Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

49 **Abstract:** Polymer multicomponent coatings such as multilayers mimic extracellular matrix
50 (ECM) that attracts significant attention for their use as functional supports for advanced cell
51 culture and tissue engineering. Herein, biodegradation and molecular transport in
52 hyaluronan/polylysine multilayers coated with gold nanoparticles was described. Nanoparticle

59
60

1
2
3 coating acts as semipermeable barrier that governs molecular transport into/from the multilayers
4 and makes them biodegradation resistant. Model protein lysozyme (mimics of ECM soluble
5 signals) diffuses in the multilayers as fast and slow diffusing populations existing in an
6 equilibrium. Such composite system may have high potential to be exploited as degradation-
7 resistant drug delivery platforms suitable for cell-based applications.

17 The extracellular matrix (ECM) provides not only a structural support for cellular growth, but
18 also a biochemical milieu, which together define cell fate.¹ Artificial ECM is designed to mimic
19 real ECM and to achieve cellular functions in laboratory designed materials similar as in nature.
20 Artificial ECM consists of degradable supports made of natural or (semi)synthetic polymers
21 which: i) recapitulate physical-chemical properties of real ECM, ii) host bioactive signaling
22 molecules (e.g. hormones, cytokines, growth factors) to be presented to cells, and iii) possess
23 tuned biodegradability.²⁻³ The issues above are challenging for the fabrication of artificial ECM
24 but are essential for successful applications in tissue engineering, diagnostics, and animal-free
25 studies.

37

38 Introduced in the early nineties,⁴ layer-by-layer deposition proved to be extremely useful in
39 the field of bio-functional coatings. It is powerful technique for the fabrication of polymer-based
40 multilayer films with dimensions from nano to micro, adjusted composition, and tunable cellular
41 response.⁵⁻¹¹ Control over cellular functions such as adhesion, differentiation, and
42 proliferation,¹²⁻¹⁵ along with reservoir properties for a variety of biomolecules such as proteins,
43 growth factors, genes, and drugs^{7, 16-20} makes these films an attractive platform for cell-based
44 applications.
45

52
53

54 Despite the evident biological potential to employ the multilayers to recapitulate ECM,³ the
55 options to tune multilayer biodegradability are mostly limited to multilayer chemical
56
57
58
59
60

1
2
3 crosslinking^{13, 21-22} that can significantly change multilayer properties. There is also a lack in
4
5 understanding the mechanism of biomolecule-multilayer interaction that obviously defines
6
7 biomolecule presentation/release from multilayers to cells and, as a result, cellular response.²³⁻²⁴
8
9

10 In this work a new approach for the design of artificial ECM with controlled biodegradation
11 based on the coating of multilayers with gold nanoparticles (GNPs) is present. The multilayers
12 were assembled from glycosaminoglycan hyaluronic acid (HA) and polyaminoacid poly-L-lysine
13 (PLL). Molecular transport through the GNP-coated multilayers is investigated. The model
14 protein lysozyme (Lys) has been loaded into multilayers as a mimic of ECM soluble signaling
15 molecule. Protein mobility has been assessed by Fluorescence Recovery after Photobleaching
16 (FRAP) to reveal protein availability to cellular receptors. The schematics in Figure 1A-C
17 illustrates the multilayer biodegradation and the exchange of Lys in solution and in multilayers.

Figure 1. Schematics of cellular interaction with (A) bare and (B) GNP-coated (HA/PLL)₂₄ multilayers. The coating protects the multilayer from degradation by the cells adhering on it. (C) illustrates exchange of Lys (red cycles) between bulk and the multilayers where fast and slow diffusive populations are present. (D) CLSM fluorescence and (E, F) transmission images of

1
2
3 L929 fibroblasts cells cultured for three days on (HA/PLL)₂₄ and on (F) GNP-coated (HA/PLL)₂₄
4
5 multilayers ($\gamma = 3$). Red and yellow lines in (D) represent scratch boundaries before and after cell
6
7 cultivation, respectively.
8
9

10
11 Firstly, cellular interaction with the (HA/PLL)₂₄ multilayers has been assessed. The multilayers
12
13 have been scratched by a needle to form a visible scratched area of about 20 μm (Figure S1).
14
15 This followed by seeding of L929 fibroblast cells which grow preferentially within the scratch
16
17 (Figure 1D-E) due to soft nature of bare multilayers.^{21, 25} The scratch width has significantly
18
19 widened up to 100 μm demonstrating the enzymatic degradation potential of cells. The
20
21 multilayers incubated without cells are stable, whereas those incubated with cells underwent
22
23 considerable degradation, most probably due to hydrolytic enzymes secreted by cells (Figure 1,
24
25 S1). Reduction of fluorescence in PLL-FITC containing multilayers is most likely caused by
26
27 biodegradation (Figure S1).
28
29
30
31

32
33 Figure 1F shows a transmission image of the GNP-coated multilayers after 3 days of cell
34
35 culture. The amount of GNPs corresponds to three theoretical monolayers of compactly packed
36
37 spheres ($\gamma = 3$). Improved cellular adhesion (Figure 1F and Figure S2) compared to uncoated
38
39 multilayers correlates well with our previous results showing that better adhesion of cells was
40
41 attributed to multilayer stiffening induced through the presence of nanoparticles on the
42
43 multilayer surface.²⁶⁻²⁷ Hence, the coated multilayers become not only cell-adhesive but also
44
45 resistant to biodegradation, as indicated by a constant width of the scratch during and after
46
47 cellular growth (Figure 1F). One can assume that the coating acts as a barrier and prevents
48
49 diffusion of cell-expressed enzymes into the multilayers and, as a result, suppresses multilayer
50
51 biodegradation.
52

60

1
2
3 To prove this assumption, transport of the molecules of different sizes and charges into the
4 GNP-capped multilayers has been studied. A small dye 5(6)-carboxyfluorescein (376 Da, CF),
5 large positively charged PLL-FITC (15-30 kDa), and dextrans-FITC of various molecular masses
6 (10-500 kDa) have been employed as probes. The level of GNP coverage (GNPs covers only the
7 multilayer surface) has been varied by adjusting the number of theoretical GNP monolayers ($\gamma =$
8 1.5 or 3).²⁶ The diffusion of CF into the film occurs almost instantaneously, regardless of γ
9 (Figure S3A). However, the situation is essentially different for larger PLL-FITC. While PLL-
10 FITC saturates the bare films within 20-30 min, its diffusion is slowed down for the coated films
11 ($\gamma = 1.5$) and totally blocked if $\gamma = 3$ (Figure 2A and Figure S3B). The fact that the diffusion of
12 PLL-FITC is not significantly reduced for $\gamma = 1.5$ compared to that at $\gamma = 1.5$ may be related to
13 defects in the GNP coating. The coating is not ideally homogeneous as proven by microscopy
14 analysis. GNPs form clusters of several hundred nanometers and significant reinforcement of
15 mechanical properties of the GNP coated (HA/PLL)₂₄ multilayers takes place at γ more than 1.5
16 when the clusters are well interconnected.²⁶

17

19
20
21
22
23
24
25
26
27
28
29
30
31
32
33
34
35
36 One can assume that the GNP coating provides a kind of size-exclusion semipermeable barrier
37 that does not possess diffusion limitations for small molecules. Diffusion of macromolecules is
38 significantly reduced and depends on γ . However, molecular transport into the coated multilayers
39 can not only be driven by the size of diffusing molecules but also by the interactions between the
40 probe and multilayers. In the case of charged molecules (CF, PLL) electrostatics may play a
41 significant role because of a large number of both positive and negative uncompensated charges
42 in multilayers.²³ Negative charge on citric acid stabilized nanoparticles may thus also play a role.
43
44
45
46
47
48
49
50
51

52
53 Therefore, uncharged molecules - dextrans - of various molecular masses (10, 70, and 500
54 kDa) have been employed to evaluate the impact of molecular mass to permeability. Figure 2B
55
56
57
58
59
60

shows that the cut-off of the uncoated films is between 70 and 500 kDa. Diffusion of 500 kDa dextran is fully hindered and 10 and 70 kDa dextrans can rather easily penetrate into the film, reaching saturation levels after 30 min of incubation (Figure 2B). A similar time is necessary to saturate the film with charged PLL (Figure 2A). This allows one to assume that the mesh size of the polymer network of the film plays the pivotal role in diffusion of macromolecules. In the case of the GNP-coated multilayers ($\gamma = 3$) the dextrans do not diffuse into the films at all (Figure 2C). Systematic analysis of molecular diffusion through the GNP coating may allow adjusting the diffusion rate of a molecule of chose. Altogether, the coating can effectively suppress the degradation of the multilayers by preventing the diffusion of rather large enzymes such as hyaluronidase (Mw \sim 54 kDa) and proteases (Mw are usually few tens of kDa). At the same time, transport of smaller protein-based biomolecules such as growth factors into/from the multilayers could still be possible and can also be adjusted by the γ .

Figure 2. (A) Relative fluorescence of bare and GNP-coated (HA/PLL)₂₄ multilayers in the presence of PLL-FITC; the coating at $\gamma=1.5$ or $\gamma=3$. (B) Relative fluorescence of the bare and (C) coated multilayers ($\gamma = 3$) in the presence of 10, 70, and 500 kDa dextran-FITC.

The semipermeable nature and potential to adjust molecular transport into/from the multilayers make the coating attractive for the design of biomaterials with controlled degradability and controlled presentation/release of the loaded bio-molecules. The (HA/PLL)₂₄ multilayers can host

1
2
3 bio-macromolecules such as proteins which are rather mobile in the multilayers. Diffusion
4 coefficient (D) of proteins papain, lysozyme, and catalase were found to be about $2-4 \mu\text{m}^2/\text{s}$ ²³
5
6 that shows the multilayers as good mimics of ECM in terms of mobility of proteins/growth
7
8 factors. The mechanism of protein loading/release into/from multilayers is still not clear showing
9
10 complex character of protein-multilayer interaction because of no systematic effect of protein
11
12 charge and size.²³
13
14
15

16
17 For the reasons given above, the interaction of the model protein lysozyme with the
18
19 multilayers has further been examined. Lys-FITC has been loaded into the multilayers, washed
20
21 out with Tris buffer and further with cell culture medium with systematic assessment of the D of
22
23 Lys and protein fluorescence in the multilayers. D of Lys in the multilayers has been evaluated
24
25 by FRAP according to the procedure described elsewhere, which is based on the analytical
26
27 solution of Fick's law of diffusion.^{23, 28-29} The protein-loaded multilayers have been bleached
28
29 within a predefined area (marked with a yellow rectangle in Figure 3A) and the averaged 2D
30
31 fluorescence profile has been taken perpendicular to the bleached line. During the time course
32
33 the bleached and non-bleached Lys-FITC molecules exchange in the multilayers, resulting in the
34
35 widening of the fluorescence profile (profile width w) and reduction of the depth of the profile
36
37 (A) (Figure 3B and 3C). The intensity of fluorescence $I(x,t)$ across the bleached region has been
38
39 approximated by the Gaussian function and is described by Equation 1:
40
41
42
43
44

$$I(x, t) = I_0 - A(t) \cdot \exp\left(-\frac{x^2}{2w^2}\right) \quad (\text{Equation 1})$$

45
46 where I_0 is the intensity of fluorescence before bleaching; $A(t)$ is the depth of dip after time t
47
48 following the bleaching; x is the spatial distance from the minimum of the dip and w describes
49
50 the half width of the Gaussian curve at the inflexion point.
51
52
53
54
55
56
57
58
59
60

1
2
3 High level of consistency of the experimental data fitted by the Equation 1 allows D to be
4 determined reliably from the slope of linear regression of w^2 plotted versus t (Figure 3D). The
5 mean D of the protein loaded into the film has been found to be $1.2 \pm 0.1 \mu\text{m}^2/\text{s}$ (in cell culture
6 medium). Further two protein populations have been revealed in the multilayers (for details see
7 Experimental part). The time evolution of the dip depth A was meant to test if a complete
8 fluorescence recovery takes place, which would be indicative for a single protein diffusing
9 population. Extrapolation of the initial kinetics of the changes of A indicates that A approaches a
10 constant value (Figure 3E) which represents the fraction of protein molecules (about 10 % of all
11 protein) that diffuse much slower compared to the main protein population in the multilayers.
12 Thus, one can identify two populations of the protein molecules in the multilayers: Fast diffusing
13 (major fraction, 90%, D_{fast}) and slow diffusing proteins (minor fraction, 10%, D_{slow}). Both D_{fast}
14 and D_{slow} contribute to the mean D measured with $D_{\text{fast}} \gg D_{\text{slow}}$. The slow diffusing fraction is
15 approximated as immobile; diffusion slower than $0.01 \mu\text{m}^2/\text{s}$ is undistinguishable from immobile
16 behaviour because of spatiotemporal resolution of the experiment. Due to the small content of
17 slow diffusing protein with D_{slow} , its contribution can be considered as minor, thus assuming that
18 $D_{\text{fast}} \approx 1.0 \mu\text{m}^2/\text{s}$. This value indicates rather fast protein diffusion and differs only by two orders
19 of magnitude to protein diffusion in solution (D_{bulk}) which is approximately $100 \mu\text{m}^2/\text{s}$,
20 according to Stokes-Einstein equation and reported literature data.²³ Figure 1C depicts exchange
21 of Lys molecules between bulk and the film where fast and slow diffusive populations are
22 present.

23
24
25 To understand if equilibrium between the diffusing populations is established, both the protein
26 content in the film reflected by Lys-FITC fluorescence intensity and the content of immobile
27 protein fraction have been considered during the protein loading and after sequential washing out
28

with Tris-buffer and further with cell culture medium (Figure 3F). It is of note that cell culture medium does not affect Lys-FITC fluorescence (data not shown) meaning that the change in fluorescence indicates loss of protein washed out of the multilayers. After washing with buffer and finally with cell culture medium, the amount of protein in the multilayer film has been significantly reduced down to $11 \pm 2\%$ compared to the initial protein content. At the same time, the content of the slow diffusing fraction is not enhanced and did not exceed 10% of the total protein (Figure 3F). This means that equilibrium is established between slow and fast protein fractions in the films within the time scale of tens of minutes (washing time).

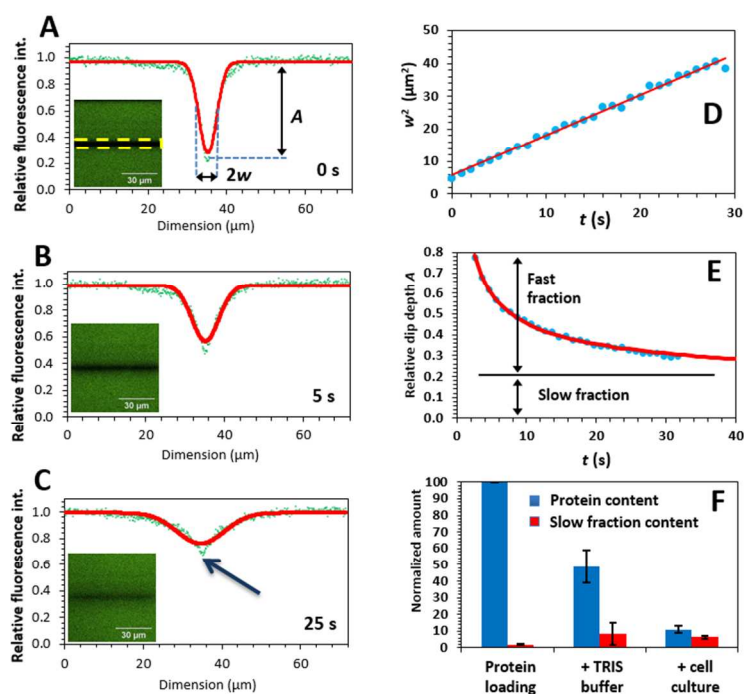

Figure 3. (A-C) - The recovery profiles at various time points (0, 5, and 25 s) after bleaching of $(\text{HA}/\text{PLL})_{24}$ multilayers loaded with Lys-FITC (fluorescence images are as insets, the bleached area is marked by the dashed yellow rectangle). The experimental data are in green and the fitting curve in red; the fitting is performed using the Eq. 1. Gaussian width of the profiles (w) and the relative dip depth (A) have been determined as shown in (A). The blue arrow in (C) points to a dip in the recovery curve that indicates a protein fraction diffusing much slower than

1
2
3 the majority of protein molecules in the film. (D) - w^2 versus recovery time t after bleaching, (E)
4 - time dependence of relative dip depth A after bleaching plotted versus recovery time t , (F) -
5 normalized fluorescence of multilayers loaded with Lys-FITC (in blue) and content of slow
6 diffusing protein fraction (in red) after the protein loading followed by washing with TRIS and
7 further with cell culture medium.
8
9

10
11
12
13
14
15
16 The presence of two protein populations in the film with significantly different mobility may
17 be attributed either to i) the presence of two types of protein binding sites in the multilayers or ii)
18 the formation of protein aggregates which are significantly larger than single protein molecules
19 and thus diffuse much slower. The increase of the slow diffusing fraction with time during
20 protein loading into the film³⁰ suggests that the slow diffusing fraction exists due to inter-protein
21 interactions in the multilayers (protein aggregation). The presence of different protein binding
22 sites would result in preferential protein binding to the site with stronger affinity and as a result
23 reduction of the amount of slow diffusing proteins during the protein loading. The findings of
24 this study stimulate further investigation, which we plan in the future in order to better
25 understand the interactions between proteins and multilayers and tune multilayer biodegradation
26 rate.

39
40
41

42 In conclusion, the coating of biopolymer-based (HA/PLL)₂₄ multilayers with GNPs results in
43 the formation of a size-exclusion semipermeable membrane on the multilayer surface with a cut-
44 off tuned by GNP density. The GNP coating significantly improves cellular adhesion and protect
45 the multilayers from biodegradation Analysis of protein (Lys) diffusion in the multilayers has
46 revealed that the loaded protein molecules are present in two populations with high ($D \approx 1.0$
47 $\mu\text{m}^2/\text{s}$) and low ($D_{\text{slow}} < 0.01 \mu\text{m}^2/\text{s}$) mobility. The populations are in equilibrium with each other
48 and the fast diffusing population dominates, representing about 90% of the loaded protein. The
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3 slow diffusing population is likely a result of protein aggregation. High mobility of the proteins
4
5 in the multilayers shows high promise to use the multilayers as hosts to present the loaded
6
7 bioactive molecules (e.g. growth factors, cytokines, hormones) to cell receptors. Finally, this
8
9 study demonstrates that GNP-coated (HA/PLL)₂₄ multilayers can potentially be exploited as
10
11 degradation-resistant drug delivery platforms suitable for cell culture and tissue engineering.
