Abstract:

There is much interest in being able to combine crowdsourced data. One of the critical issues in information sciences is how to combine data or information that are discordant or inconsistent in some way. Many previous approaches have taken a majority rules approach under the assumption that most people are correct most of the time. This paper analyses crowdsourced land cover data generated by the Geo-Wiki initiative in order to infer the land cover present at locations on a 50km grid. It compares four evidence combination approaches (Dempster-Shafer, Bayes, Fuzzy Sets and Possibility) applied under a geographically weighted kernel with the geographically weighted average approach applied in many current Geo-Wiki analyses. A geographically weighted approach uses a moving kernel under which local analyses are undertaken. The contribution (or salience) of each data point to the analysis is weighted by its distance to the kernel centre, reflecting Tobler's 1st law of geography. A series of analyses were undertaken using different kernel sizes (or bandwidths). Each of the geographically weighted evidence combination methods generated spatially distributed measures of belief in hypotheses associated with the presence of individual land cover classes at each location on the grid. These were compared with GlobCover, a global land cover product. The results from the geographically weighted average approach in general had higher correspondence with the reference data and this increased with bandwidth. However, for some classes other evidence combination approaches had higher correspondences possibly because of greater ambiguity over class conceptualisations and / or lower densities of crowdsourced data. The outputs also allowed the beliefs in each class to be mapped. The differences in the soft and the crisp maps are clearly associated with the logics of each evidence combination approach and of course the different questions that they ask of the data. The results show that discordant data can be combined (rather than being removed from analysis) and that data integrated in this way can be parameterised by different measures of belief uncertainty. The discussion highlights a number of critical areas for future research.

Key words: Crowdsourcing, land cover, data quality, VGI, data mining

1. Introduction

One of the critical areas of research in information sciences is how to combine data or information that are discordant or inconsistent in some way. Discord may arise from different spatial frameworks, different measurement devices, different classifications or measurement units. However there is much scientific interest in being able to combine data from different sources to enhance information value and utility, to measure change if the data are temporal, to compare different treatments and so on. This research develops, applies and compares a number of geographically weighted evidence combination approaches to a crowdsourced land cover problem. The aim was to use the sometimes conflicting crowdsourced data to describe or infer the land cover present at specific locations and to generate some measure of confidence or belief in the inference.

There has been much recent interest in the potential opportunities for extracting information contained in large datasets arising through big data initiatives and the many crowdsourcing activities. Much of this interest relates to the high data volumes and low cost of crowdsourced data and to the opportunities for extracting useful and novel knowledge by integrating information from the many data silos under big data. A number of publications have described the potential opportunities arising from analysis of crowdsourced data [1-4] but one of the critical and as yet unaddressed issues is how to deal with conflicting information. Most of the current solutions to this problem adopt a Linus law or majority rules approach, where the majority view of contributors is deemed to be correct. In many situations this approach is intuitive and logical. However, it implicitly assumes that every contribution (or datum) has equal salience, that the majority of observations are correct and pragmatically treats the observers and their observations as independent. In reality some observations and some observers may be more reliable than others [4, 5], which may matter in some circumstances but not in others [5, 6] and observations may be exhibit spatial non-stationarity and strongly influence by local processes reflecting Tobler's First law of geography¹ [7].

¹ *“Everything is related to everything else, but near things are more related to each other”*

1 Critically Tobler's First law infers that local information and context should be
2 considered when combining spatial data and Geographically Weighted approaches
3 have been proposed to do this [8]. In this paper geographically weighted evidence
4 combination approaches based on Bayesian Probability, Dempster-Shafer, Fuzzy Sets
5 and Possibility theories were developed and applied. Geographically weighted
6 approaches use a moving kernel to weight data inputs by their distance to the location
7 being considered [8]. The geographically weighted evidence combination approaches
8 were applied to crowdsourced data describing land cover to infer the presence of land
9 cover at each location in a study area. Other research has shown how different
10 evidence combination methods partition uncertain evidence in different ways. This is
11 due to their different underlying assumptions and logics and consequently they ask
12 different questions of the evidence they combine [9 -11]. The paper develops and
13 applies these methods for handling uncertain evidence under a geographically
14 weighted framework for the first time. In so doing, it explores their utility for
15 generating useable spatial information from crowdsourced data, parameterised by
16 uncertainty, and considers their performance under different sized kernels overall and
17 for specific land cover classes.

32 **2. Background**

36 There has been much interest in crowdsourced data with applications ranging from
37 astronomy to zoology [12]. Data are varied and include all kinds of digital
38 information from microblogs, tagged photographs to web based interfaces. These data
39 are easily shared with others via dedicated servers to which information is uploaded
40 or through informal social networks. The result is a very dynamic data environment
41 and there is huge scientific interest in opportunities afforded by the high data volumes
42 at low cost. Of note is that data contributed by citizens are increasingly spatially
43 referenced due to the increasing number of portable GPS- and web-enabled digital
44 devices (e.g. smartphones, tablets, etc.).

54 The terms 'crowdsourced', 'citizen science' and 'volunteered geographic information'
55 have their own nuanced meanings and recent work has developed a typology of
56 crowdsourced data to try to capture some of this [13]. The term '*crowdsourcing*'
57 originally referred to the ability of citizens to validate and correct the errors that an

1 individual might make and to potentially arrive at some truth [14]. A recent example
2 is the Geo-Wiki project. This web-based interface to Google Earth was initially used
3 to validate a global biofuels availability dataset [15, 16] and has subsequently been
4 used for a number of other campaigns. Typically Geo-Wiki campaigns captures data
5 describing the land cover class at a series of locations. In some campaigns additional
6 information is captured for example on the amount of human disturbance in the scene,
7 the user confidence in their class allocation, etc, and, depending on the campaign, the
8 points may be selected at random or they may be repeatedly sampled. Currently many
9 Geo-Wiki analyses apply a geographically weighted averaging approach as described
10 in Comber et al [4] to combine crowdsourced land cover data.

11
12
13
14
15
16
17
18
19
20 In contrast to much of the initial research using crowdsourced data to validate other
21 data products, recent work has focussed on methods for assessing the *quality* of the
22 crowdsourced data itself. Studies of the data generated by the Geo-Wiki campaigns
23 have compared them with external data [4], with control data [5] and have applied
24 internally based latency measures [3]. Overall quality, in terms of the correctness of
25 land cover class allocation, has been found to vary only marginally between experts
26 and non-experts [5] but significant differences have been found for specific land cover
27 types in specific areas [6] and in relation to the ‘experiential distance’ of the observer
28 to the phenomena being considered [17].

29
30
31
32
33
34
35
36
37
38 One of the critical issues in citizen science and crowdsourcing is how to deal with
39 conflicting information, opinions or versions. Platforms and activities such as
40 Wikipedia and OpenStreetMap benefit from crowdsourcing in its original sense: that
41 of different citizens arriving at a collective view of what the truth is (with apologies to
42 Pickles [18]). This consensual ‘Linus’s Law’ approach generally produces acceptable
43 outcomes, although with some known socio-scientific problems, for example on
44 occasion the versions of the ‘super user’ or views of the user with the greatest edit
45 persistence will win out despite conflicting or contrary edits in so called ‘tag wars’
46 [19].

47
48
49
50
51
52
53
54
55
56 In many cases, the capture of crowdsourced data is much less nuanced and detailed
57 than Wikipedia or OpenStreetMap. Consider the Geo-wiki initiative. Anyone can
58 login and evaluate land cover at discrete locations. This may result in people with
59
60
61
62
63
64
65

1 different backgrounds and experiences identifying different land cover types as being
2 present at the same location [20]. As a result one of the critical issues is how to
3 manage conflicting user evaluations of the land cover class. In many citizen science
4 research conflicts over what different observers consider to be there are managed by
5 taking the majority view, many eyes or Linus's Law approach. Haklay et al [2] used
6 this approach to determine feature locations and found that locational accuracy
7 increased as more people contributed to the solution. However, this was not to
8 classify or identify the feature itself and in such contexts other authors have noted that
9 Linus's Law may not be as effective for establishing geographic facts [14, 21].
10 Goodchild and Li [14] comment that Linus Law approaches may be most suited to
11 what they refer to as 'prominent' geographic facts – that is those that are not obscured
12 by being in a sparsely populated or under-explored location, that persist over time and
13 interest many people. The obvious gap in this list are geographic features that are
14 inherently subjective such as land cover classification where few natural kinds exist
15 [22].

29 Other research from the information sciences has noted some of the problems
30 associated with multiple crowdsourced opinions. As Zook et al [23, pp 27-28] note
31 “duplication is not necessarily a bad thing as it can provide multiple avenues to access
32 information. It can, however, make interpretation of a situation more complicated as
33 multiple sources can provide conflicting versions of the built and natural
34 environments”. Welinder and Perona [24] identified the challenges related to
35 conflicting crowdsourced labels for images, for example when different users assert *A*
36 and other users *not-A*. Some research has suggested that the crowd itself is used to
37 deal with conflicts, by supplying rules to resolve disagreements and to merge
38 conflicting inputs and to generate automatic solutions by weighting user scores [25,
39 26]. Other approaches propose that users contribute to an overall knowledge base in
40 order to generate weighting probabilities [27]. Thus there is a belief that data from
41 multiple sources and data from multiple but imperfect sources are desirable, because
42 they offer the opportunity of insight and knowledge. However many of the solutions
43 that have been proposed thus far are aspatial – they do not consider geographic
44 context – and are not generic – they rely on specific, local conflict resolution
45 strategies to determine whether one assertion should override another [28].

1 Evidence combination is a strong and long standing area of research within the
2 information sciences. Many methods are available to combine conflicting or uncertain
3 information – Bayesian Probability, Dempster-Shafer, Fuzzy Sets, Possibility theory,
4 etc. – each with different underpinning logics. A number of reviews exists and the
5 interested reader is directed to [29-33]. As yet no research has:
6
7

- 8 1) considered how approaches that explicitly facilitate reasoning under
9 uncertainty may be used to integrate conflicting crowdsourced data, or
10
11 2) applied these methods under explicitly geographical frameworks such as
12 geographically weighted kernels [8].
13
14
15

16 This paper develops a number of evidence combination approaches that are typically
17 used to handle information uncertainty [11] under a geographically weighted
18 framework in order to combine potentially conflicting crowdsourced data on land
19 cover. The aim was to combine this data and then to describe or infer the land cover
20 present at discrete locations with some indication of the degree of belief in that
21 inference. The evidence combination methods operate in different ways, answering
22 different questions in relation to the data, and the use of geographic kernel explicitly
23 addresses Tobler’s first law of geography by considering geographic context. In this
24 way the methods explicitly address the ‘geographic approach’ to quality assurance of
25 data created by citizens suggested by Goodchild and Li [14].

36 **3. Methods**

37
38
39

40 In overview, crowdsourced land cover data from the Geo-Wiki initiative [15] were
41 analysed using geographically weighted evidence combination approaches to infer the
42 actual land cover class present at each location on a 50km grid. These were applied
43 under a series of different kernel sizes. At each location on the grid, data falling under
44 the kernel were weighted by their distance to the kernel centre and this *evidence* was
45 then combined using different methods.
46
47
48
49
50
51
52

53 **3.1 Data and study area**

54
55
56

57 This analysis used Geo-Wiki land cover data. The Geo-Wiki initiative [15] collects
58 volunteered data on land cover in order to support a number of activities that range
59 from land cover data validation to land cover data creation [16]. Geo-Wiki has web
60
61
62
63
64
65

and smartphone app interfaces, is open to anyone and volunteers can contribute to different campaigns. In these they allocate what they observe from Google Earth imagery at a series of randomly selected locations, to one of a predefined set of 10 land cover classes. This legend was chosen to be consistent with the generalized land cover classes proposed by Herold et al. [34], which allows for comparison of different land cover products. More details of these competitions can be found in See et al. [35]. In order to provide some form of validation, the inferred land cover at each location on the 50km sampling grid was compared with GlobCover 2009², reclassified into the 10 classes and resampled to 50km. The reclassification was the same as that reported in [4]. It was devised by the Geo-Wiki team led by Steffen Fritz and the class to class relations were agreed by consensus by 3 experts using images and discussing them together. The GlobCover thematic aggregations are shown in Table 1. In this research, data from two Geo-Wiki campaigns were combined from 2011 and 2012 for a South American case study containing some 13,738 data out of a global datasets of 100,808 points. The study area, spatial distribution of Geo-Wiki data and the reclassified, spatially aggregated GlobCover data are shown in Figure 1. Note that geographically weighted approaches, as described below, develop local analyses of data that fall under a moving window or kernel. Thus the 50km grid provide a series of locations at which the local analyses take place, irrespective of the number of data points within each grid cell.

Geo-Wiki class	GlobCover class
(1) Tree cover	40, 50, 60, 70, 90, 100, 110, 160, 170
(2) Shrub cover	130
(3) Herbaceous / Grassland	120, 140

3.2 Geographically weighted crowdsourced data

A discontinuous geographic kernel was used to select crowdsourced data at each location on a 50km grid as shown in Figure 1. The idea was to use the land cover data points falling under the kernel to infer the land cover present at the centre of the kernel (i.e. a grid point), with data points further away from the kernel centre contributing less to the overall. The geographical extent of the kernel is determined by its bandwidth. In this analysis bandwidths from 5km to 150km at intervals of 5km were examined to explore the interactions of the evidence combination approaches with different scales of aggregation. Each crowdsourced data point records the contributor's opinion of the land cover at that location. It provides evidence in support of a hypothesis of the presence of that land cover class at the centre of the kernel. Each single piece of evidence was weighted according to its distance to the location under consideration (centre of the kernel) to produce a distinct geographically weighted crowdsourced data subset at every grid point. For the smallest bandwidths,

1 these localised data sets will be at their most local but relaying the least information.
2 For the largest bandwidths these localised data sets will be at their least local but
3 relaying the most information. This is the common bias-variance trade-off
4 encountered in any geographically weighted approach [8].
5
6
7

8
9 A number of discontinuous kernel functions can be specified as discussed in Gollini et
10 al [36]. In this study a tri-cube function was applied, rather than weights derived
11 under Gaussian or linear functions, as this generates a greater plateau of higher
12 weights near to the kernel centre with a sharp drop off at approximately half the
13 bandwidth. For each crowdsourced data point (P_j) under the kernel (with a given
14 bandwidth), a weight $w_{i,j}$ was calculated based on its distance to the centre of the
15 kernel (K_i) as follows:
16
17
18
19
20
21
22

$$23 \quad w_{i,j} = 1 - ((d_{i,j})^3/b^3) \quad (\text{Eqn 1})$$

24
25
26
27 where $d_{i,j}$ is the distance in metres from the centre of the kernel K_i to the
28 crowdsourced data point P_j and b is the bandwidth at that location. (Note that the tri-
29 cube kernel function specified here is not identical to that in Gollini et al [36] as they
30 incorrectly specified their function in that publication - Paul Harris, *pers com*). The
31 way that distances to the kernel centre are rescaled by Equation 1 to create distance
32 based weightings is shown in Figure 2 for a bandwidth of 1000.

3.3 Evidence combination methods

Four classic approaches for combining uncertain evidence were applied to the weighted data under the kernel: Bayesian Probability, a modified Dempster-Shafer, Fuzzy Sets and Possibility theory. These were compared with a geographically weighted average that simply calculated the proportions of all weights associated with each land cover class. The choice of evidence combination approaches was driven by their ability to handle / partition evidence uncertainty, and by the different ways that they do that, as well as the inability of classic statistical inferential approaches to reason under uncertainty. Some of these have been explored in the context of generating maps from Geo-Wiki data [37] including nearest neighbour, Naive Bayes, logistic regression, classification and regression trees.

In each analysis, the set of classes allocated to the crowdsourced data points under the kernel represent a set of hypotheses to be evaluated. The evidence combination approaches were applied and the degree to which each hypothesis of was supported at the location k_i under consideration was assessed.

A Bayesian approach provides a quantitative estimate of how much belief in a particular proposition or hypothesis h_c corresponding to class c increases (or

decreases) when a new piece of evidence, e , corresponding to the data provided by the crowdsourced data points, becomes available. Mathematically this is described for class c and point K_i by:

$$p(h_c|e)(i) = \frac{p(e|h_c)p(h_c)}{\sum_{k=1,m} p(e|h_k)p(h_k)} \quad (\text{Eqn 2})$$

where, $p(h_c)$ is the prior probability of hypothesis h_c and $p(h_c|e)$ is the posterior probability of hypothesis h_c , the evidence is e , and $p(e|h_c)$ is the probability of observing this evidence given that h_c is true and m is the number of classes. In this case, $p(e|h_c)$ was given by the weighted mean of the normalised distances $w_{i,j}$, between the location under consideration and the data points under the kernel that were assigned to class c . In this way Bayesian Probability computes a degree of belief in an uncertain hypothesis given the numerical evidence for itself and competing hypotheses. In this instance, the competing hypotheses relate to other land cover classes and posterior probabilities are computed for each land cover for location.

Dempster-Shafer is an extension of Bayes that allows for the situation where weak support for a proposition does not have to imply strong support for its negation. It assesses the belief that a proposition is provable given the evidence with some modifications (see below). Mathematically, for 2 pieces of evidence A and B , such as the weights assigned to data points of the same class, this is expressed as, the mass assignment, $m''(C)$ as follows

$$m''(C) = \sum_{A_i \cap B_j = C} m(A_i) \times m'(B_j) \frac{|C|}{|A_i| |B_j|} \quad (\text{Eqn 3})$$

where $m''(C)$, is equal to the sum of the product $m(A_i)$ and $m'(B_j)$ for all i and j such that that the intersection of sets A_i and B_j equals C . The Fixsen and Mahler modification [38], the $|C|$ etc in Equation 3, are the prior probabilities of the respective evidence sets. Dempster-Shafer does not consider the evidence hypothesis by hypothesis as Bayes does, rather the evidence is considered in light of all of the hypotheses. It generates two measures: Belief – the extent to which the evidence

1 supports the hypothesis in this case a particular land cover class – and Plausibility –
 2 the extent to which the evidence does not refute the hypothesis, i.e. Belief with
 3 Uncertainty. In this analysis, individual pieces of evidence were created from each of
 4 the crowdsourced data points under the kernel. The weight, w generated by Equation
 5 1 was assigned to the class recorded in the individual crowdsourced data point and $(1$
 6 $- w)$ was allocated to the set of all possible hypotheses for which there is evidence,
 7 the frame of discernment. The evidence was then combined using Equation 3.
 8
 9
 10
 11
 12
 13

14 Fuzzy Set theory develops models of uncertainty based on the degree to which the
 15 combined evidence indicates membership to the set under consideration (e.g. the
 16 membership to a land cover class). The support for different hypotheses can be
 17 evaluated using a suite of methods in fuzzy theory from (simple) weighted linear or
 18 convex combination of evidence to (more complex) ordered weighted averaging.
 19 Fisher [39] noted that the minimum interval is the standard approach for combining
 20 information in fuzzy sets but is counter-intuitive when it is used to compare different
 21 land cover classes – it only makes sense in the context of fuzzy land cover when
 22 comparing fuzzy sets of the same. For these reasons a number of alternative operators
 23 have been suggested. In this case the fuzzy memberships were defined using the
 24 weights, $w_{i,j}$, defined in Equation 1 which were transformed into fuzzy memberships,
 25 $F_c(i)$ for each land cover class c at the centre i of each kernel, in the following way:
 26
 27
 28
 29
 30
 31
 32
 33
 34
 35
 36
 37

$$38 \quad F_c(i) = \sum_{\substack{k=j \\ P_j \text{ classified as } c}} w_{i,k}/n_c \quad (\text{Eqn 4})$$

39 where $w_{i,j}$ are the weights derived from the Gaussian transformed distances described
 40 in Equation 1 considering the crowdsourced points P_j classified as class c by the
 41 crowd and n_c is the number of crowdsourced data points of class c .

52 Possibility Theory examines the maximum amount of support for a hypothesis (e.g.
 53 the membership to a particular land cover class) using a supremum or Possibility
 54 function and an associated uncertainty measure given by a Necessity function [40].
 55 Possibility Theory uses a supremum function (or least upper bound) that relates to the
 56 maximum support for any given hypothesis, x . The possibility function, $Poss(X)$ is the

supremum of $Poss(\{x\})$, where x are the set of elements of X and X is the set of all hypotheses.

$$Poss(\mathbf{h}) = 1 - Max(w_{i,j}) \quad (\text{Eqn 5})$$

The uncertainty associated with X is given by the corresponding necessity function (Nec). The relationship between Necessity and Possibility, in relationship to an hypothesis, \mathbf{h} , is defined as:

$$Nec(\mathbf{h}) = 1 - Max(Poss(\neg\mathbf{h})) \quad (\text{Eqn 6})$$

where $(\neg\mathbf{h})$ describes 'not \mathbf{h} '. In this way the Necessity function (Nec) gives a simple measure of the certainty of the Possibility measure relative to competing hypotheses. In this case the Possibility of the location under the kernel being any given class (i.e the hypothesis, \mathbf{h}) was determined from the maximum weight value for that class and the Necessity was calculated as above.

Finally a simple geographically weighted average (GW Average) was applied which summed the weights for each class and divided these by the sum of all weights under the kernel.

In summary, at each location in the sample grid each of the geographically weighted evidence approach approaches generated a belief in a hypothesis of the presence of each land cover class at that location. At each location the land cover with the greatest belief was identified for each method and was compared with the GlobCover 2009 land cover class. A correspondence matrix was created and the overall correspondence for that method was calculated from the diagonals. Any locations where no land cover class was allocated (ie they were classified as *NULL*) were omitted for the correspondence analyses. This was done for each of the kernel bandwidths.

All of the analyses were undertaken in R 3.2.1, the open source software (<http://cran.r-project.org>) with extensive spatial analysis and mapping functionality. The code and data used in this analysis will be provided on request.

3.4 Worked Example

Consider the following single location on the 50km sample grid described above. There are 20 data points under a 50km kernel at that location as in Figure 3. Each of these has been labelled with a land cover class and contributes evidence in support of an inference about the land cover at that location. The evidence for each point is weighted by its distance to the kernel centre, and the weights are combined using the formalisms described above. Table 1 shows the support or belief associated with the candidate hypotheses.

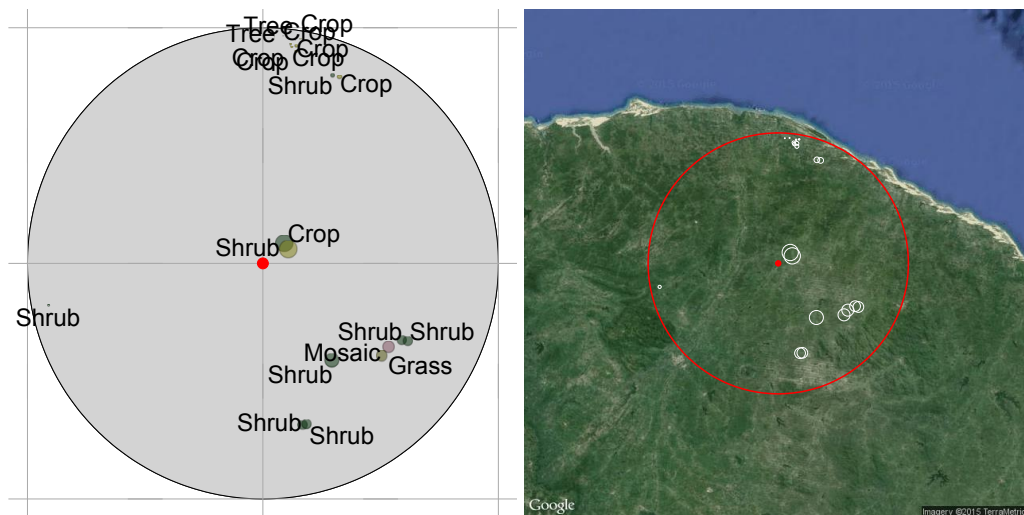

Figure 3. The location being considered in red, the crowdsourced land cover data points with class labels and a small random term added to their location (left figure) and with a Google image as context (right figure). In both figures the size of the data points are related to their distance to the kernel centre and therefore their weight.

Class	Class frequency	Dempster Shafer	Bayesian Probability	Fuzzy Sets	Possibility Theory	GW Average
Tree	2	0.000	0.000	0.000	0.001	0.000
Shrub	8	1.000	1.000	0.273	0.996	0.599
Grass	1	0.000	0.000	0.311	0.402	0.085
Crop	8	0.000	0.000	0.105	0.996	0.230
Flood	1	0.000	0.000	0.311	0.402	0.085
Urban	0	0.000	0.000	0.000	0.000	0.000
Snow	0	0.000	0.000	0.000	0.000	0.000

Barren	0	0.000	0.000	0.000	0.000	0.000
Water	0	0.000	0.000	0.000	0.000	0.000

Table 1. The inferences (beliefs, probabilities, memberships, possibilities) of the land cover present derived from the evidence combination approaches for the worked example.

This generates an interesting set of results: Dempster-Shafer and the Bayes fully support the hypothesis that the class is *Shrub*, and this is driven by the greater weights compared to the *Crop* class. For Fuzzy Sets approach the inference of *Crop* or *Shrub* class is weakened by the presence weaker weights associated with the data points at the edge of the kernel. Possibility has very strong belief in a hypothesis of *Crop* and of *Shrub* but also has some belief in the possibility of the class being *Flood* or *Grass*. The GW Average approach identifies *Shrub* as having the greatest mass of weighted evidence. Possibility Theory, Fuzzy Sets and GW Average indicate some degree of uncertainty in the inference with more than 1 hypothesis have a high degree of support in this example.

4. Results

4.1 Comparison with reference data

The analyses were run for 30 bandwidths of 5km to 150km in intervals of 5km. At each location on a 50km grid and for each evidence combination method, the class with the greatest support was identified and compared with the land cover class at the same location from the aggregated Globcover 2009 dataset. The overall correspondences for each combination method were calculated and the results are shown in Figure 4. This shows a general trend of increasing rates of correspondence with increasing kernel bandwidth for Dempster-Shafer, Bayes and GW Average. The geographically weighted average has the greatest correspondence regardless of bandwidth and Fuzzy Sets decreases with increased bandwidth (and therefore the number of data points being considered at each location) and Possibility plateaus around a kernel bandwidth of 75km.

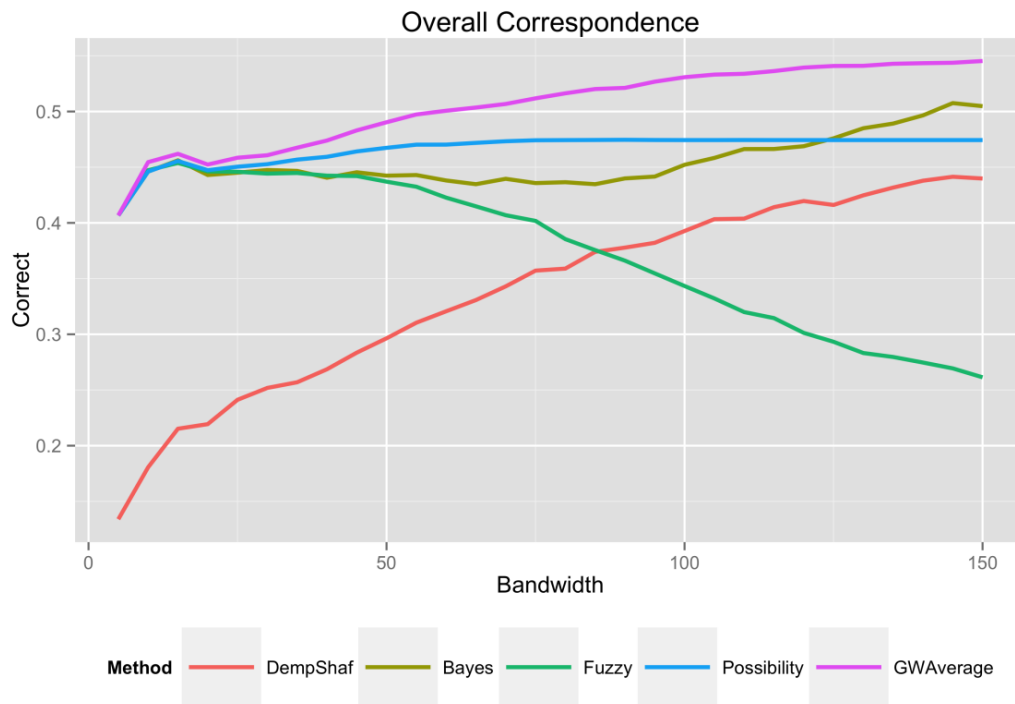

Figure 4. The trends in correspondence with GlobCover for the different evidence combination approaches as kernel bandwidth increases.

It is also instructive to consider how the correspondences vary for different land cover classes: the case study area has a particular mix of cover types and scales of ecological and anthropogenic processes. The per class correspondences were calculated from collapsed correspondence matrices (ie describing binary classes of *Class* and *Not-Class*) to determine the degree to which an inference about the presence or absence of a particular land cover class was reflected in the reference data. The results are not therefore directly comparable with the data in Figure 4. The per class correspondences are shown in Figure 5, plotted with the same Y-axis. This clearly shows that for some classes bandwidth does not matter (*Urban, Flood, Snow*) regardless of evidence combination method. It also shows that for some classes bandwidth is important (*Mosaic, Grass*) and that for some classes the importance of bandwidth depends on the evidence combination method. For example under Dempster-Shafer, *Grass* corresponds well at small bandwidths and *Water* poorly at except larger bandwidths. Table 2 summaries bandwidth and evidence combinations that generate the highest correspondences for each class.

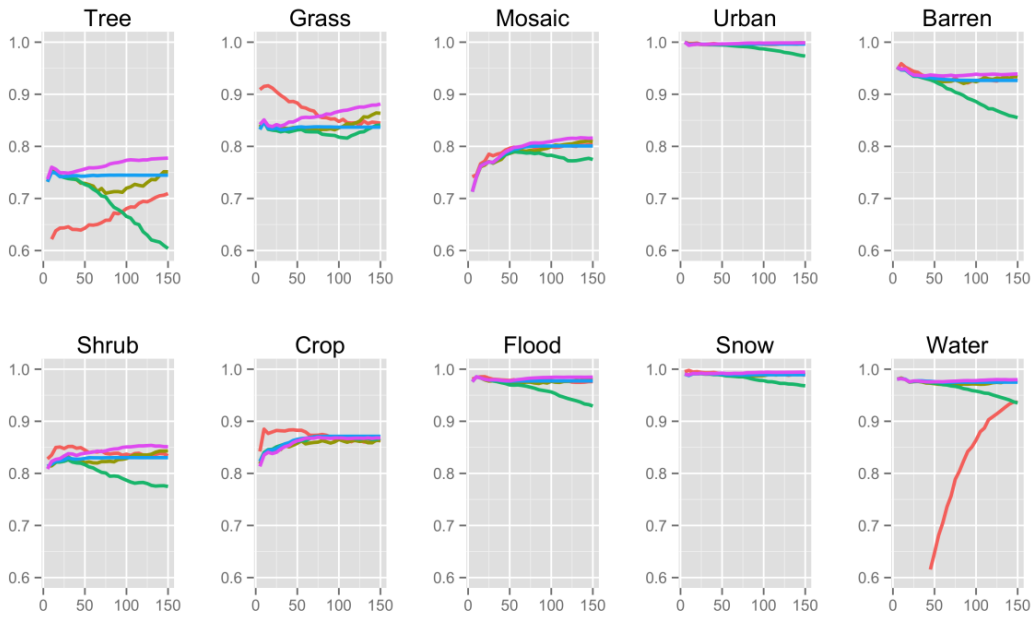

Figure 5. The per class correspondences for the different evidence combination approaches with increasing kernel bandwidth.

Class	Class	Bandwidth (km)	Method
Tree	1	150	GW Average
Shrub	2	130	GW Average
Grass	3	15	Dempster-Shafer
Crop	4	10	Dempster-Shafer
Mosaic	5	135	GW Average
Flood	6	20	Dempster-Shafer
Urban	7	5	Dempster-Shafer
Snow	8	10	Dempster-Shafer
Barren	9	10	Dempster-Shafer
Water	10	10	Bayesian Probability

Table 2. The bandwidth and evidence combination combinations that produce the highest correspondences with the reference data for each class

It is possible to generate maps of the land cover with the highest levels of belief generated by each approach. Figure 6 a) to d) shows the maps of these under 10km, 50km 100km and 150km kernels. These illustrate the interaction of the evidence combination approach and bandwidth (and of course the reference data). A number of trends are evident:

- 10km kernel: there is a large amount of land classified as *NULL* (in grey) because of an insufficient number of crowdsourced data points falling under the kernel. As the

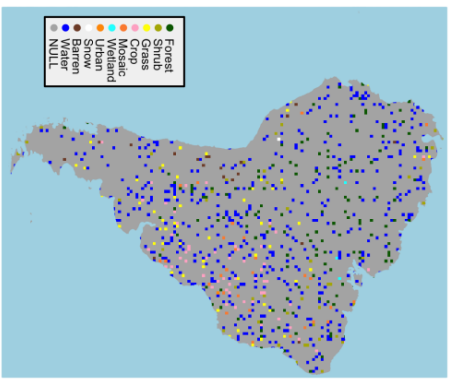

1 kernel size increases the *NULL* data decreases (note that any areas classified as *NULL*
2 were omitted for them correspondence analyses above).

3 - 50km kernel: the land cover patterns (spatial distributions) start to become more
4 similar to the reference data, with fewer *NULL* areas, with some spatial heterogeneity.
5

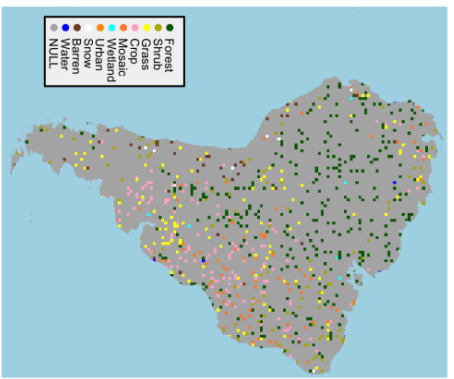

6 In many areas the Dempster-Shafer analysis identified *Water* as the class with the
7 greatest degree of belief (in blue). However, it is important to remember that the
8 Dempster-Shafer results are only considering the support for the singleton class
9 hypotheses. The maps from the other approaches start to resemble the reference data
10 but still with some large unclassified areas.
11

12 - 100km kernel: the differences between land cover are apparent with this kernel. All
13 of the approaches are converging on the reference data, but with Fuzzy sets showing a
14 much greater degree of divergence than the others and GW Average a much greater
15 degree of smoothing.
16

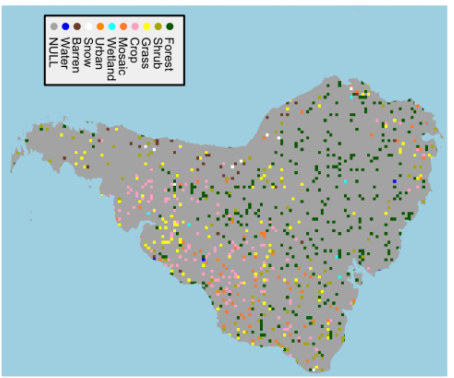

17 - 150km kernel. This trend continues with the largest kernel. Fuzzy generates
18 numerous large, heterogeneous, aggregated areas and GW Average may be over-
19 generalising (smoothing) the data. Visually the Possibility and Bayes approaches have
20 the closest spatial similarity to the reference data.

Figure 6 a to d). Maps of the land cover with the greatest belief under different evidence combination approaches and kernel sizes.

4.2 Soft classifications

It is important to remember that all of the evidence approaches generate measures of belief in the hypotheses in the interval $[0,1]$. These beliefs (or memberships) in land cover can be mapped to indicate the uncertainty associated with the competing inferences about the land covers that are present. To illustrate the outputs of such classifications, the maps in Figure 7 shows the belief in the presence of the *Tree* land cover class arising from different approaches under kernels of 80km and 100km with local detail in the north of the study area. This class was chosen to illustrate the soft, uncertain classifications because it is the most numerous in the crowdsourced data with some 5,466 points. Other classes exhibit similar but sparser spatial structures under the different evidence combination approaches.

1 There are consistent spatial trends across the different bandwidths and the different
2 evidence combination approaches. In each case a pattern similar to the distribution of
3 Tree land cover in Figure 1 is evident. As bandwidth increases there are also some
4 discernable trends in the patterns of inference associated with each of the methods.
5 Generally, as the kernel size increases the clusters of inferred land cover increase in
6 size – they become more clumped. This is to be expected because of the way that data
7 under the kernel are brought together, in a way similar to a smoothing operation.
8 Within this, the different approaches aggregate evidence in different ways which
9 relate to their logics. The modified Dempster-Shafer generates discrete clumps of high
10 belief, with clear areas of low belief between. Bayes shows similar patterns, with
11 larger clusters at wider bandwidths. There are fewer extreme beliefs, in this case
12 memberships to the set of *Tree*, in the Fuzzy Sets approach and therefore many fewer
13 clusters. This is interesting: the Fuzzy approach does not cleave the evidence into
14 belief and disbelief as does Bayes and Dempster-Shafer when there is high consensus
15 among the data points. This is because the belief in any hypothesis of fuzzy set
16 membership is diluted by the presence of other data points of the same class points
17 near the edge of the kernel. The Possibility function generates beliefs that relate to the
18 distance from the kernel centre of the nearest data point of the class being considered,
19 and thus the class with maximum Possibility is the one that has the data point closest
20 to the kernel centre. This is effectively “nearest point wins”. Possibility produces very
21 large clusters of high possibility especially at the larger bandwidths as a consequence.

41 **5. Discussion and Conclusions**

42
43
44
45 The main aims of this paper were two-fold. The first was to develop, apply and
46 evaluate novel geographically weighted evidence combination approaches for
47 integrating conflicting information. The mapped results show how these methods are able to
48 make inferences about the presence of specific land cover types at each location and
49 how each approach describes the distribution of land cover, but with different
50 spatial characteristics and interactions with the kernel bandwidth. Generally there was
51 much greater smoothing of land cover clusters under Possibility Theory, more
52 cleaving of the evidence into high and low belief under Dempster-Shafer and fewer
53 clusters of extreme Fuzzy Set memberships especially at larger kernel bandwidths.

65

1 Analysing the correspondence with the reference data suggests that GW Average is
2 the most reliable approach regardless of bandwidth, although this statement has to be
3 qualified with 2 observations. First that we do not know how reliable the reference
4 data were: a different global dataset may well have generated different results. In a
5 similar vein, the approach here was to ‘crisp off’ combined belief (essentially soft
6 classifications) into Boolean classes. This is to ignore much of the uncertainty
7 embedded in the belief in different land cover class hypotheses. Further work is
8 needed to compare the inferences arising from combining crowdsourced data with
9 soft references data in the manner suggested by Fisher et al [39] and Comber et al [41]
10 and to evaluate frames or subsets of classes such as are generated by Dempster-Shafer
11 approaches. Second, that for some land cover classes other evidence combination
12 approaches performed better as in Table 2. This may be because of the greater
13 ambiguity over what, for example, the class of *Barren* means and uncertain
14 conceptualisations of that class by different contributors, or as a result of different
15 densities of crowdsourced data or because of the interaction of these factors. On-
16 going work is exploring some of the semantic and spatial issues. However, the overall
17 performance of the GW Average approach is an important finding as this method is
18 used in most of the reported and current applications analysing Geo-Wiki data [eg 35,
19 37].

23
24
25
26
27
28
29
30
31
32
33
34
35
36 There is a paucity of approaches for dealing with conflicts in data generated by
37 crowdsourcing and citizen science activities. Previous research has dealt with
38 inconsistent data by applying a majority rules approach [13] with more recent work
39 exploring, for example, latency analyses [12] outlier identification classification [42]
40 as well as classic inferential statistics [37]. These approaches have sought to identify
41 inconsistent data so that it can be excluded from the analysis. However, the outliers
42 may tell us something about the uncertainty of the pure, crisp land cover in that
43 location. Thus a second aim of this research was explore how methods that explicitly
44 reasoned under uncertain information handled conflicting data. If crowdsourced data
45 are to be used in scientific analyses then a full panoply of approaches for handling
46 information uncertainty are needed in the absence of formal experimental design in
47 data collection, training, calibration and validation. This paper was very much
48 concerned with methods for managing conflict and not just excluding conflicting data
49 from analyses. This is a critical issue in the context of non-expert crowdsourced
50

1 citizen science since it deals with the issue of how to move beyond simple majorities
2 if, for example (most of) the crowd are all similarly confused. The results of this work
3 suggest that all of the approaches under an appropriate bandwidth are able to
4 accommodate such conflicts. The maps and other figures illustrates how they treat
5 conflicting evidence: Bayesian Probability pushes evidence into belief and disbelief
6 indicating *what is there*, Dempster-Shafer pushes it into belief and plausibility
7 indicating *what is not excluded from being there*, Fuzzy Sets generates a set
8 memberships to the hypothesis under consideration and indicates *what combinations*
9 *of things is there* and Possibility Theory indicates *what could be there*. The GW
10 Average provides a distance weighted majority rules approach.
11
12
13
14
15
16
17
18

19
20 There are a couple of further issues to note. First, here a number of bandwidths were
21 explored. Methods exist for selecting the bandwidth automatically, for example using
22 a leave-one-out cross validation procedure which optimises the prediction probability
23 for each individual data point when it is removed from the dataset. As a result,
24 optimal bandwidths may therefore be class-specific which will be explored in future
25 work. However these approaches are based on variance evaluations and may not be
26 appropriate for this kind of analysis with this kind of data. Second, the results only
27 indicate the *belief* in the hypotheses, that is the extent to which the evidence supports
28 the different hypotheses. Whereas, any uncertainty arising from the evidence is
29 implicitly included in the Fuzzy Sets memberships and is absent in Bayesian
30 Probability which partitions evidence into belief and disbelief (*what is there*), this is
31 not the case for Dempster-Shafer and Possibility Theory. The former generates a
32 measure of Plausibility describing the extent to which the evidence does not refute the
33 hypothesis – that is belief plus uncertainty. The latter generates a Necessity measure
34 describing the certainty of the belief measure relative to competing hypotheses, with
35 the effect that the lower the Necessity value, the more competition there is. Finally a
36 number of scale factors interact to generate the results under each evidence
37 combination approach. These include bandwidth, sampling grid and the granularity of
38 the data that are collected through a Google Earth interface. Future work will address
39 these issues and will explore the analysis of user confidences in their contributions to
40 provide a second weighting to complement distance weights. Future work will also
41 explore the development of a contributed R package to provide a generic
42 geographically weighted framework to support other research activities. In this work

1 bespoke code had to be developed but the provision of a suite of functions that
2 returned geographically weighted data or even geographically weighted functions
3 would be of great interest to the research community.
4
5
6

7 In conclusion, this work has suggested that the GW Average approach provides the
8 most reliable oval approach for combining crowdsourced land cover data such as are
9 collected by the Geo-Wiki initiative. There are some caveats to this statement relating
10 to the need for comparisons with soft (e.g. fuzzy) reference data and the examination
11 of the inherent conceptual and semantic ambiguity of some classes at specific grains
12 of analysis. However, the methods and results demonstrate the opportunities for
13 generating localised measures of belief to support assessments of crowdsourced data
14 quality and uncertainty. The geographically weighted evidence combination methods
15 (Dempster-Shafer, Bayesian Probability, Fuzzy Sets and Possibility Theory, GW
16 Average) provide a suite of approaches for assessing belief and for combining
17 conflicting information when mining large crowdsourced datasets, whether the data
18 are contributed actively such as in Geo-Wiki or passively like much social network
19 data. The application of a geographically weighted kernel explicitly addresses the
20 need to consider Tobler's first law of geography when mining and combining
21 crowdsourced data, reflecting the expectation that similar features and process will be
22 clustered and not randomly distributed. The approach of a geographically weighted
23 framework with evidence combination approaches allow more nuanced inferences
24 about the quality of volunteered information to be generated than simple majorities
25 and support the exploitation of large volumes of crowdsourced data about all kinds of
26 phenomenon.

Alexis Comber is the Professor of Spatial Data Analytics at the University of Leeds, UK. His research develops methods to integrate and analyse high volumes of spatial data in order to uncover hidden patterns and to provide spatial insight for social and environmental applications. The context for this work massive increase in spatially referenced data from GPS-enabled mobile devices as well as the increased availability of more traditional data through open data initiatives. He has recently published the first introductory text book for developing spatial analyses in R (*An Introduction to R for Spatial Analysis and Mapping*, Sage,)

Cidália C. Fonte has a PhD in Geomatic Engineering and is an assistant professor at the Department of Mathematics of the Faculty of Sciences and Technology and a researcher at the Institute for Systems Engineering and Computers at the University of Coimbra, Portugal. Her main research interests are quality assessment of geographic information and uncertainty modeling with applications in areas related to the classification of multispectral images and the quality aspects related to the collection and use of Volunteered Geographic Information.

Giles Foody is currently Head of the School of Geography at the University of Nottingham, UK and Professor of Geographical Information Science. His main research interests focus on the interface between remote sensing, ecology, and informatics. He is co-chair of the EU COST network: Mapping and the Citizen Sensor.

Paul Harris is an Eco-Informatics Scientist at Rothamsted Research, UK. His main research interest is the development and application of spatial statistical methods to studies in agriculture for addressing issues of sustainable intensification. He is the coordinator of the 'GWModel' package implemented in R, the open source statistical software.

Steffen Fritz is head of the Earth Observation Systems (EOS) group in the Ecosystems Services and Management (ESM) Program at the International Institute for Applied Systems Analysis (IIASA) in Austria. He is the Coordinator of a European Research Council (ERC) grant entitled 'Harnessing the power of crowdsourcing to improve land cover and land-use Information'. Dr. Fritz is the driving force behind Geo-wiki.org, a global land cover validation tool based on Web 2.0 and crowdsourcing. He also participates in the GEO Working Groups on Data Sharing and Global Land Cover Validation and is co-chair of the EU COST network: Mapping and the Citizen Sensor.

Ana-Maria Olteanu-Raimond received a PhD degree in Computer science and GIS from Paris-Est University in 2008. She is currently a senior researcher at IGN, France. Her research is focused on citizen derived data (quality, change detection in vector, spatial data matching, data fusion) and the application of Belief Theory and uncertainty modelling to decision making. She is actively involved in the COST Action TD1202 "Mapping and the citizen sensors" and leads the WG3 where researchers and national mapping agencies are working together.

Linda See is a Research Scholar in the Ecosystems Services and Management (ESM) Program at the International Institute for Applied Systems Analysis (IIASA) in Austria. She has a PhD in spatial applications of fuzzy logic from the University of Leeds, where she was a Senior Lecturer in Computational Geography and GIS for more than a decade. She is an active member of the Geo-Wiki team and has worked on a number of crowdsourcing aspects including quality issues, community building, and a branch of Geo-Wiki concerned with validation of urban land cover.
