Abstract：The construction of basements in urban areas is often associated with the possible damage to existing structures and services. The varying construction processes inevitably lead to different stress unloading patterns and therefore the dissipation of these excess pore-water pressures may lead to non-standard deformation profiles. The three main types of basement construction processes are Layered Excavation (LE), Basin Excavation (BE) and Island Excavation (IE). The effect of the various unloading patterns has been investigated by a three dimensional (3D) effective stress analysis method using the developed computer program *3DBCPE*4.0. An excavation of length 50m, width 50m and depth 9m in a certain homogenous and isotropic saturated soft soil was modelled. This included a diaphragm wall of 800mm thickness embedded 18m deep into the soft soil. The different excavation deformation profiles under different excavation patterns were related to the different unloading process, the exposure time of excavation face and the dissipation of negative excess pore-water pressures. The most favourable process for controlling the horizontal deformation of a retaining wall or the heave deformation of the formation level is suggested. The ground water potentials within the formation level are also presented.

Keywords: Excavation pattern; Finite element method (FEM); Negative excess pore-water pressure; Ground water potential

1. Introduction

Excavation will cause the deformations of retaining structure, pit base and ground surface, therefore, numerous investigations on the characteristics of excavation-induced deformations have been performed. Ou and his research group did a lot of research, they proposed an empirical method for predicting the spandrel and concave settlement profiles on the basis of a regression analysis of the field observations of settlement curves (Hsieh and Ou, 1998), studied building responses and ground movements caused by an excavation using the top-down construction method (Ou *et al.*, 2000), analysed basal heave of excavations (Hsieh *et al.*, 2008), evaluated basal heave stability (Do *et al.*, 2013), and investigated extensively the behaviour of excavations with cross walls (Hsieh *et al.*, 2012; Hsieh *et al.*, 2013; Ou *et al.*, 2013; Wu *et al.*,2013). In addition, Zdravkovic *et al.* (2005), Kung *et al.* (2007a; 2007b) and Finno *et al.* (2007) studied the deformation behaviour of excavation in other aspects.

Excavation will also cause the variation of pore pressure due to unloading. In order to investigate variation of pore-water pressure induced by excavation, 3D effective stress analysis based on Biot's consolidation theory was performed. Osaimi and Clough (1979) investigated pore-water pressure dissipation during an excavation based on Biot's consolidation theory. Benmebarek *et al.* (2006) analysed the effect of seepage flow on the lateral earth pressures acting on deep sheet piled wall excavations in cohesionless soil using the explicit finite difference method implemented in Fast Lagrangian Analysis of Continua (FLAC) code. The distribution rules of the formation level deformations and excess pore-water pressure were analysed in detail integrating the time parameter by Li *et al.* (2008). Borges and Guerra (2014) analysed the consolidation-dependent behaviour of a cylindrical excavation in a clayey soil. The study

investigated the influence of the diameter of excavation, the embedded length of the wall and the elastic modulus of the wall material on the behaviour of the formation level.

In actual engineering, there are different excavation patterns according to the surrounding environment and the stability of excavation. LE is that soil is excavated uniformly from the excavation, BE is that the soil at the formation level centre is excavated first whereas the soil around the formation level centre is excavated later, and IE refers to that the soil around the formation level centre is excavated first whereas the soil at the formation level centre is excavated later. However, as reported above, little work has focused on the effect of the excavation patterns (such as IE and BE) on the formation level. Tan and Wang (2013a; 2013b) studied the characteristics of a circular excavation and its peripheral according to a large-scale deep excavations by the Island technique. The study compared bottom-up construction of the central cylindrical shaft first and top-down construction of the peripheral rectangular excavation in Shanghai's soft clay. However, they concentrated on formation level shape (central circular and peripheral rectangular) and the construction method (bottom-up construction and top-down construction) via the analysis of formation level deformations.

In this study, to explore the effects of excavation patterns on the behaviour of the formation level, based on Biot's consolidation theory, a computer program *3DBCPE*4.0 was developed by 3D FEM. This was used to perform the coupled analysis of soil mass deformation and pore-water pressure dissipation. LE, BE and IE were modelled respectively and the results are reported in this paper.

2. Biot's 3D consolidation finite element equations

Biot's 3D consolidation finite element equations (Potts and Zdravkovic, 1999; Xie and Zhou,

2002) can be written in the following form:

$$[K]\{\Delta U\}^e = \{\Delta R\}^e \tag{1}$$

where $[K]$ is the element consolidation matrix (a symmetric matrix of 32×32 since a mesh of eight

noded hexahedral isoparametric elements is used to discretize a pit geometry in this paper),

$\{\Delta U\}^e$ is the increment column matrix of unknown terms of element node and $\{\Delta R\}^e$ is the

increment column matrix of equivalent load and water runoff of element node.

The sub matrix of the $[K]$ matrix is given by:

$$[K_{ij}] = \begin{bmatrix} [K_{eij}] & [K_{cij}] \\ [K_{cji}] & -\theta \Delta t K_{sij} \end{bmatrix} \quad (i = 1,2,\dots,8) \tag{2}$$

where θ is the integration constant which ranges from 0.5 to 1.0, $[K_{eij}]$ is the sub matrix of

element stiffness matrix, $[K_{cij}]$ is the sub matrix of element coupling matrix and K_{sij} is the

component of element seepage matrix (Xie and Zhou, 2002).

The sub matrices of the $\{\Delta U\}^e$ and $\{\Delta R\}^e$ matrices can be expressed respectively as:

$$\{\Delta U_i\} = [\Delta u_i \quad \Delta v_i \quad \Delta w_i \quad \Delta p_i]^T \quad (i = 1,2,\dots,8) \tag{3}$$

$$\{\Delta R_i\} = [\Delta R_{xi} \quad \Delta R_{yi} \quad \Delta R_{zi} \quad \Delta R_{pi}]^T \quad (i = 1,2,\dots,8) \tag{4}$$

where $\Delta u_i, \Delta v_i, \Delta w_i$, and Δp_i are the displacement increments and the pore-water pressure

increment of the ith element node, respectively, $\Delta R_{xi}, \Delta R_{yi}, \Delta R_{zi}$ and ΔR_{pi} are the equivalent

load increments and the equivalent water runoff increment of the ith element node, respectively.

The seepage effect induced by the water head difference between the inside and the outside

of the formation level cannot be taken into account when analysing excavation deformation and

pore-water pressure using Eq.(1). Thus, a ground water potential is introduced for consolidation

analysis of the excavation. When neglecting the solute potential the ground water potential of a

saturated soil is defined by:

$$P = p + \gamma_w z \qquad (5)$$

where P is the ground water potential of a saturated soil, p is the sum of pressure potential (hydrostatic pressure) and load potential (excess pore water pressure), i.e. the total pore-water pressure, the spatial coordinate z is upwards positive, γ_w is unit weight of water, and $\gamma_w z$ is the gravity potential.

The ground water potentials of element node i at time t_n and t_{n+1} are represented by $P_{i(n)}$ and $P_{i(n+1)}$, respectively. Thus Eqs.(3) and (4) may be written in the following form without regard to the influence of soil vertical displacement:

$$\{\Delta U_i\} = [\Delta u_i \quad \Delta v_i \quad \Delta w_i \quad P_{i(n+1)}]^T \quad (i = 1,2,\ldots,8) \qquad (6)$$

$$\{\Delta R_i\} = [\Delta R'_{xi} \quad \Delta R'_{yi} \quad \Delta R'_{zi} \quad \Delta R'_{pi}]^T \quad (i = 1,2,\ldots,8) \qquad (7)$$

where $\Delta R'_{xi} = \Delta R_{xi} + [K_{cij}]P_{i(n)}$, $\Delta R'_{yi} = \Delta R_{yi} + [K_{cij}]P_{i(n)}$, $\Delta R'_{zi} = \Delta R_{zi} + [K_{cij}]P_{i(n)}$ and $\Delta R'_{pi} = \Delta R_{pi} - \theta \Delta t K_{sij} P_{i(n)}$.

Based on the finite element equations derived above, a 3D consolidation finite element program *3DBCPE*4.0 was developed. In order to validate the program, an analysis of one-dimensional consolidation for homogeneous soft soils under time-dependent loading was introduced (Li *et al.*, 2008). The soil layer top is pervious and free, and the bottom is impervious and fixed. Displacements perpendicular to the boundaries are restrained and an impermeable condition is assigned at the vertical boundaries. Soil parameters are: Poisson's ratio μ=0.301, elasticity modulus E=3MPa, vertical permeability coefficient k_v=1.0×10^{-8}m/s, and thickness of soil layer H=10m. A load curve is shown in Fig.1 where maximum load q_0=100kPa and time t_0=70d.

Calculating domains in x-, y- and z-direction are 1m, 1m and 10m respectively and are

divided into 7 meshes, as shown in Fig.2.

Fig.1   Loading curve

The comparisons of pore pressure, settlement and average degree of consolidation between the FEM results and the analytical solution of 1D consolidation are shown in Figs.3 and 4. The results of FEM agree very well with those of the analytical solution, which proves the validity of the program, so it can be used for effective stress analysis.

3. Stress-strain relationship of soil

Soil behaviour was simulated using the revised Duncan-Chang model (Duncan and Chang, 1970; Kulhawy and Duncan, 1972) in this paper. The model assumes a hyperbolic stress-strain relationship and a variable Poisson's ratio by means of stress-dependent Poisson's ratio (Kulhawy and Duncan, 1972).

The initial modulus is defined as:

$$E_i = K p_a \left(\frac{\sigma_3}{p_a}\right)^n \tag{8}$$

where the modulus number K and modulus exponent n are dimensionless material parameters; σ_3 is the minor principal stress; p_a is atmospheric pressure expressed in the same pressure units as σ_3.

When the stress-strain relationship is employed in incremental form, the tangent modulus corresponding to any point on a stress-strain curve can be expressed as:

$$E_t = \left[1 - \frac{R_f(1-\sin\varphi)(\sigma_1-\sigma_3)}{2c\cos\varphi + 2\sigma_3\sin\varphi}\right]^2 K p_a \left(\frac{\sigma_3}{p_a}\right)^n \tag{9}$$

where c and φ are Mohr-Coulomb strength parameters; σ_1 is the major principal stress; and R_f is the failure ratio.

When (σ_1–σ_3) is less than its historical maximum, it is assumed that the soil is under unloading or reloading and the tangent modulus is defined as:

$$E_{ur} = K_{ur} p_a \left(\frac{\sigma_3}{p_a}\right)^n \tag{10}$$

where K_{ur} is the unloading-reloading modulus number and is always greater than the primary loading modulus number K.

The initial Poisson's ratio can be expressed as:

$$\nu_i = G - F \log\left(\frac{\sigma_3}{p_a}\right) \tag{11}$$

and the tangent Poisson's ratio

7

$$\nu_t = \frac{\nu_i}{(1-A^*)^2} \tag{12}$$

where $A^* = \dfrac{(\sigma_1-\sigma_3)D}{Kp_a\left(\frac{\sigma_3}{p_a}\right)^n\left[1-\frac{R_f(1-\sin\varphi)(\sigma_1-\sigma_3)}{2c\cos\varphi+2\sigma_3\sin\varphi}\right]}$; and D, F and G are material parameters.

4. Studies on the behaviour of foundation pit under different excavation patterns

4.1 Numerical example and finite element model

A formation level of length 50m, width 50m and depth 9m in a certain homogenous and isotropic saturated soft soil is presented. The diaphragm wall of 800mm thickness is embedded 18m deep in soft soil. The groundwater tables inside and outside the excavation were assumed to locate on the excavated surface and the ground surface respectively. Soil vertical and horizontal permeability coefficients (i.e. k_h and k_v) are both 1.0×10^{-8}m/s and the effective unit weight of soil γ' is 9.0kN/m^3 (Table 1).

Table 1   Soil parameters used during modelling

K	n	R_f	c' (kPa)	φ' (°)	F	G	D	K_{ur}	k_h (m/s)	k_v (m/s)	γ' (kN/m^3)
150	0.7	0.85	15	35	0.15	0.35	3.5	300	1.0×10^{-8}	1.0×10^{-8}	9

Two layer struts of reinforce concrete are respectively set at 3m and 6m under the ground surface. Their cross-sectional dimensions at the first tier and the second tier were 600mm by 600mm and 600mm by 700mm, respectively. The horizontal spaces between the struts within the excavation at every tier were 8.3m. Given that the influence scope of an excavation and the symmetry about the formation level centreline, the dimensions of the model in x-, y- and z-direction are 100m (length) by 100m (width) by 40m (depth). Finite element meshes of soil mass and retaining wall are shown in Fig.5 wherein the element size was fine near the walls where deformations and flow gradients are concentrated.
Fig.5　Mesh of finite elements

The bottom boundary of the excavation model was assumed to be fixed and displacements perpendicular to the boundaries were restrained at the lateral boundaries. As far as the hydraulic boundary conditions were concerned, a no-flow condition was assigned at the symmetrical plane and an impermeable condition was assigned at the vertical boundaries. The bottom boundary of the model was impermeable whereas the top was permeable and the retaining walls were double-sided impermeable.

All soil units were discretized using eight-node hexahedral isoparametric elements and was simulated using the revised Duncan-Chang model. According to the studies of many researchers (Duncan and Chang, 1970; Kulhawy and Duncan, 1972; Ou *et al.*,1996; Liao, 2009), the parameters of hyperbolic model in this paper are listed in Table 1. In Table 1 c' and φ' are the effective cohesion and the effective internal friction angle of soil respectively. Retaining walls were modelled with a linear elastic model whose modulus of elasticity and Poisson's ratio are 25GPa and 0.167 respectively. Retaining wall's elements were discretized using Wilson non-harmony elements. A row of 0.1m thick interfaces were used to connect soil mass and retaining wall elements. The two sides of the retaining wall adopted 3D thin interface elements which were derived from Yin's rigid plastic model (Yin et al., 1995) for outer friction angle=1.0° and cohesion=0.5kPa (Wang, 1994). Its other model parameters are the same as those of the soil

mass elements. Supports were simulated with the linear elastic model with 23GPa elasticity modulus and discretized using spatial bar elements.

4.2 Construction process under different excavation patterns

LE, BE and IE all involved three stages and the excavated thickness at every stage was 3m. Construction at every stage was divided into three or four stages to complete (see Figs.6-8). Excavation intermissions after every excavation stage were allowed for installation of struts or casting the formation level base concrete. Excavation duration each stage and the intermission duration after each stage under the different excavation patterns were also kept the same (as shown in Tables 2-4).

4.3 Deformation behaviour of excavation

Excavations will cause the horizontal displacement of retaining walls, ground surface settlements around the excavation and heave of the formation level. The excavation deformations under LE, BE, and IE are analysed and investigated by the comparison of the following:

1) The horizontal displacement of retaining wall,

2) The ground settlement around foundation pit, and

3) The heave of pit base.

Fig.9 shows the horizontal displacement comparison at the $x=0$ section and at the third (final) excavation stage. The maximum horizontal displacements under the different excavation patterns all occur at approximately 2m under the excavation surface (i.e. 11m under the surface level). In the case of BE the maximum horizontal displacement decreases by 12.4% and under IE it

increases by 2.5% compared with LE. The different horizontal displacements of the retaining wall under the excavation patterns were induced by changing the process of applying the earth pressure acting on the retaining structure within the excavation. Take the first excavation stage, for example, the exposure time of the retaining wall within the excavation at the end of the first excavation intermission is shown in Table 5. The horizontal displacement comparison at the $x=0$ section and at the end of the first excavation intermission is indicated in Fig.10. The retaining wall has a cantilever-type deflection because the excavation was carried out without a strut installation at the first stage.   It can be seen from Table 5 and Fig.10 that the lateral displacements of the retaining wall under BE are smaller than those under LE and IE. Since the exposure time of the retaining structure was the shortest under BE (0-2m depth range) the duration that the lateral earth pressure acting on the retaining wall inside the excavation was zero was the shortest. The moment acting on retaining wall was induced by the lateral earth pressure outside the excavation at 0-2m depth range which is larger than the one at 2-3m depth range. The duration that the lateral earth pressure acting on the 2-3m depth range of retaining wall inside the excavation under IE was zero was slightly larger than under LE leading to the lateral displacements of the retaining wall under IE and LE being very close. Therefore, the soil around the retaining structure inside the excavation under BE was excavated later and the exposure time of the retaining wall decreased. This was more favourable for controlling the deformation of retaining wall.
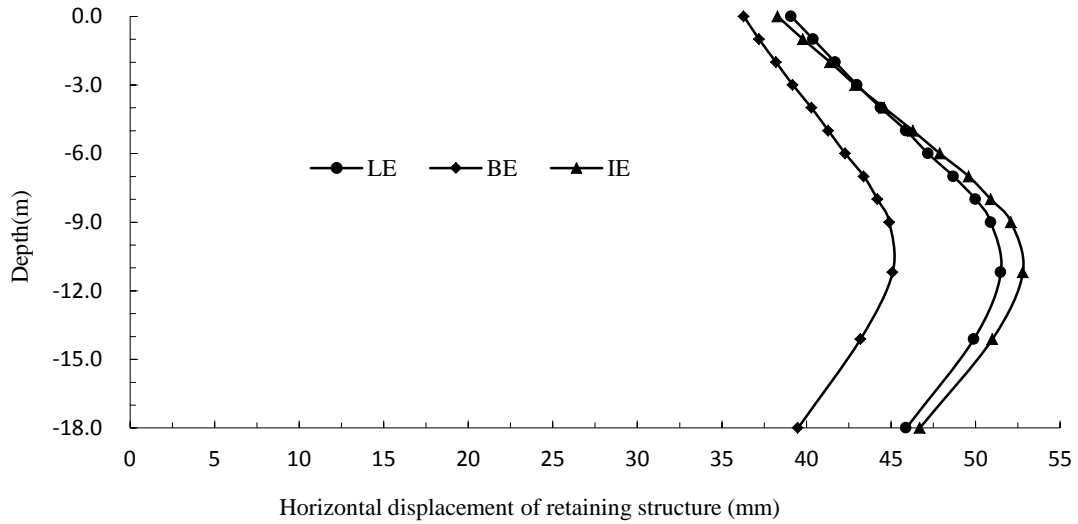

**Fig.9   Displacement of retaining structure at the third excavation stage**

Fig.10   Displacement of retaining structure at the end of the first excavation intermission

Table 5   Exposure time of retaining wall

Depth range of retaining wall	BE (d)	LE (d)	IE (d)
0~1m	10	11	11
1~2m	9	10	10
2~3m	8	8	9

Fig.11 shows the ground surface settlement around the formation level at the x=0 section under the three different excavation patterns after the third excavation stage. It can be seen from Fig.11 that the maximum settlement occurred at 15m from the formation level and the settlement

profiles were concave (similar to Hsieh & Ou, 1998). The excavation patterns have little influence on the ground surface settlement. Within 6m from the formation level the settlement values, under BE, were smaller than those of LE. IE had larger settlements because the wall deflection effects the soil near the formation level. The wall displacements under BE were smaller than the ones under LE and IE (Figs.9 and 10) and so the lateral pressures of the soil outside the excavation under BE were larger. The vertical stress of the soil outside the excavation under the three construction patterns were approximately the same, i.e. the smaller horizontal displacement means the larger confining pressure of the soil outside the excavation. This will inhibit the settlement of the soil outside the excavation thus the ground settlements under BE were smaller than those from LE and IE. Beyond 6m away from the formation level, the settlement values under BE were the largest. Settlement values under LE and IE were smaller or approximate the same. This was because the ground settlements far from the formation level were mainly influenced by the change of the effective stress from the change in excess pore-water pressure (Figs.17-19). The distributions of excess pore-water pressure outside the excavation were similar and the negative excess pore-water pressures under BE were slightly larger according beneath the retaining wall.

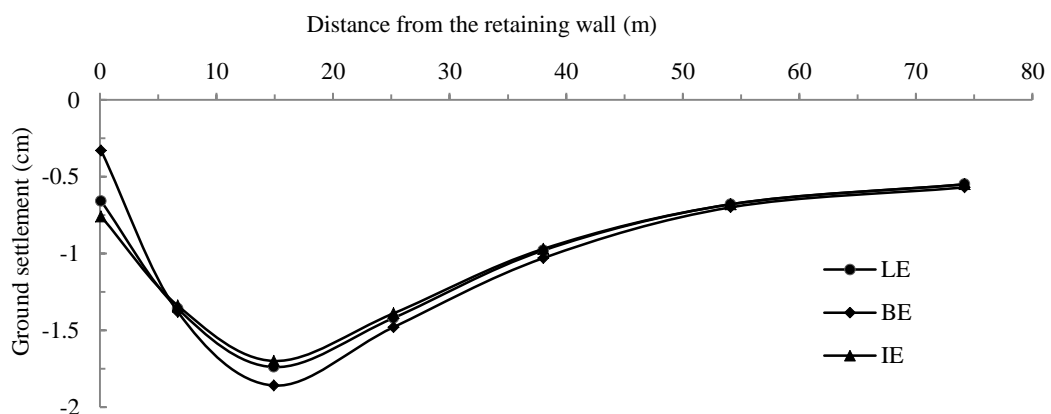

Fig.11   Ground settlement at the third excavation stage

The comparison of formation level basal heave at the $x=0$ section and under three different excavation patterns at the third excavation stage is shown in Fig.12. It can be seen from Fig.12 that within 21m from the centre of the formation level the heave values of the base under BE were the largest. The equivalent values resulting from LE were larger or almost equal and the values under IE were the smallest. However, within 21-25m from the formation level centre the heave values under different excavation patterns were very approximate and they all decreased sharply close to the retaining wall due to the friction between soil and retaining wall. For LE the soil was excavated uniformly from the excavation and the self-gravity stress was therefore released uniformly. This leads to the uniform heave of formation level base. For BE the soil at the formation level centre was excavated first, whereas the soil around the formation level centre was excavated later, so larger heave values occur at the centre. The process of IE is opposite to BE and smaller heave occurs at the centre. Compared with the maximum heave value of the formation level base under LE (within 15m from the pit centre) the BE value increases by 13.6% and under IE the value decreases by 12%. Therefore, as far as the heave stability of the formation level is concerned IE is more favourable and BE is least favourable. To further analyse the differences of formation level heave from the different excavation patterns the heave and the exposure time of excavation face at the end of the first excavation intermission were examined (see Table 6 and Fig.13). The unloading of the soil mass decreases the total stress of the soil beneath the excavation face and induces negative excess pore-water pressures. The longer the exposure time of excavation face was the more the negative excess pore-water pressure dissipated, therefore, the decrease in effective stress beneath the excavation face was greater and the heave of pit base was larger. It can be seen from Table 6 and Fig.13 that (within 8.3m from the formation level centre)

16

the exposure time under BE was the longest and therefore the heave of the base was the largest. During IE the thick soil layer in the formation level centre was excavated later (as mentioned above) and the negative excess pore-water pressures dissipated slowly. Therefore, the heave deformations under IE were smaller than those under LE and BE.

**Fig.12   Heave of formation level at the third excavation stage**

Fig.13   Heave of formation level at the end of the first excavation intermission

Table 6   Exposure time of excavation face at the end of the first excavation intermission

Distance from centre/m	LE (d)	BE (d)	IE (d)
0-8.3	8	10	8
8.3-16.6	8	9	9
16.6-25	8	8	10

4.4 Pore-water pressure of excavation

The flow of ground water depends on soil water potential and defined as the sum of excess pore-water pressure, hydrostatic pressure and the gravity potential. In order to analyse the flow of ground water inside and outside the excavation, under different excavation patterns, the contours of the soil water potentials inside and outside the excavation at the $x=0$ section and at the third excavation stage are shown in Figs.14-16, where the datum for the elevation head is at the bottom boundary of model. It can be seen from Figs.14-16 that the soil water potentials outside the excavation were all larger than the ones inside under the three excavation patterns at the third excavation stage. Therefore, ground water flows into the excavation from the outside. For BE ground water not only flows into the centre under excavation face but also observably flows into the area near to the retaining structure. Since the soil close to the retaining wall was unloaded later and the soil water potentials were also correspondingly less than the values under LE. Similarly, the soil at the formation level centre under IE was excavated later and the dissipation of the soil water potential at the centre was slow. Therefore, the ground water was more apt at flowing into the excavation at the formation level centre than during LE.

**Fig.14   Distribution of the soil water potentials under LE (unit: kPa)**

Fig.15   Distribution of the soil water potentials under BE (unit: kPa)

Fig.16   Distribution of the soil water potentials under IE (unit: kPa)

Figs.17-19 show the contours of the excess pore-water pressures inside and outside the excavation under the three patterns at the *x*=0 section and at the third excavation stage.   It can be seen from Figs.17-19 that at the third excavation stage the horizontal distribution range of the negative excess pore-water pressures beneath excavation face under LE were the smallest. The values under BE were the largest and the values under IE were between these two. However, the vertical distribution range of the negative excess-pore water pressures beneath excavation face under IE was the largest and the value under LE was the least. The comparison among the values of negative excess pore-water pressure under different excavation patterns shows that the dissipation of negative excess pore-water pressure under IE was the slowest.
19

**Fig.17   Distribution of excess pore-water pressures under LE (unit: kPa)**

Fig.18   Distribution of excess pore-water pressures under BE (unit: kPa)

Fig.19   Distribution of excess pore-water pressures under IE (unit: kPa)

The distribution difference of excess pore-water pressure is related to the unloading process

of the three excavation patterns. The unloading process of LE was uniform and the exposure time

of the whole excavation face was kept the same. This was favourable to the uniform dissipation of

excess pore-water pressure and so its scope was small. During the process of BE and IE the

unloading above the excavation face was non-uniform. The unloading under BE was from the formation level centre to the retaining wall and it was just contrary under IE which is unfavourable for the dissipation of the excess pore-water pressures. The negative excess pore-water pressures under BE and IE dissipated slower and their areas were larger. In the process of BE larger negative excess pore-water pressures were generated in the nearby retaining structure than the values under LE as the result of the later unloading nearby retaining structure under BE. Moreover, the process of IE was contrary to the one of BE and so its negative excess pore-water pressures at the formation level centre were larger than the LE values.

5. Conclusions

3D effective stress analysis of an excavation under Layered, Basin and Island Excavation processes was performed and reported in this work. This has led to the following conclusions:

(1) The soil around retaining wall was unloaded later under BE which decreased the exposure time of the retaining structure and induced small horizontal displacements. It is, therefore, favourable when controlling the deformation of a retaining wall. The soil at the formation level centre was unloaded later under IE which decreased the exposure time of excavation face and caused small heave of base and can be considered favourable when controlling any heave deformation of the formation level.

(2) The settlement of the soil near the retaining wall was related to the wall deflection; however, the settlement of soil at a reasonable distance from the wall was related to the dissipation of negative excess pore-water pressure. For example the greater the negative excess pore-water pressure was then the greater the effective stress of soil was and resulting in larger soil settlement.

(3) The distributions of total soil water potential and negative excess pore-water pressure

21

were both very similar under the three excavation patterns. Since the order of unloading inside the excavation was different then the scope of the negative excess pore-water pressure was larger (at the excavation face) for the soil which was unloaded last.

In this work only the excavation patterns were focused on, however, excavation is an over-consolidation problem due to unloading. Therefore, over-consolidation problem should be considered when choosing a constitutive model of soil in future investigations.
