logic in only one DPR.

An example of expanded DPRs used for DSP-to-DSP communication is shown in Figure 7. Here, two DSP56001s communicate using three 8-bit wide DPR chips in a MASTER/SLAVE configuration to provide a word-wide dual-ported memory. If the MASTER device activates BUSY, the dedicated DPR SLAVE chips, which incorporate a BUSY input pin, will internally disable their write enables. Note that the BUSY signals from the MASTER are also fed to the WAIT pins of the DSPs, forcing them to stall when their side of the DPR block is BUSY.

#### 6.2.4 DPR and FIFOs Compared

Each 2K x 24-bit DPR block provided for inter-DSP communication requires three 48-pin ICs, plus components for memory decoding. A bi-directional 2K x 24-bit FIFO channel requires a total of six 28-pin ICs. With each doubling in size of a DPR block, 2 address pins must be added to the chip package. Larger FIFOs never need to change their package size, since the cells within the FIFO are not directly addressed. Thus FIFO technology scales better than comparable DPR technology. However, DPRs provide considerably more communications flexibility.

#### 6.3 Novel Devices

Serving as a complex four bus interconnection network, quad-ported RAMs (QPRs) greatly simplify the task of creating generalised M-P systems for audio processing with conventional DSPs. Although typically three times as expensive as comparable DPR devices, QPRs have a considerable interconnectivity advantage over DPRs. For example, in order to fully interconnect four DSPs requires 1 bank of QPR as opposed to 6 banks of DPR, as shown in Figure 8.

Implementing multi-DSP systems with processors not specifically designed for parallel processing can cause IPC to quickly saturate device I/O and adversely affect processing efficiency. DSP manufacturers made the first step in addressing the need for parallel processing by providing designers with two external memory interfaces. Novel devices such as the **Texas** Instruments TMS320C40 steps go several further incorporating on-chip hardware dedicated communications ports [10].

Each of the six bidirectional communication ports provides glueless processor-to-processor communication at a transfer rate of 20 Mbytes/s. Without these ports, the corresponding 120 Mbytes/s of processor throughput would have to be squeezed into one or both of the external memory interfaces, as Figure 9. With the communication ports, IPC bandwidth is plentiful and scales with the number of processors. In this

way the TMS320C40 can support of a wide variety of complex M-P configurations to meet the needs of real-time audio processing applications.

#### 7 CONCLUSIONS

Parallel DSP systems are an economic reality in today's digital audio environment, due to the wide availability of low cost DSPs devices. The fundamental advantage of such multi-DSP designs is their generality, since software algorithms govern the manipulation of samples and so dictate the audio processing performed. Although it is easy to replicate the processing resources required for multi-DSP audio systems, such replication can introduce serious problems with respect to communications bandwidth.

IPC networks are of fundamental importance in parallel DSP systems as they directly effect system throughput and have a bearing on modularity, extensibility and overall system performance. In order to implement digital audio systems through such replication, interconnection networks are required which provide sufficient IPC bandwidth for the range of processing applications being planned.

Utilising design techniques from conventional uniprocessor systems allows small M-P systems to communicate through a common bus and shared memory. However, the inherent advantages of low cost and simplicity must be balanced against the significant problems encountered when this approach is used for large-scale audio systems.

Integrated interconnection components, such as FIFOs and multi-ported RAMs, provide simple static RAM interfaces which connect transparently to almost any existing DSP design. As a result, they enable conventional DSP modules designed for uni-processor or small shared-bus systems to be directly employed in a variety of scalable M-P architectures. In particular, the multi-ported RAM scheme presents a cost effective method for message-passing between DSP modules.

Knowledge accumulated through the research of the past 25 years into parallel architectures and programming is making considerable impact on the design of products for the digital audio environment. For example, software techniques, such as semaphore flags, guarantee the integrity of audio samples shared by multiple DSPs. Task allocation strategies minimise the effect of IPC saturation and maximise the processing efficiency of multi-DSP systems [7].

Novel devices, such as the Texas Instruments TMS320C40, are beginning to emerge which integrate multiple IPC ports directly on-chip with high-speed DSP cores. Although currently expensive, their cost compares favourably with the pricing of conventional DSPs, such as the Motorola DSP56001, when they were first released.

The design of multi-DSP audio products is extremely challenging: one cannot simply lash together 100 DSP devices and expect to obtain 100-times the performance of a sole DSP. Although the amount of raw processing power is important for audio processing applications, factors such as efficiency and cost are of considerable consequence in the marketplace. Understanding of the architectural approaches available and the implications of design decisions enables the construction of well-engineered parallel DSP audio systems.

## Appendix H

## Glossary of Abbreviations

A glossary of abbreviations used in this thesis is given below. Abbreviations which appear in only one section may not be listed here, but are always defined when they are first used.

A-D : analogue-to-digital

ADC : analogue to digital conversion (or converter, depending on context)

ADT : automatic double-tracking

AES : Audio Engineering Society

ALL : all task-processor pairs/heuristics — DYN/HRT control code used in DCS

ALU : arithmetic logic unit

ANSI : American National Standards Institute

AOT : adjusted on test

ASIC : application specific integrated circuit

ASP : audio signal processing

AST : A* dynamic programming

BG: bus grant

BR : bus request

CD : compact disc

CO : combinatorial optimisation

CMOS : complementary metal oxide semiconductor

CPM: critical-path method

CPU : central processing unit

D-A : digital-to-analogue

DAC : digital-to-analogue conversion (or converter, depending on context)

DLL : dynamic-link library

DMA : direct memory access

DMC : digital mixing console

DPR : dual-ported RAM

DSP : digital signal processing (or processor, depending on context)

DYN : dynamic-level list scheduling

EBU : European Broadcasting Union

EIAJ : (Japanese Electronics Manufacturers' Association).

EQ : equalisation

EMI : external memory interface

EVB : evaluation board

FET : field effect transistor

FFT : fast Fourier transform

FIFO : first-in first-out

FIR : finite impulse response

FM: frequency modulation

FWE : fully-overlapped with execution

GA : genetic algorithm

G-P : general-purpose

H-F: high-frequency

HLE : highest level first, estimated times

HLN: highest level first, no estimated times

HMF: high mid-frequency

H-P

: high-pass

**HRTF** 

: head-related transfer-function

I/O

: input/output

**IEEE** 

: Institute of Electrical and Electronic Engineers

Ш

: inter-aural intensity difference

IIR

: infinite impulse response

IN

: interconnection network

IPC

: inter-processor communication

**ISO** 

: International Standards Organisation

**ISPW** 

: IRCAM Signal Processing Workstation

ITD

: inter-aural time delay

LC

: link connectivity

**LCE** 

: lowest co-level first, estimated times

**LCN** 

: lowest co-level first, no estimated times

L-P

: low-pass

LCD

: liquid crystal display

**LED** 

: light emitting diode

L-F

: low-frequency

**LFO** 

: low-frequency oscillator

**LGDF** 

: large-grain data-flow

**LMF** 

: low mid-frequency

μP

: micro-processor

**MAC** 

: multiply accumulate

**MADI** 

: multi-channel audio digital interface

MFLOPS: million floating-point operations per second

**MIA** 

: minimum independent assignment

MIDI : musical instrument digital interface

MIMD : multiple-instruction multiple-data

MIPS : million instructions per second

MISD : multiple-instruction single-data

MMI: man-machine interface

M-P : multi-processor

MPC: minimum processor cost

MRC : maximum remaining critical-path

MTBF : mean time between failures

NC : node connectivity

NML : non-overlapped, multiple links

NMOS : n-type metal oxide semiconductor

NON : none — DYN/HRT control code used in DCS

NP: non-deterministic polynomial-time

NSL : non-overlapped, single link

P : polynomial-time

PAM: pulse-amplitude modulation

PC: program counter

PCM: pulse-code modulation

PE : processing element

PFL : pre-fader listen

PPM: peak programme meter

PRO: processor with lowest index

PWM : pulse-width modulation

QPR : quad-ported RAM

R&D : research and development

RAM: random access memory

RISC : reduced instruction set computer

RND : random static labelling

ROM: read only memory

RSS : Roland Surround Sound

SA : simulated annealing

SCFET : smallest co-level first, estimated times

SCFNET: smallest co-level first, no estimated times

SCI : serial communications interface

SIMD : single-instruction multiple-data

SISD : single-instruction single-data

SMPTE : Society of Motion Picture and Television Engineers

SNR : signal-to-noise ratio

SP-DIF : Sony/Phillips Digital Interface Format

SPW: Signal Processing Worksystem

SQNR : signal-to-quantisation-noise ratio

SSI : synchronous serial interface

SU : super-unitary

TDA : total dynamic automation

TDM: time-division multiplexing

TI : Texas Instruments

TLB: translation lookaside buffer

TRC : Torus Routing Chip

TSK : task with lowest static level

TSP : travelling salesman problem

VCA : voltage-controlled amplifier

VDU : visual display unit

VHDL : VLSI hardware description language

VLSI : very large-scale integration

VU : volume unit

XLL : Excel add-in DLL

# Appendix I Bibliography

### Colophon

This thesis was written, illustrated and published using Frame Technology 's FrameMaker on NeXT and IBM-PC compatible workstations. Analytical results from both TPG and DCS deliverables were analysed and charted using Microsoft Excel. Additional graphics were generated using Mathematica, from Wolfram Research, running under NeXTstep.

The TPG C source included in Appendix C was developed using Microsoft's Visual C++ IDE and built as an XLL dynamic-link library for Excel. Borland's Turbo Prolog compiler was used to develop the DCS Prolog application presented in Appendix D. Version control for both projects was managed with SourceSafe from One Tree Software.
