It is desirable for many reasons to know antenna polar patterns and efficiencies accurately. In the past, calibration measurements have been made using balloons and aircraft and more recently satellites. These techniques are usually very expensive. We show that under certain circumstances it is possible to use a simpler and inexpensive technique by connecting together the antenna under test with another antenna (not necessarily the same) to form a phase-switched interferometer as first described by RYLE (1952).

For two antennas separated by a distance d in the EW direction and with respective amplitude polar patterns of the form E $_1$  ( $\theta$ ) and E $_z$  ( $\theta$ ), the interference pattern is given by

$$P(0) = k_1 k_2 E_1(\theta) E_2(\theta) \cos(\pi d/\lambda)$$
 (1)

Here  $\mathbf{k}_1$  and  $\mathbf{k}_2$  are constants determined by preamplifier gains and cable losses. If a point radio source drifts through the center of the beams then the envelope of the interference pattern is determined by the combined polar patterns of the antennas; if one antenna is much larger than the other then  $P(\theta)$  is essentially determined by the larger antenna and its pattern can be so measured and compared with the theoretical pattern. We have applied this technique to measurements of the polar diagram of the co-co transmitting array (dimensions of  $16\lambda \times 16\lambda$ ) used with the Adelaide VHF radar (BRIGGS et al., 1984). The second antenna was one of the yagi receiving arrays  $(4\lambda \times 4\lambda)$ .

What does not so far appear to have been recognized is that this technique can also be used to measure the effective area and hence the efficiency, of arrays. This is because  $E(\theta)$  is proportional to  $\sqrt{A}$ , where A is the effective area such that the received power can be written

$$P_{12} = k_1 k_2 (A_1 A_2)^{1/2}$$
 (2)

Suppose that the first antenna is replaced by a third antenna of known area e.g., a dipole located  $\lambda/4$  above a perfect ground, then

$$P_{23} = k_1 k_2 (A_3 A_2)^{1/2}$$
 (3)

The ratio of (2) to (3) gives the ratio of the areas for antennas 1 and 3 in terms of the ratio of the measured interferometer powers. In principle, this technique is very simple. It does require a suitable radio source which gives measurable powers when using small antennas (e.g., dipoles) and since dipoles have broad patterns, radio sources with similar right ascensions but different declinations to the primary source can be a problem. These problems can partly be overcome by filtering the interference pattern. Measurements of the efficiencies of the Adelaide antennas are in progress.
