Body-mass index and cause-specific mortality in 900 000 adults: collaborative analyses of 57 prospective studies

Prospective Studies Collaboration*

Summary

Background The main associations of body-mass index (BMI) with overall and cause-specific mortality can best be assessed by long-term prospective follow-up of large numbers of people. The Prospective Studies Collaboration aimed to investigate these associations by sharing data from many studies.

Methods Collaborative analyses were undertaken of baseline BMI versus mortality in 57 prospective studies with 894 576 participants, mostly in western Europe and North America (61% [n=541 452] male, mean recruitment age 46 [SD 11] years, median recruitment year 1979 [IQR 1975–85], mean BMI 25 [SD 4] kg/m²). The analyses were adjusted for age, sex, smoking status, and study. To limit reverse causality, the first 5 years of follow-up were excluded, leaving 66 552 deaths of known cause during a mean of 8 (SD 6) further years of follow-up (mean age at death 67 [SD 10] years): 30 416 vascular; 2070 diabetic, renal or hepatic; 22 592 neoplastic; 3770 respiratory; 7704 other.

Findings In both sexes, mortality was lowest at about 22·5–25 kg/m². Above this range, positive associations were recorded for several specific causes and inverse associations for none, the absolute excess risks for higher BMI and smoking were roughly additive, and each 5 kg/m² higher BMI was on average associated with about 30% higher overall mortality (hazard ratio per 5 kg/m² [HR] 1·29 [95% CI 1·27–1·32]): 40% for vascular mortality (HR 1·41 [1·37–1·45]); 60–120% for diabetic, renal, and hepatic mortality (HRs 2·16 [1·89–2·46], 1·59 [1·27–1·99], and 1·82 [1·59–2·09], respectively); 10% for neoplastic mortality (HR 1·10 [1·06–1·15]); and 20% for respiratory and for all other mortality (HRs 1·20 [1·07–1·34] and 1·20 [1·16–1·25], respectively). Below the range 22·5–25 kg/m², BMI was associated inversely with overall mortality, mainly because of strong inverse associations with respiratory disease and lung cancer. These inverse associations were much stronger for smokers than for non-smokers, despite cigarette consumption per smoker varying little with BMI.

Interpretation Although other anthropometric measures (eg, waist circumference, waist-to-hip ratio) could well add extra information to BMI, and BMI to them, BMI is in itself a strong predictor of overall mortality both above and below the apparent optimum of about 22·5–25 kg/m². The progressive excess mortality above this range is due mainly to vascular disease and is probably largely causal. At 30–35 kg/m², median survival is reduced by 2–4 years; at 40–45 kg/m², it is reduced by 8–10 years (which is comparable with the effects of smoking). The definite excess mortality below 22·5 kg/m² is due mainly to smoking-related diseases, and is not fully explained.

Introduction Body-mass index (BMI) is a reasonably good measure of general adiposity, and raised BMI is an established risk factor for several causes of death, including ischaemic heart disease, stroke, and cancers of the large intestine, kidney, endometrium, and post-menopausal breast. In many populations, the average BMI has been rising by a few percent per decade, fuelling concern about the effects of increased adiposity on health. Some uncertainties persist, however, about the relation between BMI and mortality, including whether some of the reported positive or inverse associations have been distorted by weight loss because of pre-existing disease (reverse causality) or by inadequate control for the effects of smoking; whether the shape and strength of associations with specific diseases differ between smokers and non-smokers; how the relative and absolute risks for BMI compare with, and also combine with, those for smoking; whether the relative risks differ much by sex or age (and whether any substantial association continues into old age); how the absolute excess risks for vascular disease compare with those for neoplastic or respiratory disease; and the extent to which some less common causes of death, such as kidney or liver disease, are associated with BMI.

Some of these uncertainties can best be addressed by large prospective observational studies—or by large collaborative analyses of individual data from such studies, as in this report—that follow up generally healthy adults for many years and identify large numbers of deaths from specific causes. In the
Prospective Studies Collaboration (PSC), the investigators of 61 prospective studies have shared individual data for a million adults. The collaboration was established chiefly to assess the relevance of blood pressure and blood cholesterol to cause-specific mortality, but for 57 of the studies information was also available for BMI (although generally not for waist circumference). This PSC report examines the relevance of BMI to cause-specific mortality 5 or more years after recruitment into these studies.

Methods
Data collection
Previous PSC reports have described the methods of study selection, data collection, and statistical analysis, and similar methods were used in this report. BMI was calculated as weight in kg divided by the square of height in m. In three studies of US health professionals, height and weight were self-reported by participants. Following WHO convention, BMI of 30 kg/m² or more is termed obese. Individuals with missing data for age, sex, or BMI were excluded, as were those with BMI less than 15 kg/m² (188 excluded) or 50 kg/m² or more (297), those with a baseline history of heart disease (54347) or stroke (4349), and those with no follow-up in the age range 35–89 years (25949), leaving 894576 participants. Information about blood pressure (882032) and total cholesterol (814109) was available for most participants, as was information about tobacco smoking (849723) and diabetes mellitus (698255). Information was, however, available for relatively few of the participants about alcohol drinking (297584), HDL cholesterol (114939), and LDL cholesterol (42937). Of current drinkers, 78% (155900) had information about grams of alcohol consumed per day, and of current cigarette smokers, 57% (166724) had information about daily number of cigarettes smoked.

Generally, the underlying cause of death was obtained from the death certificate (information about contributory causes was not available), but in many studies confirmation was then sought from other sources, such as medical records and autopsy findings. The cause of death was coded to 3 digits using any of International Classifications of Diseases (ICD) 6–10. The cause of death was coded to 3 digits using any of sources, such as medical records and autopsy findings. This PSC report examines the relevance of BMI to cause-specific mortality 5 or more years after recruitment into these studies.

Statistical analysis
Cross-sectional associations between BMI and risk factors were estimated by multiple linear regression or logistic regression, with adjustment for study, baseline age (in 10-year groups), and baseline smoking (three groups: current cigarette smoker [32%]; never smoked any type of tobacco regularly [35%]; and other smoker, ex-smoker of any type of tobacco, or unknown [8%, 19%, and 5%, respectively]). Any individuals with missing values of BMI or the particular risk factor were excluded. Associations between baseline BMI and mortality were estimated by Cox regression, with stratification for study, sex, age at risk (in 5-year groups), and baseline smoking (as above), but not for blood pressure, blood lipids, or diabetes (since these are mechanisms by which BMI affects vascular mortality). The resulting relative risks were not corrected for the regression dilution bias, since one BMI measurement is highly correlated with the long-term usual BMI (self-correlation 0.90 between baseline BMI and a re-measurement of BMI some 6 years later; webappendix p 11). In categorical analyses, the boundaries of BMI categories were always multiples of 2.5 kg/m², and the boundaries used in particular analyses are indicated by tick marks in the figures. Values exactly on a boundary went above it. In continuous analyses, log risk was regressed on BMI as a continuous variable within the range 15–25 kg/m² (termed the lower range), 25–50 kg/m² (upper range), or 15–50 kg/m² (full range), yielding in each range the hazard ratio per 5 kg/m² higher BMI (HR). To limit effects of pre-existing disease on baseline BMI, the main analyses exclude all person-years and deaths in the first 5 years of follow-up.

Relative risks for different BMI categories are presented as floating absolute risks by multiplying all of them by a common constant to make their inverse-variance-weighted average match the uniformly age-standardised death rate per 1000 person-years at ages 35–79 years (i.e., the simple mean of the nine age-specific rates at ages 35–39 years to 75–79 years) either in the PSC population, or in the European Union (EU) population in 2000 (i.e., the combined population of 15 western European countries). Multiplication of all the relative risks by this common constant means that the floating absolute risks (and the SEs of the log risks) do not depend on the choice of an arbitrary reference group. Hence, an appropriate SE and CI can be assigned to the log of the floating absolute risk in each BMI category. This SE—described more simply as the SE of the log rate (Julian Peto, London School of Hygiene and Tropical Medicine, London, UK; personal communication)—does not depend on the common constant that was chosen, and is roughly equivalent to the coefficient of variation of the risk in that one group.

The webappendix provides further information, including details of the collaborating studies, endpoint definitions, BMI re-measurement results, and findings for specific causes of death.

Role of the funding sources
The funders of the study had no role in the study design, data collection, data analysis, data interpretation, or writing of the report. GW, PS, and SL had full access to the data in the study, and the writing committee had final responsibility for the decision to submit for publication.

Results
In the 57 studies with information for BMI, individual records with information about BMI were available for 894576 adults. 92% of these participants were in Europe,
Figure 1: Vascular risk factors versus BMI at baseline in the range 15–50 kg/m²

Adjusted for baseline age, baseline smoking status (apart from the smoking findings), and study. Numerical values are shown for 20–22.5 kg/m², for 30–32.5 kg/m², and for the extreme BMI groups. Boundaries of BMI groups are indicated by tick marks. 95% CIs are not shown, but most are narrower than the heights of the plotted symbols. (A) Blood pressure (in 533 342 males and 348 790 females). (B) Blood cholesterol fractions (in 62 364 males and 52 575 females with total and HDL cholesterol both measured); dashed line indicates the ratio of mean non-HDL cholesterol to mean HDL cholesterol (mean of the individual ratios would be about 8–12% greater). (C) Prevalences in males for alcohol drinking (168 283), cigarette smoking (334 496), and diabetes (378 854). (D) Prevalences in females for alcohol drinking (129 301), cigarette smoking (226 307), and diabetes (319 401).
Israel, the USA, or Australia; the remaining 8% (accounting for just 3% of the deaths) were in Japan. 85% (763 274) of participants were recruited during the 1970s or 1980s. Across all studies, median year of recruitment was 1979 (IQR 1975–85), mean recruitment age was 46 (SD 11) years, and 61% (n=541 452) were male. Mean age at risk (years) was 1979 (IQR 1975–85), mean recruitment age was 46 (SD 11) years, and 61% (n=541 452) were male. Mean age at death was 67 (SD 10) years.

Hazard ratio per 5 kg/m² higher BMI (HR). HR less than 1 if BMI inversely associated with risk. All analyses exclude the first 5 years of follow-up and adjust for study and age at risk (in 5-year groups). The overall and age-specific analyses also adjust for sex, and the all-participant analyses also adjust for baseline smoking status.
Above this minimum, mortality was on average about 30% higher for every 5 kg/m² higher BMI. Although the proportional increase was somewhat greater at younger ages (35–59 years), each 5 kg/m² higher BMI was still associated with almost 30% higher mortality at 70–79 years of age (table 1). In the lower BMI range (15–25 kg/m²), the inverse association of mortality with BMI (HR per 5 kg/m² higher BMI 0.79 [95% CI 0.77–0.82]) became less extreme either when the analysis was restricted to lifelong non-smokers (0.87 [0.81–0.94])...
or when a further 10 years of follow-up were excluded (0·85 [0·81–0·91]; webappendix p 14).

Ischaemic heart disease accounted for more than a quarter of all deaths of known cause. BMI and mortality from ischaemic heart disease were associated strongly, positively, and roughly log-linearly throughout the BMI range from 20 to 40 kg/m², and perhaps at even greater BMI (figure 3). In the upper BMI range (25–50 kg/m²), each 5 kg/m² higher BMI was associated with about 40% higher ischaemic heart disease mortality (figure 4, table 2). The association was a little stronger in middle than in old age, but was still definite even at ages 80–89 years (HR 1·30 [1·17–1·45]; figure 4A). In the European and Israeli studies the association was about as strong as it was in the US and Australian studies (HRs 1·38 [1·33–1·44] and 1·40 [1·32–1·50], respectively, for deaths at ages 35–89 years; only 44 deaths from this disease occurred in the Japanese studies), and there was no significant heterogeneity (p=0·13) across the HRs for the 16 larger studies (with >200 deaths from ischaemic heart disease) and the aggregated smaller studies (webappendix p 5).

Stroke accounted for a third as many deaths as ischaemic heart disease did. In the upper BMI range (25–50 kg/m²) each 5 kg/m² higher BMI was, as for ischaemic heart disease, associated with about 40% higher mortality (table 2), largely irrespective of follow-up period (after the first 5 years), smoking status, or stroke subtype (figure 4B). As with ischaemic heart disease, there was no significant heterogeneity (p=0·64) across the HRs from the eight larger studies (with >100 stroke deaths) and the aggregated smaller studies (webappendix p 5). By contrast with ischaemic heart disease, however, the association of BMI with stroke was much stronger in middle than in old age (figure 4; for both diseases, allowance for the older age at death of women eliminates the apparent relevance of sex). Furthermore, in the lower BMI range (15–25 kg/m²) there was, if anything, a slightly inverse association, but in the upper range each 5 kg/m² higher BMI was again associated with about 40% higher mortality. Among particular other vascular causes, the associations in the upper BMI range were particularly strong for mortality attributed to heart failure (HR 1·86 [1·55–2·23]) and to hypertensive disease (2·03 [1·75–2·36]).

In the upper range (25–50 kg/m²), BMI was associated strongly and positively with mortality attributed to diabetes, to non-neoplastic kidney disease, and to non-neoplastic liver disease (table 2), which was mainly cirrhosis (HR 1·79 [1·54–2·08]).

In the range 25–50 kg/m², neoplastic disease accounted for nearly two-thirds as many deaths as did
vascular disease, but the association with BMI was much weaker: only 10% higher neoplastic mortality, compared with 40% higher vascular mortality, for each 5 kg/m² higher BMI (neoplastic HR 1·10 [1·06–1·15]). Even across the full BMI range (15–50 kg/m²) the 95% CIs for site-specific cancers were wide (web-appendix p 15), but nonetheless there were positive associations for several sites, including the liver (HR 1·47 [1·26–1·71]), kidney (1·23 [1·06–1·43]), breast (1·15 [1·02–1·31]) for deaths at ages 60–89 years and, identically, for deaths at 35–59 years, endometrium (1·38 [1·08–1·77]), prostate (1·13 [1·02–1·24]), and large intestine (1·20 [1·12–1·28]; male 1·29 [1·19–1·40], female 1·05 [0·94–1·18]).

In the lower range (15–25 kg/m²), BMI was associated inversely with mortality from cancer as a whole, mainly because of steep inverse associations with the cancers most strongly related to smoking (table 2; upper aerodigestive cancer includes oesophagus cancer, which had HR 0·52 [95% CI 0·38–0·72], and cancer of the mouth, pharynx, and larynx). The inverse association of BMI with lung and upper aerodigestive cancer (combined) weakened with increasing duration of follow-up but was still definite during years 10–14 (0·65 [0·53–0·79]) and years 15 and more (0·75 [0·62–0·91]). Even among lifelong non-smokers, there was a definite inverse association for upper aerodigestive cancer (0·35 [0·16–0·74]), although not for lung cancer (0·90 [0·48–1·80]).

Respiratory disease accounted for an eighth as many deaths as did vascular disease (table 2). In the lower range, BMI was strongly and inversely associated with mortality from each main type of respiratory disease, of which the most common was chronic obstructive pulmonary disease (COPD). After exclusion of the first 5 years of follow-up, COPD mortality in this BMI range was four times higher for 5 kg/m² lower BMI (HR 0·26 [95% CI 0·22–0·30]). In the first 5 years (excluded from all the main analyses), the inverse association at low BMI was even greater (COPD). After exclusion of the first 5 years of follow-up, COPD mortality in this BMI range was four times higher for 5 kg/m² lower BMI (HR 0·26 [95% CI 0·22–0·30]). In the first 5 years (excluded from all the main analyses), the inverse association at low BMI was even greater

### Figure 4: Ischaemic heart disease (A) and stroke mortality (B) versus BMI in the upper BMI range (25–50 kg/m²) only (excluding the first 5 years of follow-up, except as indicated)

Hazard ratios are per 5 kg/m²—eg, 30 kg/m² versus 25 kg/m²—and are, when appropriate, adjusted for age at risk, sex, smoking, and study. Mean ages at death are given, but the dependence of the HR on mean age at death is not corrected for in analyses of factors other than age. The area of each square is inversely proportional to the variance of the log hazard ratio. White squares include the first 5 years of follow-up; black squares and white diamonds do not. Subarachnoid=subarachnoid haemorrhage (not included in haemorrhagic stroke).

</table>

In males, and twice as great for vascular as for neoplastic disease in females. Below 22.5–25 kg/m², there was a pronounced excess of lung cancer, upper aerodigestive cancer, and respiratory disease, particularly in males (figure 5).

Both in current cigarette smokers and in lifelong non-smokers, overall mortality was lowest at about 22.5–25 kg/m², but the excess mortality below this range was both relatively and absolutely much greater in smokers (figure 6, again plotted on an additive scale). In both smoking groups, the excess at 25–27.5 kg/m² was slight, and although the excess at 30–35 kg/m² was substantial, it was still much less than the excess attributable in this study to cigarette smoking itself (as shown in figure 6 by the vertical separation of the curves; the excess attributable to persistent cigarette smoking throughout adult life would be even greater than this). Throughout the range 25–50 kg/m², the effects of BMI and smoking seemed to be roughly additive, rather than multiplicative, both for vascular mortality (webappendix p 8) and for all-cause mortality (figure 6).

### Discussion

In this collaborative analysis of data from almost 900 000 adults in 57 prospective studies, overall mortality was lowest at about 22.5–25 kg/m² in both sexes and at all ages, after exclusion of early follow-up and adjustment for smoking status. Above this range, each 5 kg/m² higher BMI was associated with about 30% higher all-cause mortality (40% for vascular; 60–120% for diabetic, renal, and hepatic; 10% for neoplastic; and 20% for respiratory and for all other mortality) and no specific cause of death was inversely associated with BMI. Below 22.5–25 kg/m², the overall inverse association with BMI was predominantly due to strong inverse associations for smoking-related respiratory disease (including cancer), and the only clearly positive association was for ischaemic heart disease.

In laboratory studies, BMI is moderately strongly correlated (30–50%) with fat-free mass, but it is much more strongly correlated (60–90%) with fat mass.° BMI is also strongly correlated (80–85%) with measured waist circumference." in the EPIC prospective study of 360 000 adults in Europe, for example, the two variables have about an 85% correlation, so each has a similar association with mortality.° (In EPIC, waist-to-hip ratio was not quite as strongly related either to BMI or to mortality.) In such populations, either measurement can thus be used to help assess the causal relevance of obesity to mortality, and each could well add some predictive information to the other. Neither, however, directly measures visceral fat.

Although BMI and waist circumference are not directly causal, both are closely correlated in such populations with aspects of adiposity that directly affect blood pressure, lipoprotein particles, and diabetes (figure 1). Effective interventions for weight loss lower blood
pressure, favourably affect lipoprotein particles, and increase insulin sensitivity,\(^1\) and drugs that substantially lower blood pressure\(^1\) or LDL particle numbers\(^2\) reduce vascular disease. At least some of the major adverse effects of obesity are, therefore, reversible.

For ischaemic heart disease, the magnitude of the positive association with BMI in this study can be largely accounted for by blood pressure, lipoprotein particles, and diabetes. The associations of baseline BMI with baseline measurements of SBP and of the non-HDL/HDL cholesterol ratio (figure I) can be taken as the associations of BMI with the usual levels of these variables over the past and next few years, so they would predict at least a doubling of mortality from ischaemic
heart disease between 20 kg/m² and 30 kg/m² (if the combined effects of SBP and the ratio of cholesterol fractions were approximately additive\textsuperscript{(10,11)}) which is what was observed. (Merely adjusting regression analyses for single measurements of blood pressure and total cholesterol would understate the mediating effects of blood pressure and, especially, of lipoprotein particles\textsuperscript{(4,5,21,22)\). Above 30 kg/m², further increases in BMI have little further effect on the ratio of cholesterol fractions (figure 1B), but could be associated with other adverse changes in lipoprotein particles that cannot be inferred from cholesterol fractions (eg, an increase in the number of small dense LDL particles). Diabetes becomes particularly important at BMI greater than 30 kg/m² (figures 1C and 1D). Other hypothesised intermediate factors (eg, fibrinogen, C-reactive protein, obstructive sleep apnoea) were not assessed.

Confounding by diet, physical activity, or socioeconomic status could have somewhat affected the ischaemic heart disease results. The cardioprotective effects of physical activity might not be due solely to reduced adiposity\textsuperscript{(11)} so variation in physical activity could have caused the independent effects of adiposity to be somewhat overestimated. Confounding by socioeconomic status could have caused the independent effects to be either overestimated or underestimated. In the three prospective studies of US health professionals, however, there would have been relatively little socioeconomic confounding, yet for all-cause mortality in the upper BMI range (there were too few deaths to subdivide by cause), the association seemed to be broadly similar across these three studies to that in the PSC as a whole (webappendix p 14).

The weakening of the association between BMI and mortality from ischaemic heart disease above age 70 years is probably a result of the weaker associations at older ages of blood pressure and cholesterol with risk\textsuperscript{(1,3,25)\), and the slightly weaker associations of BMI with these intermediate variables. (At older ages, BMI might depend increasingly on muscle loss\textsuperscript{24\).}

For stroke, the findings in the upper and lower BMI ranges were quite different from each other. In the upper range, BMI was associated positively with ischaemic, haemorrhagic, and total stroke, and each of these associations can be largely accounted for by the effects of BMI on blood pressure. In the lower BMI range, however, there was no evidence of a positive association for ischaemic, haemorrhagic, or total stroke, despite the strong positive association between BMI and blood pressure. (For a specific blood pressure, therefore, BMI in this lower range would actually be inversely related to stroke.) These findings for stroke in the lower BMI range were not materially affected by exclusion of participants who had ever smoked (by contrast with the findings reported from a large Chinese prospective study\textsuperscript{25\}). The evidence from previous large studies of BMI and stroke subtype is not as consistent as might be expected\textsuperscript{1,9,10,12–26}, but generally suggests that the association of BMI with stroke risk is strongly positive at BMI greater than 25 kg/m² for both ischaemic and haemorrhagic stroke, and, less definitely, that at BMI less than 25 kg/m² it is still positive for ischaemic but not for haemorrhagic stroke. In the lower BMI range, however, the PSC found no evidence of an association for ischaemic stroke (although the possibility of a weak positive association is not excluded), and found only

---

**Figure 6:** All-cause mortality at ages 35–79 years versus BMI in the range 15–50 kg/m², by smoking status (excluding the first 5 years of follow-up)

Relative risks at ages 35–79 years, adjusted for age at risk, sex, and study, were multiplied by a common factor (ie, floated) so that the mean for all participants (including ex-smokers and anyone with missing smoking data) matches the European rate at ages 35–79 years in 2000. Results for ex-smokers and those with missing smoking data not shown (but are, taken together, only slightly above those for never smokers). Note that many smokers were at only limited risk, since they had not smoked many cigarettes during early adult life, or had stopped shortly after the baseline survey. Risk is indicated on an additive rather than multiplicative scale. The estimates for 35–50 kg/m² are based on limited data, so lines connecting to those estimates are dashed. Floated mortality rates shown above each square and numbers of deaths below. Area of square is inversely proportional to the variance of the log risk. Boundaries of BMI groups are indicated by tick marks. 95% CIs for floated rates reflect uncertainty in the log risk for each single rate.
slight evidence of an inverse association for haemor-
ragic stroke. These findings for stroke in the lower
BMI range are not fully explained.

For kidney and liver disease, positive associations
with BMI could have resulted mainly from the effects of
adiposity on blood pressure, diabetes, and blood lipids.
Central adiposity can cause non-alcoholic fatty liver
disease, which could predispose to cirrhosis or
hepatocellular carcinoma (the commonest type of liver
cancer). The positive associations of BMI with cirrhosis
and liver cancer are unlikely to have been due to
confounding by alcohol, since drinking was not strongly
related to BMI in males and was inversely related to it in
females.

For cancer, the evidence of several positive associations
complements that from other million-person prospective
studies (eg, the Cancer Prevention Study-II and the
Million Women Study). Possible mechanisms by which
obesity could cause cancer at particular sites have been
associated positively: histological subtype is, however,
most are likely to have been squamous cell carcinomas, which are reported to be associated inversely with BMI,
mostly because they were of the commonest type of liver
cancer).9 The positive associations of BMI with cirrhosis
and liver cancer are unlikely to have been due to
confounding by alcohol, since drinking was not strongly
related to BMI in males and was inversely related to it in
females.

For COPD and other respiratory diseases, the inverse
associations with BMI in the range 15–25 kg/m² were
remarkably strong. In each sex, the inverse association
for respiratory mortality accounted for about 60% of the
difference in all-cause mortality between 15–20 kg/m²
and 22.5–25 kg/m² (figures 2 and 5). COPD can cause
weight loss over many years, so the inverse association
(even after exclusion of the first 15 years of follow-up)
might have been due mainly to reverse causality (ie, to
low BMI being an indicator of progressive COPD). However, some close correlate of low BMI itself could
increase COPD progression and, hence, mortality.

The inverse associations with COPD, lung cancer,
and upper aerodigestive cancer were much steeper in
smokers than in non-smokers. Smoking is a major
cause of all three diseases, and the greater steepness
in smokers might have been due at least partly to
uncontrolled confounding by smoking intensity.
Smoking can cause weight loss, and if greater intensity
of smoking were to cause increased weight loss, then
there would be a substantially greater proportion of
intensive smokers in the lower BMI categories, who
would be at greater risk of these conditions (both
through direct effects and, possibly, as a result of being
less likely to quit). Although cigarettes smoked per day
varied little with BMI in this study, other evidence
(webappendix p 13) suggests that, for a specific number
of cigarettes per day, leaner smokers have substantially
higher blood cotinine concentrations than other
smokers do (and also substantially more lung cancer,
upper aerodigestive, and COPD). Hence, smoking intensity might confound associations with
BMI even in the absence of an association between BMI
and daily cigarette consumption. Alternatively, lower
BMI might somehow exacerbate the effects of smoking
on respiratory cancer or other respiratory disease. The
steep inverse associations for these diseases among
smokers are still largely unexplained.

This study did not assess measures of central obesity,
but other large epidemiological studies have done so.
In the ten-country EPIC prospective study (with
12 000 deaths of known cause, of which 3000 were
vascular [vs 36 000 vascular deaths in the PSC]), waist
circumference improved the ability of BMI to predict
vascular and all-cause mortality. In the 52-country
INTERHEART case–control study of acute myocardial
infarction (with 12 000 cases), a difference of 5 kg/m²
in BMI seems, for reasons that are not clear, to be of
much less relevance to heart disease (odds ratio ~1.2
[95% CI 1.08–1.16]) than it was in the PSC (HR 1.39
[1.34–1.44]) or in EPIC (HR ~1.4), and hence to be of
much less relevance than measures of central obesity
are. Since case–control studies have greater potential
for some types of bias, disentangling the interdepen-
dent associations of closely correlated anthropometric
variables with particular diseases might need
progressive studies that are even larger than this PSC
study.

This report cannot quantify the effects of present
levels of childhood obesity on adult mortality over the
next few decades; the relevance of obesity to mortality
in different ethnic groups; the substantial effects of
obesity on disability, quality of life, or non-fatal disease
(e.g., osteoarthritis, obstructive sleep apnoea); or the
positive effects of some types of adiposity on prognosis
after some chronic disorders (e.g., heart failure,“
respiratory disease”) have already developed. It does,
however, quantify particularly reliably both the excess
mortality associated with low BMI (much of which
might be somewhat lower than the apparent optimum
of about 23 kg/m² or 24 kg/m².

The absolute excess mortality at BMI greater than
22.5–25 kg/m² was mainly vascular, but also partly
neoplastic, and was probably largely causal (ie, due to

causal factors closely associated with BMI). Figure 7 shows, for different BMI levels in middle age, estimates of the lifetime probabilities of surviving from age 35 years, which are calculated by applying the relative risks that were considered likely to be causal (webappendix p 18) to disease-specific mortality rates at ages 35–79 years from the EU in 2000. The absolute differences in median survival (but probably not in survival to age 70 years) should be robust to changes in mortality rates, and therefore generalisable decades hence. (A) 3 main BMI categories. (B) 3 main and 2 higher BMI categories. (The 2 higher BMI categories account for just 2% of PSC participants, and so are indicated by dashed lines.)

Figure 7: BMI versus lifespan in western Europe, year 2000
Estimated effects of the BMI that would be reached by about 60 years of age on survival from age 35 years, identifying European Union (EU) mortality rates in 2000 with those for BMI 25–30 kg/m² and combining the disease-specific EU mortality rates with disease-specific relative risks (for details, see webappendix pp 18–20). The absolute differences in median survival (but probably not in survival to age 70 years) should be robust to changes in mortality rates, and therefore generalisable decades hence. (A) 3 main BMI categories. (B) 3 main and 2 higher BMI categories. (The 2 higher BMI categories account for just 2% of PSC participants, and so are indicated by dashed lines.)
and partly because many who were current smokers at baseline in the PSC would have quit during follow-up (which is taken account of in the doctors’ study, but not in the PSC). The difference in mortality between smokers and non-smokers in figure 6 therefore underestimates the effects of smoking throughout adult life, but it could likewise underestimate the effects of becoming obese well before middle age.

These PSC relative risks for BMI, combined with recent population BMI values,27,28 suggest that in the present decade, about 29% of vascular deaths and 8% of neoplastic deaths in late middle age in the USA (where mean BMI at age 50 years was 28.5–29 kg/m² in 2000) would have been attributable to having a BMI greater than 25 kg/m²; for the UK (where mean BMI at that age was about 1 kg/m² lower), the corresponding proportions would have been about 23% and 6%, respectively. In both countries, as elsewhere, these proportions will probably increase if average BMI in middle age continues to rise, even if rates of vascular and neoplastic mortality continue to fall because of decreases in smoking, improvements in treatment, or other reasons. Moreover, since BMI is an imperfect measure of visceral and other adiposity, the number of vascular and other deaths attributable to all adiposity-related factors is probably appreciably greater than these calculations suggest.

In adult life, it may be easier to avoid substantial weight gain than to lose that weight once it has been gained. By avoiding a further increase from 28 kg/m² to 32 kg/m², a typical person in early middle age would gain about 2 years of life expectancy. Alternatively, by avoiding an increase from 24 kg/m² to 32 kg/m² (ie, to a third above the apparent optimum), a young adult would on average gain about 3 extra years of life.

Contributors
All members of the writing committee contributed to the collection and analysis of the data, and to the preparation of the report. All collaborators had an opportunity to contribute to the interpretation of the results and to the re-drafting of the report.
