Abstract

As more urban solid waste is generated, managing it becomes ever more challenging and the potential impacts on the environment and human health become greater. Handling waste – including collection, treatment and final disposal – carries risks of work accidents. This article assesses the perception of waste management workers in Belo Horizonte, Brazil, in domestic and health service contexts regarding work-related accidents. These are compared with national data from the Ministry of Social Security on accidents involving workers in solid waste management. A high proportion of accidents involves cuts and puncture injuries; 53.9% among workers exposed to domestic waste and 75% among those exposed to health service waste. Muscular lesions and fractures accounted for 25.7% and 12.5% of accidents, respectively. Data from the Ministry of Social Security diverge from the local survey results, presumably owing to under-reporting, which is frequent in this sector. Greater commitment is needed from managers

and supervisory entities to ensure that effective measures are taken to protect workers' health and quality of life. Moreover, workers should defend their right to demand an accurate registry of accidents in addition to monitoring by health professionals trained in risk identification. This will contribute to the better recovery of injured workers and will require managers in waste management to prepare effective preventive action.

Keywords: accidents, occupational risks, solid waste, domestic waste, healthcare waste, occupational accidents registry.

Introduction

As more solid waste is generated, managing it in urban areas becomes more challenging owing to greater potential impacts on the environment and human health. Professionals in solid waste management are considered to be exposed to potential health risks. Their frequent exposure to hazardous materials makes waste collection a potentially unhealthy activity (Poulsen *et al.*, 1995; An *et al.*, 1999; Santos & Silva, 2011). Human contact with waste implies biological, chemical and physical risks to the health of workers involved mainly in waste collection and transportation. Notable factors are associated with exposure to solar radiation, excessive muscular strain, pathogens, such as bacteria, fungi, viruses and parasites, in addition to toxic chemical substances (Rushton, 2003; Wouters *et al.*, 2006; Oliveira, 2007; Domingo & Nadal, 2009).

Other relevant aspects associated with waste collectors' vulnerability to work accidents have to do with the inappropriate conditions in which waste is kept, the type of truck used in collection and the often precarious conditions of public urban roadways (Oliveira, 2007). Furthermore, collection hours often coincide with peak traffic hours, implying risks of traffic accidents with vehicles or personnel (Velloso *et al.*, 1997).

In many developing countries, waste collection is still carried out in precarious conditions. Waste collection professionals generally work outdoors and in direct contact with frequently inappropriately conditioned materials containing sharps and corrosive objects. Excess weight

further increases the risk of muscular injuries in several regions of the body. Moreover, with waste collection often being carried out at high speeds, the risks are high for work accidents possibly involving sharp-related injuries and muscular or spinal cord problems (Silva *et al.*, 2014).

Cleaning staff in hospital facilities report a significant amount of accidents, as demonstrated in several studies (Santos & Silva, 2011; Dias *et al.*, 2012; Blenkharn & Odd, 2008; Vieira *et al.*, 2011; Lima *et al.*, 2011; Giancotti *et al.*, 2014; Borges *et al.*, 2013; Costa, 2007), indicating that locations subject to periodic verifications by sanitary surveillance entities are nevertheless at-risk environments. Urban waste management is even more critical due to the careless way in which waste is deposited by those generating it and by the high speeds at which it is often collected. In sum, workers are exposed to constant danger.

This article aims to assess the vision of waste collection workers in Belo Horizonte, Brazil, regarding their exposure to waste and possible health impacts. It focuses on the accounts of their work accidents as related via a questionnaire. To better apprehend the gathered information, data from the Ministry of Social Security was also compiled on work accidents throughout the country. That data served as a reference for discussion and for possible public health interventions based on the association between work and the health-disease process.

Methods

The methods adopted in this research consist of a questionnaire applied to workers in domestic waste collection and healthcare waste (HCW) collection in Belo Horizonte, Brazil, and data from Brazil's Social Security work accident registry. Sample size calculation was based on the Kelsey model (DEAN et al, 2013) adopting the ratio of eight domestic waste workers for each healthcare waste worker. This ratio was adopted due to the small number of healthcare waste workers in the city where the study took place.

Questionnaires

The structured questionnaires were applied between November 2014 and January 2015 by the researcher and ten other duly trained volunteers. Worker participation in the study suffered losses owing to unwillingness or no-shows on the scheduled dates for interview. In total, 61 workers exposed to HCW and 461 workers exposed to domestic waste participated in the study. Workers were invited to participate in the research study after having been informed on how the structured questionnaire would be applied. With the participants' understanding and consent, each of them filled out an informed consent form (*Termo de Consentimento Livre e Esclarecido* – TCLE in Brazil).

Among the subjects of interest, notable aspects were those related to the occupational conditions of task execution, types of accidents already having occurred while on the job, exposure times and potential impacts on health. Other factors of interest included workers' personal characteristics, such as gender, race, level of education and family income. The research was

carried out in conformity with the ethical requirements determined by the National Research Ethics Committee (CONEP/CNS in Brazil) and were approved by the Research Ethics Committee at the Federal University of Minas Gerais, on 18 June 2014, under protocol CAAE – 28018714.6.0000.5149.

The main criteria for inclusion in the study was the type of activity performed by workers: those considered to be “exposed” handled HCW while domestic waste workers were “unexposed”. All individuals exposed to waste were included independently of how long they had been working, their age or their gender.

The analysis of the questionnaire data was performed with R software, version 3.2.0. For comparison of categorical variables according to the type of waste handled by the worker, the Chi-Square test was applied and also, when necessary, Fisher’s Exact Test (Agresti, 2003).

Occupational accident registration

Work accidents registered with official Brazilian authorities were also used as a source of data. Groups of workers were separated between those responsible for collection and those carrying out treatment and final disposal. The categories of the Brazilian National Classification of Economic Activities (CNAE in Brazil) selected to describe these groups were 3811 (collectors of non-dangerous solid waste, i.e. similar to domestic waste), 3812 (collectors of dangerous solid waste, i.e. flammable, corrosive, reactive, toxic or pathogenic, in accordance with ABTN (2004) standard 10004/2004), 3821 (workers responsible for treatment and disposal of non-

dangerous waste) and 3822 (workers responsible for treatment and disposal of dangerous waste).

Results

Brazil's Social Security data registered a total of 2 152 524 accidents nationwide for all classes of workers in the period between 2011 and 2013. For workers collecting, treating or disposing of domestic and/or dangerous waste, 27 460 accidents were registered nationwide in the same period, representing less than 1% of the total. Only in 2013, with 7 056 registered cases, accidents registered by workers collecting non-dangerous waste were the 14th most frequent type in that year compared to all other registered activities (Brasil, 2015).

The sicknesses and accidents most frequently associated with solid waste management may be estimated by means of the benefits attributed by the INSS, bearing in mind that activities associated with CNAE and cases of underreporting interfere in the representativeness of the results. TABLE 1 presents benefits grants according to their causes. Data related to workers exposed to dangerous waste were not included due to the considerable absence of registered cases.

In addition to the granting of benefits, the incidence of occupational illnesses or accidents were also used as indicators to assess negative impacts on worker health, as expressed in TABLE 2. It may be noted that the frequency of occupational sicknesses observed among workers in non-

dangerous waste treatment and disposal was greater than in the remaining groups in the same periods.

Questionnaire responses

The structured questionnaire that was applied to waste collection workers in Belo Horizonte, Brazil, provided elements to better understand domestic and health service waste collection from the point of view of these professionals. Among the participants, 461 (88.3%) collected domestic waste and 61 (11.7%) collected health service waste. Regarding gender, 21.5% (112) of participants were women and 78.5% (410) were men. Regarding race, 34.2 % (178) declared themselves black, 47.0% (245) brown or mulatto, 2.9% (15) indigenous or metis, and 15.9% (83) white or yellow. Regarding participants' level of education, eight (1.5%) individuals reported illiteracy, while the vast majority, 64.2% (335), had completed primary-level education and 33.7% (176) had completed at least a secondary-level. The median age of participants was 35 years.

TABLE 3 presents a few aspects related to participants' self-reported use of personal protective equipment (PPE). Being the subject of a security standard that is obligatory under national legislation (Brasil, 2015; Brasil, 2005), there may be information bias owing to participants' fear of reporting their own infraction. However, a significant number of accounts nevertheless reported that activities were executed without the appropriate use of PPE.

Regarding the frequency of work accidents, TABLE 4 indicates that 33.2% of workers exposed to domestic waste reported having suffered some type of accident, while this was the case for 26.2% of workers handling HCW. In assessing workers' perception of health-related nuisances, workers were asked if they felt discomfort in a certain part of their body as a result of excess

weight or wear related to their occupation. The information provided indicated that the spinal cord and the inferior members of the body were those presenting the greatest discomforts, while no statistically significant difference was identified between those exposed to domestic waste or HCW.

Risk factors considered to be present in the work routine and potentially harmful to health were also investigated, as presented in TABLE 5. The responses vary, indicating differences in the participants' perspectives. Nevertheless, the available information suggests that some dangers to which workers are exposed are not well recognized.

Discussion

Data from Social Security indicate that the granting of benefits is high in Brazil for workers handling non-dangerous waste. Muscular injuries, poisoning and other external causes, damage to the musculoskeletal system and connective tissue account virtually always for more than 30% of the total benefits paid out between 2010 and 2013.

TABLE 1 indicates low rates of benefit disbursements for infectious and parasitic diseases as they represent less than 3% of total benefits disbursed to workers exposed to non-dangerous waste. That information coincides with other research indicating a low prevalence of infectious diseases, relative to the prevalence of occupational injuries, in association with waste management (Rushton, 2003; Porta, *et al.*, 2009).

The benefits disbursed to collectors of non-dangerous waste were high specifically for the injury group comprising lesions, poisoning and other consequences from external causes, these three sub-categories making up 30% of the total. This overall category accounts for a great deal of the most common accidents among waste collectors: those provoked by sharps, traffic accidents or falls from the collection vehicle (Lazzari & Reis, 2011; Ferreira & Anjos, 2001). Such accidents may possibly derive from a lack of training and may be aggravated by high worker turnover and overall inadequate work conditions.

Benefits distributed for diverse damage to the musculoskeletal system and connective tissue were significantly high for workers in the collection, transport and treatment of non-dangerous

waste, accounting for more than 20% of all registered accidents in 2013. That possibly derives from the excessive strain that is inherent to the working conditions. Indeed, some authors assert that lifting excess weight is frequent in waste collection workers' routine and, moreover, that their work rhythm is fast and constant. Other aggravating factors contributing to such stressors include workers' efforts to climb up and down ladders, and the vibration created by collection trucks (Oliveira, 2007; Velloso, *et al.*, 1997; Costa, 2007; Ferreira & Anjos, 2001).

The rate of workers having been temporarily incapacitated from a work accident was higher for workers collecting, treating and disposing of non-dangerous waste than it was for those exposed to dangerous waste (TABLE 2).

For the year 2012, mortality rates (per 100,000 contacts with waste) for the activities of dangerous waste collection, non-dangerous waste collection, and non-dangerous waste treatment/disposal were, respectively, 25.21, 16.84, and 14.04. Those values are greater than the country's total mortality rate for the same year, which was 6.60. The fatality rate for dangerous waste collection was also greater (10.99) than the national average of registered accidents (3.88). In this way, exposure to waste is demonstrably dangerous as compared to non-exposure (Domingo & Nadal, 2009; Porta, *et al.*, 2009; Athanasiou, *et al.*, 2010).

It is complex to determine the representativeness of the findings, mainly owing to high underreporting of work accidents, which is common in several professions in Brazil (Binder & Cordeiro, 2003). Among the possible factors that can influence the rate of accidents with waste

handlers, notable ones are: inadequate training of workers; negligence during the work routine; the informality of this profession; inadequate working conditions and infrastructure. Underreporting of work accidents in Brazil – and worldwide – is frequent, especially for less serious accidents and those occurring in less developed areas (Englehardt *et al.*, 2003; Correa & Assunção, 2003).

Regarding the use of personal protective equipment, 93.5% and 97.6% among those exposed to domestic waste declared that they use gloves and boots, respectively. For those exposed to HCW, those percentages were 98.4% and 100.0%. In a separate research study in Ethiopia, involving waste collection workers in hospital settings, 41.3% of individuals did not use such equipment regularly due to its unavailability or difficulty in using it related to discomfort in the performance of their tasks (Shiferaw *et al.*, 2011).

Differences may be expected regarding the types of protective equipment used by workers handling domestic or health service waste. Domestic waste collectors generally work with trucks and use different equipment than workers who collect HCW. The use of masks and aprons was more common for workers handling HCW and was reported infrequently among domestic waste collection workers. The use of sun block also presented particularities depending on the work hours and where the work activities are carried out.

Liquid splashes during waste collection are another type of danger that workers are exposed to. Among domestic waste collectors, 33.3% declared having been exposed to at least one splash,

while 37.7% of health service collectors declared the same. Similar studies in other countries reported that 23.2% and 27.8% of domestic and hospital waste collectors, respectively, had been exposed to foreign bodily liquids during their work duties (Shiferaw *et al.*, 2011; Luksamijarulkul *et al.*, 2008). Another study focusing on hospital environments identified that 44.0% of workers collecting HCW reported exposure to bodily liquids (Anagaw *et al.*, 2012). Bodily liquids are often found in both domestic and health service waste, and can present a potential risk of infection. Particularly, strains of the hepatitis virus can persist in the environment and a dose capable of causing infection can be very small (Sattar *et al.*, 2001).

Three-hundred twenty-seven (327) reports of accidents were identified among workers exposed to domestic waste and 30 among those exposed to HCW. Considering the average time reported by workers that they had been performing their jobs, it was estimated that accidents occurred at a rate of 70.93 and 70.26 per 1,000 moments of contact with domestic and health waste, respectively. These values are greater than the rates calculated by Social Security in 2013, of 56.71 and 33.2 accidents per 1,000 contacts, for workers handling non-dangerous and dangerous waste, respectively. The differences observed between data from Social Security and the data retrieved via this study may be due to several causes, among which the number of unreported accidents and the possible information bias. Also, it may be noted that waste handlers in health service settings are classified by Social Security as a profession with exposure to dangerous waste. However, this group encompasses other activities as well, which may compromise the comparability of the results.

Studies about occupational safety risks in Floridian (USA) solid waste systems pointed out that the injury rates among refuse collectors in both musculoskeletal and dermal injuries have decreased from 88 and 15 to 16 and three injuries per 1000 workers, respectively. On the other hand, injury rates among recycling workers, for whom musculoskeletal and dermal injuries have increased from 13 and four injuries to 14 and six injuries per 1000 workers, respectively (Bastani & Celik, 2015). Period studied was 2005–2012 compared with historical statistics (1993–1997) (An et al., 1999).

Regarding the data on leave from work due to accidents, worker health appears to be subject to delicate circumstances; 102 (60.4%) individuals who reported a work accident required leave due to the accident. Upon assessing the amount of time that these leave periods lasted, it was discovered that 49.4% and 42.9% of workers handling domestic waste and HCW, respectively, required more than ten days. It may be noted that health service waste handlers incurred a greater amount of accidents in a smaller amount of time as compared to domestic waste handlers, indicating a greater risk of accidents for the former.

Accidents that were not followed up with a CAT (Work Accident Communication) were observed in 31.8% of worker accounts for those exposed to domestic waste and 8.3% of those exposed to HCW; without a statistically significant difference between the two groups. The estimated lack of CAT registries in the state of Minas Gerais and in Brazil as a whole, from 2011 to 2013, was 15% and 10%, respectively (Brasil, 2015). Notwithstanding information bias deriving from workers' fear to disclose potentially compromising information linked to their

jobs, a high number of unregistered work accidents was observed, which may represent the occurrence of accidents for which workers did not seek health care. Moreover, workers often only recognize that a work accident has occurred when they are unable to perform their activities or when a wound presents a large amount of blood.

Injury by sharps

The high percentage of accidents involving sharps – 53.9% among domestic waste handlers and 75.0% among HCW handlers – underscores the danger of being stuck or cut. Muscular lesions or fractures were reported by 25.7% and 12.5% of workers exposed to domestic waste and HCW, respectively. The number of reported accidents is high in both groups of workers. These percentages are worrying as information may still be biased due to workers' fear of disclosing information related to their job. Furthermore, it is noted that due to high turnover many workers had only been working for a short period of time. That may explain why some workers had not reported the accidents, which are common in the activities of waste handlers.

A study performed in Brazil (Velloso *et al.*, 1997) indicated that, among 67 accidents related to waste handling, 50.7% were clinically diagnosed as cuts and wounds, while 34.3% were either a twist or other muscular or lumbar pain. Another study performed in Bangkok, Thailand, indicated that 77.4% of domestic waste collectors reported being victim to at least one cut-stick accident (Luksamijarulkul *et al.*, 2008). A study on hospitals in Ethiopia identified that 19.8% of all accidents among waste collection workers were related to sharps (Shiferaw *et al.*, 2011). In Gondar, Ethiopia, another study indicated that 43.0% of workers collecting health service

waste reported having suffered an accident involving a cut or stick injury (Anagaw *et al.*, 2012). Tsovili *et al.* (2014) found six (28.6%) Anti-HBc (previous contact with hepatitis B virus) positives associated with needlestick accident reported, vs. one (3.4%) unexposed to wastes with a similar accident. Rachiotis *et al.* (2012) found a RR of 2.64 (95% CI=1.01 – 6.96) for the association between reported needlestick accidents and HBV positivity. Similar studies also confirm the danger of sharp-related accidents associated with waste collection (Poulsen *et al.*, 1995; Domingo & Nadal, 2009; Silva *et al.*, 2014; Lazzari & Reis, 2011).

Research studies on healthcare facilities, including on waste collection workers in these settings, have identified the following information linked to sharp-related accidents:

- They represent 46% of all registered accidents (Machado & Machado, 2011);
- 22% are directly associated to contact with waste (Guilarde *et al.*, 2010);
- 87% are associated with biological material (Dias *et al.*, 2012);
- 23% are associated with poorly conditioned sharps in waste (Chiodi *et al.*, 2010);
- 73% of percutaneous exposures, with 14% of these being directly associated to sharp waste (Vieira *et al.*, 2011);
- 16% associated with the inappropriate disposal of sharp waste (Lima *et al.*, 2011);
- 55% of registered cuts and/or sticks during disposal of hospital waste (Özdelikara & Tan, 2012).

Reasons for leave from work indicate that muscular pains account for 39.0% of all participants' reports. The differences between the groups of domestic waste and HCW handlers were not

statistically significant, although the general average value underscores the prevalence of excessive muscular strain that is inherent to this activity, as pointed out similarly in other studies (Oliveira, 2007; Velloso *et al.*, 1997; Costa, 2007; Ferreira & Anjos, 2001).

Risk Perception

In assessing the risks associated with workers' activities, factors such as *dust, sharps, excessive muscular strain, presence of biological material* and *presence of chemical substances* were highlighted in 72.1%, 70.5%, 54.5%, 57.8% and 47.2% of all workers' accounts from the present study, respectively. The difference between workers exposed to domestic waste and HCW was statistically significant for the factors: *dust, solar radiation, ground with potholes and speed bumps, sharps, presence of biological material* and *presence of chemical substances*. The accounts of workers exposed to domestic waste for the risk factors *chemical substances, biological material* and *cuts-sticks* were proportionately less than the responses provided by HCW workers, indicating their little recognition of the dangers associated with waste handling.

A series of precautionary measures are required to protect workers dealing directly with waste, especially given the potential dangers to health to which they are exposed. The elevated frequency with which workers' health is negatively impacted on as a result of their activities appears to have become a trivial set of circumstances, which workers often accept as a part of their routine without having received appropriate warning of the attendant risks.

Limitation

Information presented by workers may still be biased due to interview process, in particular because some qualitative aspects and questions about the past. High turnover can be associated with some workers had not reported any accidents.

Conclusion

In this article, a high rate of accidents was reported by waste workers from Belo Horizonte (Brazil) if comparing with the official information registered by Social Security and scientific publications. In addition, there are indications that work accidents involving waste management professionals in Belo Horizonte may be underreported, especially due to workers' concept of what constitutes a work accident, which is considered only to account for extreme damage to their health.

The research findings suggest that workers would do well to exercise their right to demand that their employers correctly register work accidents via the CAT registry. This measure could contribute to the optimal recovery of victims and to more accurate registers, which may consequently lead to more preventive action being taken by managers in the public hygiene and waste treatment and disposal sectors.

In conclusion, it is important to expand the research body on the relevant occupational risks for waste handlers, with a view to improving their working conditions and quality of life. Furthermore, there is a particular need to increase the representation of this group of often marginalized workers in the context of public policy on sanitation.

Acronyms

A list of acronyms used in this study is presented in TABLE 6.

TABLE 6 – Acronyms list.

Acronym	Definition
CAT	Work Accident Communication
CID	Statistical Classification of Diseases and Related Health Problems
CNAE	National Classification of Economic Activities
HCW	Healthcare Waste
INSS	National Social Security Institute
PPE	Personal Protective Equipment
TCLE	Informed Consent Form

Funding

The authors disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: Financial support provided by the Fundação Ezequiel Dias (Funed), Fundação de Amparo à Pesquisa do Estado de Minas Gerais (FAPEMIG) and Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq).
