

NASA TECH BRIEF

Langley Research Center

NASA Tech Briefs announce new technology derived from the U.S. space program. They are issued to encourage commercial application. Tech Briefs are available on a subscription basis from the National Technical Information Service, Springfield, Virginia 22151. Requests for individual copies or questions relating to the Tech Brief program may be directed to the Technology Utilization Office, NASA, Code KT, Washington, D.C. 20546.

GaAs Transistors Formed by Be or Mg Ion Implantation

The n-p-n transistor structures have been formed in GaAs by implanting n-type substrates with 45-keV Mg or 40-keV Be ions to form the base regions and then implanting them with 20-keV Si ions to form the emitters. SiO₂ films, sputter deposited at room temperature, are used as implantation masks to define the lateral geometry of the transistors. Because Mg and Be are light ions they penetrate more deeply into the lattice for a given ion energy and hence are particularly useful in applications where a relatively thick doped layer is required.

The p-type layers have been produced in GaAs by implantation of either Mg or Be ions, with the substrate at room temperature, followed by annealing at higher temperatures. The ion source in both cases was a hot-cathode electron-bombardment type. The Mg ions were generated by placing metallic magnesium in an axial probe inserted into the source, while the Be ions were produced by placing BeCl₂ in the probe. The n-type $\langle 111 \rangle$ substrates were implanted with 45-keV Mg or 40-keV Be ions and subsequently annealed for 15 minutes at temperatures up to 900° C. The dependence of surface carrier concentration and mobility on ion dose, and on post-implantation annealing temperature, was determined using the van der Pauw-Hall technique.

The GaAs substrates were $\langle 111 \rangle$ oriented wafers ($\pm 3^\circ$) with the β -face chemically polished prior to implantation. The wafers were intentionally misaligned 8°, with respect to the ion beam, during implantation

to minimize ion channeling. Implantation was performed with substrates at room temperature. Treated substrates were subsequently coated with a sputtered layer of SiO₂, 200 nm thick, prior to annealing at higher temperatures in a flowing N₂ atmosphere. This oxide coating has been found effective in preventing dissociation of the GaAs as well as in reducing out-diffusion of the implanted ions during annealing.

The results show that Be and Mg can be used as ion-implanted dopants in GaAs, producing p-type layers with reasonably large hole concentrations. Hole mobilities are in the range 100-200 cm²/V sec.
