Running heading: *Measuring soil aggregate stability by laser granulometry*

Correspondence: B. G. Rawlins. E-mail: bgr@bgs.ac.uk

1 **Summary**

2 Aggregate stability is an important physical indicator of soil quality, and so methods
3 are required to measure it rapidly and cost-effectively so that sufficient data can be
4 collected to detect change with adequate statistical power. The standard methods to
5 measure water stable aggregates (WSA) in soil involve sieving, but these have limita-
6 tions that could be overcome if the aggregates were measured with a laser granulometer
7 (LG) instrument. We present a novel method in which a LG is used to make two mea-
8 surements of the continuous size distribution ($<2000\ \mu\text{m}$) of a sample of aggregates.
9 The first measurement is made on the WSA after these have been added to circulating
10 water (initial air-dried aggregate size range 1000 to 2000 μm). The second measure-
11 ment is made on the disaggregated material (DM) after the circulating aggregates have
12 been disrupted with ultrasound (sonication). We then compute the difference between
13 the mean weight diameters (MWD) of these two size distributions; we refer to this
14 value as the disaggregation reduction (DR; μm). Soils with more stable aggregates,
15 which are resistant to both slaking and mechanical breakdown by the hydrodynamic
16 forces during circulation, have larger values of DR. We applied this method to 6 and
17 10 sub-samples, respectively, of soil aggregates (each *ca.* 0.3 g) from bulk soil material
18 from two contrasting soil types from England, both under conventional tillage (CT).
19 The mean DR values were, respectively, 178.4 and 30 μm , with coefficients of varia-
20 tion of 12.1 and 19% suggesting the DR value is reproducible for the small mass of
21 soil used. We attribute the larger DR values to the greater abundance of micaceous
22 clay minerals in one of the soils. The DR values computed for each Blackwater Drain
23 (BD) sample after removal of organic matter (with hydrogen peroxide) were compa-
24 rable to those subject to sonication suggesting that most of the aggregate structure
25 is removed by sonication. We used aggregates (1000 to 2000 μm) from soil samples
26 collected at 30 locations under CT (median soil organic carbon (SOC) =1.4%) across
27 two types of parent material in the Blackwater drain sub-catchments of the Wensum
28 catchment (Norfolk, England). These soils had no coarse WSA, so we rescaled the size

29 distributions to estimate DR for particle diameters $<500 \mu\text{m}$. Dithionite extractable
30 iron concentration, plus a minor contribution from parent material class, accounted
31 for 64% of the variation in rescaled DR highlighting the importance of crystalline iron
32 oxyhydroxides for aggregate stability in this region where long-term arable production
33 has reduced top-soil SOC concentrations. We discuss how this technique could be
34 developed to monitor aggregate stability as a soil physical indicator.

35 **Introduction**

36 Soil aggregation is a fundamental property of soils and is a primary control of aeration,
37 hydrological properties such as water-holding capacity and the storage of organic car-
38 bon (Bronick & Lal, 2005). The stability of soil aggregates is also important because
39 it influences how these properties change with time, and the susceptibility of soils to
40 erosion by both wind and water. In this paper our focus is on the stability of soil ag-
41 gregates in water. There is evidence that the stability of soil aggregates in temperate
42 climates may decline in soils with organic content below some critical threshold (Webb
43 & Loveland, 2003). To detect long-term trends in soil aggregate stability (AS), a key
44 soil physical indicator, regulatory authorities require sensitive, rapid and cost-effective
45 techniques which can be applied to samples collected from soil monitoring networks
46 (Merrington *et al.*, 2006).

47 A wide range of methods for measuring water stable aggregates (WSA) has been
48 developed and applied (Le Bissonais, 1996; Amezketa, 1999). A framework for assessing
49 AS was presented by Le Bissonais (1996) incorporating both fast and slow-wetting of
50 aggregates, the latter typically reducing the effects of slaking relative to the other
51 aggregate breakdown mechanisms. In most of these methods, aggregates are passed
52 through a set of sieves of particular mesh size. The limitations of sieve-based methods to
53 measure the stability of soil macro-aggregates include: (i) the mass of stable aggregates
54 is measured for only a few, discrete, sieve size fractions, (ii) no account is taken of the
55 particle size distribution of the sub-sampled material and (iii) they are labour intensive.

56 With modification, these limitations could be overcome by undertaking AS mea-
57 surements with a Laser Granulometer (LG) instrument, but this technology has not
58 been widely applied to the quantification of AS of soils. We have developed a novel
59 method to quantify the stability of macro-aggregates (1–2 mm) in circulating water
60 of low ionic strength. We used a restricted size range because analyses have shown
61 that results are more reproducible when this is the case (Kay & Dexter, 1990). In our
62 method, soil aggregates suspended in water are circulated from a vessel through an LG

63 analytical cell. Hydrodynamic forces in the circulating water lead to the breakdown of
64 unstable aggregates; the particle size distribution (psd) of WSA is then determined by
65 the LG instrument. The suspension remains in the vessel connected to the LG instru-
66 ment, and the particles are thoroughly disaggregated by ultrasound (sonication), and
67 the psd of the disaggregated material is measured. A major advantage of this tech-
68 nique is that we use the difference in the continuous size distribution of WSA and the
69 disaggregated material (DM) to quantify the magnitude of aggregated material. We
70 do so by computing the difference in mean weight diameter MWD (μm) between these
71 two continuous distributions which we refer to as disaggregation reduction (DR - the
72 reduction in MWD on disaggregation by sonication). This method accounts for both
73 slaking and the mechanical breakdown of aggregates, the latter often associated with
74 raindrop impact, but not the physico-chemical dispersion influenced by the electrolyte
75 concentration of the soil solution.

76 A number of studies have used a LG to investigate the impact of specific mineral
77 phases or organic matter (OM) on changes in soil aggregates (Buurman *et al.*, 1997;
78 Muggler *et al.*, 1999) and more specifically, aggregate stability (Bieganowski *et al.*
79 2010; Mason *et al.*, 2011; Fristensky & Grismer, 2008). In a comparison between soil
80 aggregate disintegration (stability) measured by continuous water circulation through
81 a LG and a wet-sieve based method, Bieganowski *et al.* (2010) concluded that the
82 former gave similar results to the latter for three different soil types. However, in
83 contrast to the approach that we adopt in our study, the aggregate structure of the
84 samples analysed by LG by Bieganowski *et al.* was not destroyed and so the psd of
85 the WSA and the DM could not be compared. Aggregates of varying stability were
86 observed in the same size class for LG-based analyses of several aeolian sediments
87 studied by Mason *et al.* (2011). The energy required to disrupt aggregates has been
88 studied by the application of sonication to disaggregate soil material, and the size
89 distribution measured using a combination of wet-sieving and pipette methods (Zhu
90 *et al.* 2009), electrical sensing approaches (Coulter principle) for the finer (2-50 μm)

91 fractions and also LG (Fristensky & Grismer, 2008). An effective technique should
92 be able to measure small differences in AS between soil samples to determine those
93 soil properties which confer greater stability. Previous studies have identified a range
94 of soil properties which influence the stability of aggregates in water including OM
95 (Haynes & Swift, 1990), iron oxyhydroxide concentration and crystallinity (Duiker
96 *et al.*, 2003), exchangeable sodium percentage (Emerson, 1967), and clay mineralogy
97 (Emerson, 1964).

98 We applied our LG-based technique to determine the magnitude of sub-sampling
99 plus analytical variation of DR by analyses of numerous sub-samples of two, bulk soil
100 samples. We then compared the magnitude of DR for two contrasting topsoils under
101 conventional tillage to determine whether these differed with respect to the sizes of
102 water-stable aggregates, and whether these differences were consistent with their soil
103 properties. Finally, we measured DR for a set of 30 top-soil samples from across a set
104 of four, small arable catchments (Blackwater drain; BD) part of the larger Wensum
105 catchment of Norfolk where the transport of fine sediments to watercourses frequently
106 leads to deterioration of water clarity (Coombes *et al.*, 1999). Median top-soil organic
107 carbon (SOC) concentrations from these catchments (1.4%) are below the average SOC
108 concentrations for soils in arable land for this region (2.5%; unpublished data from the
109 British Geological Survey). We wished to determine whether specific soil properties
110 in soils from these catchments, the quantity of soil sesquioxides, inorganic and organic
111 carbon, could account for quantitative differences in AS.

112 **Materials and Methods**

113 *Study sites and soil sampling*

114 The locations of the two study sites are shown in Figure 1. The soils of the BD
115 catchments are dominantly classed as Cambisols (IUSS Working Group WRB, 2006)
116 and their texture class varies from sandy loam to clay based on the Soil Survey of
117 England and Wales classification (Hodgson, 1974). More than 90% of the land across
118 the catchments is cultivated by conventional tillage (CT). Across the BD catchments

119 top-soil samples were collected from fifty locations; twenty-five soil sampling sites were
120 selected independently and at random from within each of the two dominant parent
121 materials (glacial till and sands and gravels: see Figure 1). Mean annual rainfall is
122 around 620 mm. The soil sample locations were recorded with a kinematic differential
123 GPS (2 cm accuracy). At each sampling location, a Dutch auger was used to collect
124 top-soil (between 0 and 15 cm depth from the soil surface) at the corners and centre
125 of a square of side length 2 metres to form a composite sample. The soil samples
126 were collected during February 2011. The soils at the Bunny farm (BF) site have
127 developed over a mudstone parent material and the soils are dominantly classed as
128 Luvisols (IUSS Working Group WRB, 2006) with a soil texture class of clay loam or
129 clay. The dominant crops grown at this and the BD site are cereals and oilseed rape,
130 also under CT. Mean annual rainfall is around 600 mm. The top-soil sample from BF
131 was a composite of material from four cores collected from locations separated by 1
132 metre along a transect; the soil was collected at depths between 2.5 and 7.5 cm from
133 the soil surface during August 2011.

134 For each soil sample around 1 kg of topsoil was collected and returned to the
135 laboratory in plastic bags and was immediately air-dried at room temperature, then
136 sieved to pass 2 mm. The samples were then coned and quartered to retrieve a 50-g sub-
137 sample and this material was ball-milled and used for a range of chemical analyses. The
138 remainder of the <2-mm size sub-sample was retained to measure AS and mineralogy.

139 *Total Organic Carbon*

140 For the BD soil samples, a mass of 0.2 g of milled sample was weighed out and placed
141 in a crucible. Cold 10% hydrochloric acid (HCl) was then added dropwise to each
142 sample until it was wet, and a vacuum bath on which the crucibles were standing was
143 turned on. More 10% HCl was added until the mixture ceased to react. This process
144 was then repeated using 10% HCl at 95°C, followed by concentrated HCl at 85°C.
145 Each aliquot of HCl was allowed to drain through the crucible prior to addition of the
146 next aliquot. The purpose of this was to remove all inorganic carbon from the sample

147 in order to obtain the TOC content. Each sample was then washed with hot (95°C)
148 distilled water and placed in an oven at 105°C for at least two hours to dry. The
149 samples were then cooled in a dessicator for at least thirty minutes, re-weighed and
150 TOC determined with an ELTRA CS800 analyser (Eltra GmbH, Neuss, Germany). An
151 internal reference material with a known quantity of organic carbon was also analysed
152 five times throughout the analyses to assess accuracy and precision; the coefficient of
153 variation was 1%.

154 For the BF sample, TOC was measured by loss on ignition. Samples were initially
155 dried at 105°C to remove any residual water. Each soil was weighed prior to, and after,
156 heating, the decrease in weight was calculated as a proportion of the initial weight and
157 expressed as a percentage weight loss. Samples were heated in a furnace at 450°C
158 for four hours and allowed to cool in a dessicator prior to weighing to produce loss
159 on ignition data, which was used as a measure of the organic carbon content of the
160 sample. It has been reported that the average carbon content of OM is approximately
161 58% (Broadbent, 1953), therefore an estimate of carbon content was calculated by
162 multiplying the OM content (%) by 0.58.

163 *Calcium carbonate content*

164 The calcium carbonate (CaCO_3) content of the BD samples was determined by acidi-
165 fying the soil and back-titration with alkali using an indicator. Ten grammes (± 0.01 g)
166 of air-dried soil sample was weighed into a 250-ml conical flask and 20 ml of 2N volu-
167 metric hydrochloric acid was added by pipette. The flask was transferred to a hotplate
168 and gently heated before boiling for ten minutes. After cooling, the suspension was
169 transferred quantitatively into a 100-ml volumetric flask via a filter funnel and What-
170 man No.1 filter paper and made up to volume. Ten ml of the resulting solution was
171 pipetted into a 250-ml conical flask. Approximately 50 ml of deionised water and a few
172 drops of phenolphthalein indicator were added. The solution was titrated with 0.2N
173 NaOH until a permanent pink colouration remained. The endpoint of NaOH titration
174 was used to calculate the mass of calcium carbonate in each sample and expressed on

175 a dry mass basis. Repeated analyses of sub-samples showed the reported values were
176 reproducible.

177 *Dithionite and oxalate extractable iron and aluminium*

178 These analyses were undertaken for the top-soil samples from the BD catchments. For
179 the dithionite extraction, 1 g ground soil was weighed into a 30-ml centrifuge tube and
180 20 ml of 25% (w/v) sodium citrate ($\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2\text{H}_2\text{O}$) was added. A further 5 ml
181 of 10% (w/v) sodium dithionite ($\text{Na}_2\text{S}_2\text{O}_4$) was added and the suspension was shaken
182 overnight. The samples were then centrifuged at 1370 g for four minutes. A 10-ml
183 aliquot was then removed by pipette. For the oxalate extraction, 1.5 g of ground soil
184 was weighed into a centrifuge tube and 25 ml of ammonium oxalate ($28.4 \text{ g l}^{-1} =$
185 0.2M) and oxalic acid (15.76 g l^{-1}) was added. The sample was shaken in darkness
186 for two hours, and the supernatant filtered through a 0.45- μm filter membrane. The
187 concentrations of Fe and Al in each of the two extracts was determined by ICP-AES
188 and the results were expressed on a dry mass basis (mg kg^{-1}) as the concentration
189 of dithionite extractable iron (Fe_d) and aluminium (Al_d), and oxalate extractable iron
190 (Fe_o) and aluminium (Al_o), respectively. No duplicate extractions were undertaken on
191 subsamples.

192 *Particle size distribution of soil material*

193 The psd of both the soil aggregates (between 1 and 2 mm diameter) and the full size
194 range of soil material (0 to 2000 μm range) was also measured for each of the BD and
195 BF samples. We placed 1 g of soil in a test tube and added 10 ml H_2O_2 (30% in water).
196 The mixture was allowed to stand for one hour, then heated at 60 °C for an hour and
197 finally boiled for one hour while the volume was maintained at 10 ml by addition of
198 water. After the mixture had stood for one hour a further 5 ml H_2O_2 was added
199 and the mixture heated as above for two hours. The mixtures were then boiled for a
200 further hour whilst the volumes were maintained at 10 ml, and boiling was continued
201 as necessary until frothing ceased. Finally, 25 ml of calgon solution (35 g $(\text{NaPO}_3)_6$

202 plus 7 g NaCO₃ dissolved in 1 litre of distilled water) was added to the residue and the
203 mixture was shaken and then allowed to stand for 30 minutes after which the psd was
204 determined using LG specifying an an 8µm threshold between the clay and silt size
205 fractions (Konert & Vandenberghe, 1997).

206 *Soil mineralogy*

207 The BF sample and a single sample from the set BD soils were selected to determine
208 their mineralogy. Repeated sub-samples of this material were those also subject to
209 AS analysis (see below). Around 100 g of <2-mm soil was passed through a 63-µm
210 sieve and this material was used in the XRD analysis. This was carried out using a
211 PANalytical X'Pert Pro series diffractometer (PANalytical, Almelo, The Netherlands)
212 equipped with a cobalt-target tube, X'Celerator detector and operated at 45kV and
213 40 mA. The samples were scanned from $4.5-85^{\circ}2\phi$ at $2.76^{\circ}2\phi$ per minute. The diffrac-
214 tion data were then initially analysed using PANalytical X'Pert Pro software coupled
215 to the latest version (2009) of the International Centre for Diffraction Data (ICDD)
216 database. Following identification of the mineral species present in the samples, min-
217 eral quantification was achieved using the Rietveld refinement technique (Snyder and
218 Bish, 1989) using PANalytical HighScore Plus software.

219 *Preparation of samples for aggregate stability*

220 The samples from BD and BF had been stored in plastic bags (air-dried) for nine and
221 six months respectively prior to assessing their AS. A mass of around 500 g of each
222 soil sample was sieved to select aggregates in the size range between 1 and 2 mm;
223 a subsample of around 10 g of aggregates was then transferred to a petri dish and
224 examined under a strong light source. Any single mineral fragments (typically large
225 quartz or flint grains) were removed with tweezers and stored separately to exclude
226 them from AS measurement. Examples of single mineral fragments and fragments
227 with partial mineral associations (between 1 and 2 mm diameter) removed from the
228 BD soil samples are shown in Figure 2.

230 Our aggregate stability measure is the difference between two measurements of MWD
231 for a soil specimen. The first MWD measurement is made after the soil has been
232 subject to circulation in water and the resulting mild disruptive forces (water stable
233 aggregates). The second measurement is made after applying a sonication treatment
234 which subjects soil aggregates to strong disruptive forces. The difference between the
235 first and second MWD is called the disaggregation reduction or DR. If two soils differ
236 with respect to the stability of their aggregates in water then we would expect the soil
237 with the more stable aggregates to have the larger DR.

238 Note that the soil after applying sonication is regarded as a baseline state against
239 which to compare the MWD of the water-stable aggregates. This is an operationally
240 defined baseline state, which depends on the particular way in which the sonication
241 treatment is applied which must therefore be standardized for any study in which re-
242 sults are to be compared between soils. The advantage of this procedure is that it
243 is feasible to make both MWD measurements on a single soil specimen, as described
244 later. This removes the potential source of sampling error that would be introduced
245 if the two MWD measurements were made on different sub-samples of the soil. An
246 alternative baseline state would be the soil particles after removal of organic carbon, as
247 is done in a standard particle size analysis (Gee & Or, 2002). However, it is not prac-
248 tically feasible to undertake the removal of organic carbon from the same soil material
249 used to determine the MWD of the water-stable aggregates since this would require
250 the extraction of all the soil material from the LG and the separation from the bulk
251 suspension, after rinsing of the LG vessel, of all the particles without preferential loss of
252 finer material. We regard the operationally defined baseline state, sonicated material,
253 as suitable for our purposes. This is because practical interest in aggregate stability of
254 the soil is generally concerned with the soil's ability to maintain key functions when
255 subject to mechanical stressors such as traffic, poaching by livestock and the impact
256 of raindrops. It does mean, however, that the DR does not account for the presence of

257 extremely resistant aggregates that are stabilized by organic carbon. As part of this
258 study we compared the MWD of stable aggregates from sub-samples of soil specimens
259 with that of subsamples of the same specimens after removal of organic carbon. This
260 allowed us to evaluate the difference between the DR calculated for the two baseline
261 states: material after applying sonication and material after removal of carbon. It also
262 allowed us to evaluate the effect of using separate subsamples of soil material to deter-
263 mine the MWD of the water-stable aggregates and the baseline material as is necessary
264 if the latter requires that carbon has been removed.

265 In the following paragraphs we describe in detail the procedures followed to de-
266 termine the two MWD values needed to compute the DR.

267 The measurements of MWD to compute the DR were made with a LG instrument
268 (Beckman Coulter LS 13320, Brea, CA (USA)) connected to an aqueous module; a cal-
269 ibrated temperature probe and sonicator probe were inserted into the aqueous module.
270 The instrument measures the volume proportion (%) in 117 size classes from $<0.04\ \mu\text{m}$
271 to $<2000\ \mu\text{m}$ (the number of the fixed size classes is greater in the finer size range). The
272 finest size material ($<1\ \mu\text{m}$) was measured with an additional instrument component
273 measuring particle scattering intensity difference between vertically and horizontally
274 polarized light (PIDS; Xu, 2008). This technology overcomes the problems typically
275 associated with sizing finer particles ($<1\ \mu\text{m}$) by laser diffraction. The instrument was
276 switched on at least two hours prior to analysis to ensure that it was at its operating
277 temperature. The arrangement of the LG instrument and the aqueous module to which
278 aggregates are added is shown in Figure 3.

279 First, the aqueous module, which is connected in a continuous loop with the LG
280 analytical cell *via* two pipes (total fluid volume 1250 ml), was thoroughly rinsed with
281 tap water and then flushed twice with reverse osmosis (RO; 16–17 $\text{M}\Omega$) water which
282 was at a consistent temperature (between 19 and 21°C). The water vessel was then
283 filled with RO water and the water temperature recorded. The RO water contains
284 very little excess CO_2 which can de-gas from mains water forming bubbles that can

285 cause measurement errors. The speed of the pump, which circulates water through
286 the loop between the aqueous module and the LG, was increased to the fast flow rate
287 (73 ml s⁻¹) for 30 seconds and then decreased to purge any bubbles from the system.
288 The LG detectors were then aligned and the background scatter determined across the
289 full range of detector angles.

290 Soil aggregates (total mass between 0.2 and 0.4 g) were then transferred from a
291 sample container to the RO water in the aqueous vessel until around 3% light obscu-
292 ration was reported by the LG. The pump speed was then immediately increased to
293 the fast rate (73 ml s⁻¹) to ensure all aggregates were in circulation. Preliminary tests
294 showed that at slower flow rates, larger aggregates remained at the base of the aqueous
295 vessel which leads to biased measurements of psd. After five seconds had elapsed the
296 psd of the aggregates was measured continuously for 90 seconds by the LG; the tem-
297 perature of the suspension and light obscuration (reported by the LG) at the start and
298 end of this period were recorded. The pump speed was then reduced to the slow rate
299 (14 ml s⁻¹) and the sonicator in the aqueous vessel (power rating 18 W) was switched
300 on for ten minutes. Tests showed (results not presented) that this was sufficient time
301 to break apart any aggregates which still remained; applying further sonication did not
302 lead to a significant reduction in particle size. The temperature of the solution was
303 measured again so the power used in heating could be calculated (North, 1976):

$$P_h = (m_w c_w + m_s c_s + m_v c_v) \frac{\Delta T}{\Delta t}, \quad (1)$$

304 where m_w is the mass of water, c_w is the specific heat of water (4.18 J g⁻¹ at 20°C, m_s
305 is the mass of oven-dried soil, c_s is the specific heat of the soil, m_v is the mass of the
306 container, c_v is the specific heat of the container and ΔT is the temperature change in
307 the suspension over the time period (Δt - ten minutes of sonication).

308 The pump speed was then increased to the fast rate once more and the psd
309 measured for a further 90 seconds. Light obscuration (%) at the end of each analysis
310 was also recorded. On a few occasions, when too much sample had been added initially
311 to the aqueous vessel, light obscuration after sonication exceeded 18% which can reduce

312 the accuracy of psd measurement. In such cases the sample was flushed from the
313 system and the analysis repeated with a smaller sample mass to ensure obscuration
314 after sonication was $< 18\%$. Between each analysis the aqueous cell was then rinsed
315 thoroughly with mains water before the next analysis was undertaken. In common
316 with other aggregate stability methods (Zhu *et al.*, 2009), we cannot quantify the
317 mechanical energy leading to the breakdown of the initial aggregates (between 1 and
318 2 mm in diameter). In our method, this energy comprises: (i) the hydrodynamic forces
319 of the circulating water, (ii) collisions between soil aggregates and the surfaces of the
320 circulating system, and (iii) particle–particle collisions during circulation.

321 Two standard particle size materials (supplied by Beckman Coulter; mean diam-
322 eter 32 and 500 μm) were used throughout the series of analysis to check for accuracy
323 and precision of the psd measurements by the LG instrument. The psd analyses for
324 each of the two measurements on each sample (WSA and DM) were reported as the
325 volume proportion (%) for the size classes.

326 *Calculation of disaggregation reduction*

327 For each psd measurement the mean weight diameter was calculated as:

328

$$\text{MWD} = \sum_{i=1}^n \bar{x}_i w_i, \quad (2)$$

329 where \bar{x}_i is the mean diameter of each size fraction (μm), and w_i is the volume pro-
330 portion (expressed as a decimal proportion) of the sample corresponding to that size
331 fraction. We calculated the difference between the MWD of water-stable aggregates
332 and MWD of the DM and refer to this as the disaggregation reduction (DR; μm) in
333 other words the reduction in MWD on disaggregation by applying sonication. Soil
334 types with more stable aggregates have larger values of DR since the stable aggregates
335 are resistant to both slaking and mechanical breakdown by the hydrodynamic forces
336 during circulation, and are disrupted only by applying sonication.

337 Preliminary measurements of AS using soil samples from the BD showed that

338 few, if any, of the aggregates from these soils at sizes greater than 500 μm were stable
339 in water, but in some cases there were notable changes in stability between 400 and 500
340 μm . When the data for volume percentage against particle size for both water stable
341 and sonicated material were overlain in exploratory plots the two lines were almost
342 coincident at sizes $>500 \mu\text{m}$. During LG analyses we noted that for samples with a
343 substantial quantity of coarse material (diameter $>500 \mu\text{m}$) the variation in passage of
344 these particles through the analytical cell caused large differences in estimates of MWD
345 over the 90 seconds of measurement. This could lead to a biased estimate of MWD.
346 To overcome this potential bias when comparing values of DR for the BD samples,
347 we re-scaled the volume proportions in all size ranges $<500 \mu\text{m}$ to sum to 100%, and
348 re-calculated the MWD for both distributions on the re-scaled data, and DR by their
349 difference.

350 *Measurements of aggregate stability*

351 To assess sub-sampling and analytical variation of the AS method, we used ten separate
352 sub-samples of aggregate material from a single soil sample from the BD catchments
353 and analysed each using our LG-based method. We also analysed six sub-samples from
354 the BF soil sample. In each case we calculated the coefficient of variation (%CV) of
355 DR and the standard error of the mean for different numbers of sub-samples. We also
356 measured DR for two sub-samples of soil material from each of another 29 soil samples
357 from the BD catchments (total $n=30$). In each case we calculated the DR for each
358 sub-sample, and the mean DR of each sample using the values for the two sub-samples.
359 We produced scatterplots for DR plotted against the other soil properties, which could
360 account for aggregate stability, and investigated whether they explained a significant
361 proportion of the variation in DR by fitting ordinary least squares linear regression
362 models. We also included the parent material classification (tills or sands and gravels)
363 as a categorical predictor variable.

364 As we noted earlier, our aggregate stability measure treats the sonicated soil
365 material as an operationally-defined standard state against which to compare the MWD

366 of the WSA. We argued above that this standard state allows us to measure both MWD
367 on the same subsample of soil which has practical advantages, and that it represents
368 a meaningful baseline state because many of the threats to soil aggregation, at least
369 in the short to medium term, are mechanical disruption. Ideally one might prefer
370 to treat disaggregated soil from which all organic carbon has been removed as the
371 standard state, since otherwise the DR does not represent very resistant aggregates
372 that are stabilized by organic carbon. As noted above, we do not think that it is
373 feasible to make determinations of MWD on WSA and soil after removal of organic
374 carbon for the same sub-sample. If one makes the comparison between different sub-
375 samples, then sub-sampling error will inflate the error variance of the measurements of
376 DR. To indicate the likely difference between our operationally-defined standard state
377 and disaggregated soil with organic carbon removed, and to evaluate the effect of the
378 additional source of sample error, we took an additional ten sub-samples from the single
379 BD soil specimen that we had previously sub-sampled to evaluate the variability of DR
380 measurements (previous section) and an additional sub-samples from the BF specimen.
381 Each sub-sample was then treated separately. Organic carbon was removed by the
382 procedure described earlier and MWD was determined for each. We then obtained 10
383 determinations of DR against a baseline state with organic carbon removed (DR-OMR)
384 by matching each sub-sample from which the organic carbon was removed with one
385 subsample of the same specimen for which the MWD of water-stable aggregates had
386 been determined. This matching was done at random. The statistics of DR-OMR from
387 ten replicates from the BD soil and six replicates from the BF soil were then computed.

388 **Results and their interpretation**

389 *Sub-sampling plus analytical variation of DR*

390 The overall mean DR from ten replicate measurements from one specimen of soil from
391 BD was 30.0 μm and the standard deviation was 5.7 μm , CV was 19%. For the BF
392 sample for which six sub-samples were measured repeatedly the overall mean DR was

393 substantially larger (178.4 μm), the standard deviation was 21.7 μm , CV was 12%.
394 The standard error of the mean DR estimated from the analysis of two samples would
395 be 4.0 μm and 15.3 μm for the BD and BF soils, respectively, and we considered that
396 this would be an appropriate rate of replication, given the time required to analyse the
397 subsamples.

398

399 *Comparison of DR with DR-OMR*

400 The overall mean DR-OMR from ten replicate measurements from one specimen of
401 soil from BD was 54.6 μm with a standard deviation of 27.7 μm , CV was 51%. For
402 the BF sample for which six subsamples were repeatedly measured the overall mean
403 DR was 240.8 μm , the standard deviation was 28.4 μm , CV was 12%. Note that in
404 both cases the mean DR-OMR is larger than the mean DR, which is to be expected
405 because removal of organic carbon will lead to the disaggregation of aggregates which
406 are resistant to the ultrasound treatment. The CV for DR-OMR in the case of BD was
407 more than twice that of DR, but in the case of the BF soil that CV was the same for
408 DR and DR-OMR. For both soils, the application of sonication removed most of the
409 aggregate structure because the MWD of the disaggregated material was far smaller
410 than that of the WSA.

411 *Differences in aggregate stability between soil types*

412 Using measurements of the temperature of the suspension before and after sonication
413 in Equation 1, we calculated that the mean power used in heating all samples was
414 19.3 W (1 J s^{-1}), with a minimum of 12.8 W and a maximum of 25.2 W.

415 The proportion of particle diameters for the WSA and DM (after sonication)
416 for the two soil types are shown in Figures 4a and 4b; there are several noteworthy
417 differences between the samples. First, note the small difference between the WSA
418 and disaggregated material (DM) above approximately 300 μm diameter in the BD
419 soil (Figure 4a) by comparison to much greater differences in the BF soil (Figure 4b).

420 There are very few WSA >300 μm diameter in the BD sample, but a considerable
421 proportion in the BF sample which also includes those of sizes >1 mm. The size range
422 over which the volume proportion of WSA is greater than DM highlights a net loss of
423 material; this size range is much wider (70-1500 μm) for the BF soil by comparison with
424 the range (48-310 μm) for the BD soil. The size at which there is the greatest difference
425 between WSA and DM is larger (275 μm for the BF sample than for BD sample (90
426 μm)). These features all show that the BF soil had a larger proportion of WSA by
427 comparison with the BD soil. This is supported by the mean DR values for the two
428 samples; 30.0 μm for the BD by comparison to 178.4 μm for BF. We attribute much of
429 this difference to the contrasting mineralogy of the soils; the BF soil has a considerably
430 larger (31%) quantity of micaceous clay minerals (illite and smectite) than that (16%)
431 reported for the BD soil (Table 1). The micaceous clay minerals are effective in binding
432 together soil particles because of their large surface area and are less subject to slaking
433 (Emerson, 1964). The SOC concentration of the BF sample was 2.5% larger than the
434 BD sample (1.4%); this may in part also account for the greater DR value of the former
435 as SOC can enhance aggregate stability.

436 *Variation in BD soil properties and aggregate stability*

437 A summary of the soil properties for the BD samples, all fifty sites and the sub-set of
438 thirty sites for which the AS test was applied, are presented in Table 2. The median
439 SOC concentrations are generally small (1.4%) by comparison with regional top-soil
440 SOC concentrations from unpublished data based on sampling and analysis covering
441 all of East Anglia (2.2%, see Figure 1). The calcium carbonate concentrations (median
442 2%) are consistent with the estimated values of inorganic carbon concentrations for this
443 region presented by Rawlins *et al.* (2011) using a regression model using measurements
444 of calcium and aluminium concentrations in topsoil. There is an approximate two or
445 three-fold variation in the concentrations of oxalate and dithionite extractable Fe and
446 Al for the soils across the BD catchment; the Fe_d values have the largest concentrations
447 with a median concentration of 6232 mg kg^{-1} .

448 The psd of the subset of 30 samples (size range 0 to 2000 μm ; organic matter
449 removed) is shown in Figure 5; the size distribution of the DM (post sonication; initial
450 aggregate size 1000 to 2000 μm) for the same samples are also shown for comparison.
451 The soil texture classes of the soils extend from sandy clay loam, to clay loam to clay.
452 By selecting only large aggregates, this particulate material has substantially greater
453 proportions of sand material and also slightly more silt content by comparison with
454 the size range of the bulk soil.

455 Exploratory scatterplots showed a strong linear correlation between the concen-
456 tration of Fe_d and mean DR values (rescaled from the $< 500\mu\text{m}$ size range) for the
457 subset of 30 soil samples. An ordinary linear regression model fitted with Fe_d and
458 parent material code as predictors (Figure 6) accounted for 64% of the variation in
459 DR (adjusted R^2). The significance of the parent material classification was marginal
460 ($P=0.11$), but it was retained in the regression model because the classification had
461 been used to stratify the region prior to sampling. The residuals of the regression
462 model were approximately normally distributed (skewness coefficient=1.0). None of
463 the other quantitative soil properties (SOC, calcium carbonate, Fe_o , Al_d and Al_o) were
464 strongly correlated with DR so we considered that their role in determining AS must
465 be secondary.

466 Discussion

467 Soils from the region of the BD catchments have total silicon concentrations in the top
468 decile of all soils across England and Wales (Rawlins *et al.*, 2012) and are therefore
469 likely to be among the most quartz-(SiO_2) rich samples at national scale. We think it
470 likely that the large proportion of quartz-dominated aggregates (Figure 2) in our BD
471 sample explains why we needed to re-scale our DR values to the sub-500- μm range.
472 It may not be necessary to re-scale data for other samples at a national scale because
473 they are likely to contain smaller proportions of large quartz particles. It is often not
474 clear from sieve-based methods how the presence of abundant large, single particle
475 mineral fragments are dealt with. What may be considered aggregated material at

476 the start of a wet-sieve analysis may comprise a large, single mineral grain, 1 mm in
477 diameter, for example, coated by a few, small mineral fragments. After removal of these
478 mineral coatings during the AS test, the large grain would be trapped by the 1 mm
479 sieve aperture and be classed as a stable aggregate, although it is not an aggregate
480 but a single particle. In our LG method, by contrast, we can quantify the presence of
481 such mineral fragments by comparing the size distribution of the WSA and the DM.
482 The quantity DR accounts for the size distribution of the DM, so the presence of large
483 mineral fragments cannot bias this measurement as in wet-sieve approaches.

484 The concentration of SOC across the BD catchments (median 1.4%) is likely to
485 have been reduced during the last 50 years or more by long-term arable production
486 under CT. Given that SOC content is one of the dominant controls on AS (Haynes
487 & Swift, 1990), it is likely that the latter has also declined over this period. Our re-
488 sults suggest that the current dominant control on AS across the BD catchments is the
489 concentration of iron oxyhydroxides. The spatial variation of iron oxyhydroxide con-
490 centrations across the BD catchments, where soils are prone to losses of fine sediment,
491 is likely to be far greater than any temporal change. It may be possible to estimate
492 and map iron oxyhydroxide concentrations, as a predictor of AS, cost-effectively using
493 diffuse reflectance infra-red spectroscopy, as demonstrated for sediments from other
494 parts of England (Rawlins, 2011). Exploratory analyses using the data from the 50
495 sample sites across the BD catchments show that iron oxyhydroxide concentrations ex-
496 hibit substantial autocorrelation (correlated variance 87%) at moderate length scales
497 (variogram range=4500m) which suggests that sampling intensities of 1 sample every
498 few square kilometres would capture much of the spatial variation.

499 One of the advantages of the LG-based AS method is the speed with which
500 analyses can be undertaken; there is no requirement to dry and weigh aggregates
501 trapped on sieves of differing mesh size, or for cleaning sieves between measurements.
502 With just two sub-samples, we estimate that a single operator could apply the test to
503 ten independent samples per working day; or twenty samples per day if only a single

504 sub-sample is analysed, with a small associated increase in the error of DR. Given the
505 speed of the analysis combined with an accurate, quantitative measure of aggregate
506 stability, we consider that this procedure could be used to measure AS as a soil physical
507 indicator (Merrington *et al.*, 2006) in future soil monitoring programmes which will
508 likely require analyses of many hundreds of samples. Our method needs to be tested
509 on soils which have been subject to a range of land-management practices which are
510 likely to have led to changes in AS to determine whether significant differences in DR
511 can be detected. If this can be demonstrated successfully, it suggests our technique
512 might also be able to detect small changes associated with temporal monitoring.

513 Our additional analyses to compute DR-OMR, the DR measure of aggregation
514 relative to a baseline state in which the soil organic carbon is removed, showed, as
515 expected, that some aggregates in the soil are resistant to the ultrasound treatment
516 but are disrupted by the removal of organic matter. This is a limitation of our method,
517 because it does not account for such aggregates. However, it is not feasible to make
518 measurements of MWD on water stable aggregates and on the same subsample after
519 removal of organic carbon, as we discuss below. And for one of our sites we found,
520 as expected, that determining DR-OMR by comparing the MWD of water-stable ag-
521 gregates and material after removal of organic carbon from two random sub-samples
522 introduces a substantial additional source of uncertainty. These practical considera-
523 tions are strong reasons for the use of the DR measure where the baseline state is
524 soil disaggregated by the ultrasound treatment. As we note above, for many practi-
525 cal purposes, this is a relevant baseline state because the threats to soil structure are
526 mechanical: traffic, poaching, impact of raindrops, shear-forces created by surface flow
527 and so on. However, we acknowledge that methodological developments that allowed
528 the MWD of water stable aggregates and material after removal of organic carbon to
529 be determined for the same sub-sample would be advantageous.

530 If our method, or a modified version, were to be applied more widely, a standard,
531 aggregated material would be required to ensure that the results of its application

532 were sufficiently reproducible. Such an aggregated material would need to respond
533 consistently to the disrupting forces in the circulating suspension. The field-based
534 sampling, storage and distribution of a bulk soil reference material is unlikely to have
535 consistent disaggregation properties because AS is known to increase with storage
536 time (Blake & Gilman, 1970) and also vary according to sampling period according to
537 season (Blackman, 1992) most likely because of variations in antecedent soil moisture
538 conditions (drying-wetting cycles). One effective solution might be the establishment of
539 a procedure for creating artificial soil aggregates from widely available materials; some
540 combination of geological, mineral components and fresh organic matter. A group of
541 laboratories could generate their own soil aggregates and exchange them with others
542 in the group to assess whether the results from application of the LG-based method
543 were sufficiently reproducible for its deployment in soil monitoring.

544 By using a solution of low ionic strength in our AS test, we cannot account for
545 the effects of variations in soil solution electrolyte concentrations, and specifically ex-
546 changeable sodium which can have a significant effect on aggregate stability in certain
547 soils (Barzegar *et al.*, 1994). Further work is required to investigate whether a solution
548 of specific composition would be needed for soil types with large quantities of exchange-
549 able sodium. It would also be possible use a slow aggregate wetting procedure (using,
550 for example, a tension table; Le Bissonnais, 1996) to investigate any differences in AS
551 with the fast-wetting procedure described in our method.

552 There is currently no established method for measuring aggregate bond energy
553 using sonication whilst simultaneously measuring a continuous aggregate/particle size
554 distribution where the latter does not contribute disruptive energy to the former. For
555 example, by using a LG for such measurements, energy associated with circulating
556 the soil suspension (typically water) through the LG instrument also contributes to
557 aggregate dispersion. To overcome this impediment, we suggest it may be possible to
558 use a dense (1.8 g cm^{-3}) liquid such as sodium polytungstate (SPT) in which micro-
559 aggregates ($< 250 \text{ }\mu\text{m}$) are suspended. Disruptive energy would be applied using

560 sonication with a feedback mechanism (see Zhu *et al.*, 2009). The SPT will prevent the
561 disruption of particles which typically sink rapidly in water and are subject to disruptive
562 collisions through circulation in lower density, aqueous solutions. The suspension would
563 be circulated at minimal velocity so that only minimal amount of energy is imparted
564 to the micro-aggregates during analysis. It would be a simple matter to test such an
565 approach by measuring the MWD of micro-aggregates circulated through a LG in an
566 SPT suspension to determine the extent of any disaggregation.

567 **Conclusions**

568 The main conclusions from our study are as follows:

569

- 570 1. We presented a novel method for measuring aggregate stability, based on the
571 measurement of size distributions of aggregated material by a laser granulome-
572 ter, before and after sonication. We refer to the difference in MWD (μm) of
573 these two size distributions as disaggregation reduction, a quantitative estimate
574 of aggregate stability. This method has several advantages by comparison with
575 previous sieve-based methods.
- 576 2. The coefficient of variation of DR from the analysis of six and ten sub-samples
577 of two different soil materials was 12.1 and 19%, respectively, so the method is
578 reproducible. The method is also rapid. We estimate that if two sub-samples of
579 each soil material are analysed, a single operator could complete ten analyses per
580 working day, or twenty analyses if only a single sample were analysed.
- 581 3. The DR that we determine is based on treating sonicated soil material as a baseline
582 disaggregated state. We showed that the MWD of soil material from which
583 organic carbon has been removed can be substantially smaller in contrast to
584 material which has subject to sonication, which indicates that our measurement
585 of DR does not account for very resistant aggregates stabilized by organic matter.
- 586 4. Although we acknowledge (3) above, it is not practically feasible to treat material

587 with organic matter removed as the baseline state within this proposed method
588 because the MWD of water-stable aggregates and of material with organic matter
589 removed cannot be determined from the same sub-sample of material. If different
590 sub-samples are used then the CV of the resulting determination of the DR may
591 be much larger than for our proposed method on a single sub-sample, and we
592 found this to be the case at one of our two study sites.

593 5. The two different soils we studied, both from arable sites in England under CT,
594 had substantially different values of DR; 178.4 and 30 μm , respectively. We
595 attribute this to the former having substantially larger quantities of micaceous
596 clay minerals ($<63\mu\text{m}$ fraction) compared with the latter.

597 6. We measured DR for soils from 30 sites across the Blackwater drain catchments,
598 part of the larger Wensum catchment in Norfolk, England. These soils had small
599 SOC concentrations (median 1.4%) which is caused by long-term cultivation.
600 The iron oxyhydroxide content of these soils, with a small contribution from two
601 classes of parent material, accounted for 64% of the variation in DR. This suggests
602 that the iron oxyhydroxide content of these soils is currently the dominant control
603 on AS. Other quantitative soil properties (calcium carbonate, organic carbon,
604 aluminium oxides) were not strongly correlated with AS, as measured by DR.

605 7. Soils from the Blackwater drain catchments also contained substantial proportions
606 of coarse, quartz fragments which we identified by comparing the size distribution
607 of the WSA and the DM. The quantity DR accounts for the size distribution of
608 the DM, so the presence of large mineral fragments, which are not aggregates,
609 cannot bias the AS measurement, which can be the case in wet-sieve approaches.

610 **Acknowledgements**

611 Collection and chemical analyses of the soil samples in the Blackwater drain catchments
612 was funded by Defra under its Demonstration Test Catchment initiative (Wensum

613 DTC). We would like to thank (i) Erol Uman of Meritics Ltd for his advice in developing
614 the protocol for measuring AS with the laser granulometer, (ii) Heather Harrison for
615 undertaking the measurements of soil calcium carbonate, (iii) Doris Wagner and Simon
616 Kemp for the XRD analyses, (iv) Andy Tye and Jenny Bearcock for undertaking the
617 fieldwork and (v) Gren Turner for particle size analyses. This paper is published with
618 the permission of the Executive Director of the British Geological Survey (Natural
619 Environment Research Council).

703 **Figure captions**

704 **Figure 1** Location of the study sites: 1. Bunny farm (Nottinghamshire). 2. Black-
705 water drain catchments (Norfolk) where 50 soil samples were collected over two
706 parent material types: glacial till (dark grey) and sands and gravels (pale grey).
707 The paler shaded area on the national map shows the region of East Anglia (see
708 text). Coordinates are metres of the British National Grid.

709 **Figure 2** Components of soil material (1-2 mm diameter) from the Blackwater drain
710 soil samples which were removed after examination prior to aggregate stability
711 tests: a) single mineral fragments, b) mineral fragments with partial covering of
712 finer material.

713 **Figure 3** Arrangement of apparatus used for the measurement of aggregate stabil-
714 ity (not to scale). Arrows depict the circulation of the suspension between the
715 aqueous vessel and the laser granulometer.

716 **Figure 4** Size distribution (log scale) of aggregates and sonicated disaggregated ma-
717 terial for two topsoils (with differing parent materials) : a) Blackwater drain
718 (tills or sand and gravels), b) Bunny farm (mudstone). The original distributions
719 in a) have been re-scaled by using the distribution of sizes $<500\mu\text{m}$. Areas are
720 highlighted where disaggregation leads to a net loss of coarser material which
721 accumulates at finer sizes (shown as net gain) after sonication.

722 **Figure 5** Ternary diagram showing particle size distribution for paired sub-samples of
723 material from 30 locations: i) filled discs with material of size range 0 to $2000\mu\text{m}$
724 for which organic matter had been removed, ii) open discs for sub-samples subject
725 to aggregate stability tests and sonication (initial aggregate size range 1000 to
726 $2000\mu\text{m}$ without removal of organic matter). The boundaries between soil texture
727 classes are those of the Soil Survey of England and Wales (Hodgson, 1974).

728 **Figure 6** Scatterplot of total dithionite extractable iron concentrations (Fe_d) plotted
729 against disaggregation reduction for 30 soil samples collected across the Wensum

730 catchment. The solid line is the linear regression model with Fe_d as a predictor
731 for samples over glacial till, whilst the dashed line is for the sands and gravels
732 which has a different intercept value.

733 **Table 1** The proportion of mineral phases in the < 63 μ m size fraction of a topsoil sample from each of the two study areas by x-ray
734 diffraction analysis).

Site	albite	calcite	chlorite	dolomite	hematite	^a kaolin	K-feldspar	^b mica	quartz
Bunny farm	8.8	nd	1.7	nd	0.5	1.4	7.3	30.7	49.6
Blackwater drain	6.9	<0.5	0.9	0.7	<0.5	1.3	7.4	16	66.3

735
736 nd=not detected

737 ^a undifferentiated kaolin group minerals possibly including kaolinite, halloysite etc)

738 ^b undifferentiated mica species including muscovite, biotite, illite and illite/smectite

739

740 **Table 2** Summary statistics for measurements on fifty top-soil samples from the Black-
 741 water drain catchments and a sub-set of thirty samples for which aggregate stability
 742 measurements were undertaken. Of the subset of 30 samples, 17 sites were over glacial
 till and 13 over sands and gravel parent materials.

	all soils	sub-set
Calcium carbonate (%)		
min	1.00	1.00
